Description

xtheckman fits a random-effects linear regression model with endogenous sample selection.

Quick start

Random-effects model of y on x1 using xtset data, with selection indicated by binary variable selected and predicted by v1 and x1

```
xtheckman y x1, select(selected = v1 x1)
```

Same as above, but constraining random effects to be independent

```
xtheckman y x1, select(selected = v1 x1) norecorrelation
```

Same as above, but omit random effects from selection model

```
xtheckman y x1, select(selected = v1 x1, nore)
```

indepvars and varlist_s may contain factor variables; see [U] 11.4.3 Factor variables.

depvar, indepvars, depvar_s, and $varlist_s$ may contain time-series operators; see [U] 11.4.4 Time-series varlists.

bootstrap, by, collect, jackknife, and statsby are allowed; see [U] 11.1.10 Prefix commands.

collinear and coeflegend do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

^{*}select() is required.

Options

Model '

 $select(depvar_s = varlist_s [, sel_options])$ specifies a random-effects probit model for sample selection with $varlist_s$ as the covariates for the selection model. When $depvar_s = 1$, the model's dependent variable is treated as observed (selected); when $depvar_s = 0$, it is treated as unobserved (not selected). select() is required.

sel_options are the following:

noconstant suppresses the constant term (intercept) in the selection model.

nore specifies that a random effect not be included in the selection equation.

offset($varname_o$) specifies that $varname_o$ be included in the selection model with the coefficient constrained to 1.

noconstant; see [R] Estimation options.

norecorrelation constrains the random effects in the outcome and selection equations to be independent.

offset(varname_o), constraints(numlist); see [R] Estimation options.

SE/Robust

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [XT] vce_options.

Reporting

level(#), nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels,
 allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt),
 sformat(%fmt), and nolstretch; see [R] Estimation options.

Integration

intmethod(intmethod) and intpoints(#) control how the integration of random effects is numerically calculated.

intmethod() specifies the integration method. The default method is mean-variance adaptive Gauss-Hermite quadrature, intmethod(mvaghermite). We recommend this method. intmethod(ghermite) specifies that nonadaptive Gauss-Hermite quadrature be used. This method is less computationally intensive and less accurate. It is sometimes useful to try intmethod(ghermite) to get the model to converge and then perhaps use the results as initial values specified in option from when fitting the model using the more accurate intmethod(mvaghermite). See *Methods and formulas* for more details.

intpoints() sets the number of integration (quadrature) points used for integration of the random effects. The default is intpoints(7). Increasing the number increases accuracy but also increases computational time. Computational time is roughly proportional to the number specified. See *Methods and formulas* for more details. Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace,
 gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#),
 nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are
 seldom used.

The default technique is technique(bhhh 10 nr 2).

Setting the optimization type to technique(bhhh) resets the default *vcetype* to vce(opg).

The following options are available with xtheckman but are not shown in the dialog box: collinear, coeflegend; see [R] Estimation options.

Remarks and examples

stata.com

xtheckman fits a panel-data model with endogenous sample selection. Endogenous sample selection is sometimes called nonignorability of selection, missing not at random, or selection bias. Within-panel correlation is accounted for by using panel-level random effects.

The outcome of interest y_{it} is modeled as

$$y_{it} = \mathbf{x}_{it}\boldsymbol{\beta} + \nu_{1i} + \epsilon_{1it}$$

where \mathbf{x}_{it} are the covariates modeling the outcome, ν_{1i} is the panel-level random effect, and ϵ_{1it} is the observation-level error.

We model the selection process for the outcome by

$$s_{it} = 1 \left(\mathbf{z}_{it} \boldsymbol{\alpha} + \nu_{2i} + \epsilon_{2it} > 0 \right)$$

where $s_{it} = 1$ if we observe y_{it} and 0 otherwise, \mathbf{z}_{it} are the covariates modeling selection, ν_{2i} is the panel-level random effect for selection, and ϵ_{2it} is the observation-level selection error.

The random effects ν_{1i} and ν_{2i} are bivariate normal with mean 0 and variance

$$\begin{bmatrix} \sigma_{1\nu}^2 & \rho_{\nu}\sigma_{1\nu}\sigma_{2\nu} \\ \rho_{\nu}\sigma_{1\nu}\sigma_{2\nu} & \sigma_{2\nu}^2 \end{bmatrix}$$

The observation-level errors ϵ_{1it} and ϵ_{2it} are bivariate normal, with mean 0 and variance

$$\begin{bmatrix} \sigma_1^2 & \rho \sigma_1 \\ \rho \sigma_1 & 1 \end{bmatrix}$$

These observation-level errors are independent of the random effects.

Using the Heckman estimator (heckman) for this model will provide inefficient estimates because it ignores the within-panel correlation. Instead, we use maximum likelihood to model both the selection and outcome equations and account for the panel structure of the data. This random-effects estimator is used by xteregress and was discussed in Rabe-Hesketh, Skrondal, and Pickles (2002). There is no parametric fixed-effects estimator for panel data from an endogenously selected sample. See Honoré, Kyriazidou, and Powell (2000) and Kyriazidou (1997) for semiparametric fixed-effects estimators of panel-data endogenous sample-selection models.

Example 1

Suppose that we wish to study the relationship between wage, job tenure, and age for collegeeducated adults. We have fictional data on 600 adults observed from 2013 to 2016. We use these data to model hourly wage as a function of age, age squared, and job tenure. However, an individual's wage is observed only if he or she works, and not everyone was employed on the dates the data were collected. We are not interested in modeling only the subpopulation of individuals who were employed at the time. We are also interested in the relationship of job tenure and age with the wage an individual would have received if he or she had been employed.

We suspect that the unobserved factors that affect an individual's wage are related to the unobserved factors that affect employment status. These unobserved factors could include person-level characteristics like ability and time-varying factors like an individual's family situation. We suspect that we have an endogenously selected sample. We have data on the local job market conditions (market). This variable is used with age and tenure to model the employment status of an individual.

Before we can fit a random-effects model to our data, we need to specify the panel structure of the data using xtset. Our panel variable is personid, the identification code for the individual. The time variable is year, and it ranges from 2013 to 2016.

```
. use https://www.stata-press.com/data/r18/wagework
(Wages for 20 to 77 year olds, 2013-2016)
. xtset personid year
Panel variable: personid (strongly balanced)
```

Time variable: year, 2013 to 2016 Delta: 1 unit

We are now ready to fit our model.

The first two sections of the output provide the estimated coefficients for the wage equation and the selection (working) equation. We can interpret the coefficients in the wage equation using the standard linear regression interpretation. For example, we expect an increase of \$0.59 per hour for an additional year of job tenure.

Next we see var(e.wage), an estimate of the variance of the observation-level error for wage; this is followed by corr(e.working,e.wage), an estimate of its correlation with the observation-level error for the selection model. The next section of the output reports estimates of the variances of the random effects, var(wage[personid]) and var(working[personid]). The last section reports an estimate of the correlation of these random effects. If at least one of the correlations is significantly different from zero, we can conclude that we have endogenous sample selection. In our case, the correlation between the observation-level errors is 0.41, and the correlation between the random effects is 0.60. Because both are positive and significantly different from zero, we conclude that we have endogenous selection and that unobserved individual-level factors that increase the chance of being employed tend to increase wage. Additionally, unobserved observation-level (time-varying) factors that increase the chance of being employed tend to increase wage.

We estimated coefficients for age and age squared. We can use margins and marginsplot to gain a clearer understanding of the effect of the individuals' age on hourly wage. We use margins with at() to profile the expected wages for individuals between ages 30 and 70 and with 0 and 5 years of job tenure. Then, we use marginsplot to graph the estimates.

- . margins, at(age=(30(5)70) tenure = (0 5))
- . marginsplot

Based on this model, and assuming the data are from a random or otherwise representative sample, the plotted points represent the expected wage for individuals with the specified job tenure and age. We see that age has an increasing effect on expected wage until the mid-60s and then attenuates. Having 5 years of job tenure instead of none shifts the curve up by about \$3.00 per hour.

In addition to the above, the following is stored in r():

Matrices

r(table)

matrix containing the coefficients with their standard errors, test statistics, p-values, and confidence intervals

Note that results stored in r() are updated when the command is replayed and will be replaced when any r-class command is run after the estimation command.

Methods and formulas

xtheckman fits a random-effects linear regression model with endogenous sample selection via maximum likelihood estimation. For details on maximum likelihood estimators, see the results in Wooldridge (2010, chap. 13) and White (1996).

The log-likelihood function maximized by xtheckman is implied by the triangular structure of the model. Specifically, the joint distribution of the outcome and selection variables is a product of conditional and marginal distributions because the model is triangular. For a few of the many relevant applications of this result in literature, see Amemiya (1985, chap. 10); Heckman (1976, 1979); Maddala (1983, chap. 5); Maddala and Lee (1976); Wooldridge (2010, sec. 15.7.2, 15.7.3, 16.3.3, 17.5.2, and 19.7.1; 2014). Roodman (2011) and Bartus and Roodman (2014) used this result to derive the formulas discussed below.

We have panels i = 1, ..., N and observations $t = 1, ..., N_i$. We model y_{it} as

$$y_{it} = \mathbf{x}_{it}\boldsymbol{\beta} + \nu_{1i} + \epsilon_{1it}$$

where \mathbf{x}_{it} are the outcome covariates, ν_{1i} is the panel-level random effect, and ϵ_{1it} is the observationlevel error.

The selection process for the outcome is modeled by

$$s_{it} = 1 \left(\mathbf{z}_{it} \boldsymbol{\alpha} + \nu_{2i} + \epsilon_{2it} > 0 \right)$$

where $s_{it} = 1$ if we observe y_{it} and 0 otherwise, \mathbf{z}_{it} are the selection covariates, ν_{2i} is the panel-level random effect for selection, and ϵ_{2it} is the observation-level selection error.

The random effects ν_{1i} and ν_{2i} are bivariate normal with mean 0 and variance

$$\boldsymbol{\Sigma}_{\nu} = \begin{bmatrix} \sigma_{1\nu}^2 & \rho_{\nu}\sigma_{1\nu}\sigma_{2\nu} \\ \rho_{\nu}\sigma_{1\nu}\sigma_{2\nu} & \sigma_{2\nu}^2 \end{bmatrix}$$

The observation-level errors ϵ_{1it} and ϵ_{2it} are independent of the random effects and are also bivariate normal, with mean 0 and variance

$$\mathbf{\Sigma} = \begin{bmatrix} \sigma_1^2 & \rho \sigma_1 \\ \rho \sigma_1 & 1 \end{bmatrix}$$

When we condition on the random effects ν_{1i} and ν_{2i} , we can write the joint density of the y_{it} and s_{it} using the conditional density of the selection error ϵ_{2it} on the outcome error ϵ_{1it} .

For the selection indicator s_i , we have lower limit l_{it} and upper limit u_{it} ,

$$l_{it} = \begin{cases} -\infty & s_{it} = 0 \\ -\mathbf{z}_{it}\boldsymbol{\alpha} - \nu_{2i} - \frac{\rho}{\sigma_1} \left(y_{it} - \mathbf{x}_{it}\boldsymbol{\beta} - \nu_{1i} \right) & s_{it} = 1 \end{cases} \qquad u_{it} = \begin{cases} -\mathbf{z}_{it}\boldsymbol{\alpha} - \nu_{2i} & s_{it} = 0 \\ \infty & s_{it} = 1 \end{cases}$$

Then, the joint density of y_{it} and s_{it} conditional on the random effects is

$$f(y_{it}, s_{it} | \nu_{1i}, \nu_{2i}) = \begin{cases} \Phi\left(\frac{-l_{it}}{\sqrt{1-\rho^2}}\right) + \phi\left(\frac{y_{it} - \mathbf{x}_{it} \boldsymbol{\beta}}{\sigma_1}\right) & s_{it} = 1\\ \Phi\left(\frac{u_{it}}{\sqrt{1-\rho^2}}\right) & s_{it} = 0 \end{cases}$$

Note that each panel has the same random effects for each observation. So the likelihood for panel i is

$$L_{i} = \int_{\Re^{2}} \left[\prod_{t=1}^{N_{i}} f(y_{it}, s_{it} | \nu_{1i}, \nu_{2i}) \phi_{2} \{ (\nu_{1i}, \nu_{2i}), \Sigma_{\nu} \} d\nu_{1i} d\nu_{2i} \right]$$
(1)

This multivariate integral is generally not tractable. We can use a change-of-variables technique to transform it into a set of nested univariate integrals. Let \mathbf{L} be the Cholesky decomposition of Σ_{ν} ; that is, $\Sigma_{\nu} = \mathbf{L}\mathbf{L}'$. It follows that $(\nu_{1i}, \nu_{2i})' = \mathbf{L}\psi_i$, where ψ_i is a vector of independent standard normal random variables.

We can rewrite (1) as

$$L_{i} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left\{ \prod_{t=1}^{N_{i}} f(y_{it}, s_{it} | (\nu_{1i}, \nu_{2i})' = \mathbf{L} \psi_{i}) \right\} \phi(\psi_{1i}) \phi(\psi_{2i}) d\psi_{1i} d\psi_{2i}$$

Now the univariate integral can be approximated using Gauss-Hermite quadrature (GHQ). For q-point GHQ, let the abscissa and weight pairs be denoted by (a_k^*, w_k^*) , where $k = 1, \ldots, q$. The GHQ approximation is then

$$\int_{-\infty}^{\infty} f(x) \exp(-x^2) \, dx \approx \sum_{k=1}^q w_k^* f(a_k^*)$$

Consider a 2-dimensional quadrature grid containing q quadrature points in both dimensions. Let the vector of abscissas $\mathbf{a}_k = (a_{k_1}, a_{k_2})'$ be a point in this grid, and let $\mathbf{w}_k = (w_{k_1}, w_{k_2})'$ be the vector of corresponding weights.

The GHQ approximation to the likelihood for a given panel is

$$L_i = \sum_{k_1=1}^q \sum_{k_2=1}^q \left[\left\{ \prod_{t=1}^{N_i} f(y_{it}, s_{it} | (\nu_{1i}, \nu_{2i})' = \mathbf{L} \mathbf{a}_k) \right\} \left\{ \prod_{s=1}^2 w_{k_s} \right\} \right]$$

Rather than using regular GHQ, we can use mean-variance adaptive GHQ. Fixing the observed variables and model parameters in the integrand of (1), we see the posterior density for ψ_i is proportional to

$$\left\{ \prod_{t=1}^{N_i} f(y_{it}, s_{it} | (\nu_{1i}, \nu_{2i})' = \mathbf{L} \boldsymbol{\psi}_i) \right\} \phi(\boldsymbol{\psi}_i)$$

It is reasonable to assume that this posterior density can be approximated by a multivariate normal density with mean vector μ_{vi} and variance matrix τ_{vi} . Instead of using the prior density of ψ_i as the weighting distribution in the integral, we can use our approximation for the posterior density,

$$L_i = \int_{\Re^2} \frac{\left\{ \prod_{t=1}^{N_i} f(y_{it}, s_{it} | (\nu_{1i}, \nu_{2i})' = \mathbf{L} \boldsymbol{\psi}_i) \right\} \phi(\boldsymbol{\psi}_i)}{\phi(\boldsymbol{\psi}_i, \boldsymbol{\mu}_{vi}, \boldsymbol{\tau}_{vi})} \phi(\boldsymbol{\psi}_i, \boldsymbol{\mu}_{vi}, \boldsymbol{\tau}_{vi}) \, d\boldsymbol{\psi}_i$$

The likelihood is then approximated by

$$L_i = \sum_{k_1=1}^{q} \dots \sum_{k_2=1}^{q} \left[\left\{ \prod_{t=1}^{N_i} f(y_{it}, s_{it} | (\nu_{1i}, \nu_{2i})' = \mathbf{L} \alpha_k) \right\} \left\{ \prod_{s=1}^{2} \omega_{k_s} \right\} \right]$$

where α_k and ω_{k_s} are the adaptive versions of the abscissas and weights after an orthogonalizing transformation, which eliminates posterior covariances between elements of ψ_i . The posterior means μ_{vi} and posterior variances τ_{vi} are computed iteratively by updating the posterior moments by using the mean-variance adaptive GHQ approximation, starting with a 0 mean vector and identity variance matrix.

The log likelihood for all panels is then

$$\ln L = \sum_{i=1}^{N} \left(\ln \sum_{k_1=1}^{q} \dots \sum_{k_2=1}^{q} \left[\left\{ \prod_{t=1}^{N_i} f(y_{it}, s_{it} | (\nu_{1i}, \nu_{2i})' = \mathbf{L} \alpha_k) \right\} \left\{ \prod_{s=1}^{2} \omega_{k_s} \right\} \right] \right)$$

The conditional mean of y_{it} is

$$E(y_{it}|\mathbf{x}_{it}) = \mathbf{x}_{it}\boldsymbol{\beta}$$

xtheckman results are obtained using xteregress; see Methods and formulas of [ERM] eregress.
