Description

nlogit performs full information maximum-likelihood estimation for nested logit models. These models relax the assumption of independently distributed errors and the independence of irrelevant alternatives inherent in conditional and multinomial logit models by clustering similar alternatives into nests.

By default, nlogit uses a parameterization that is consistent with a random utility model (RUM). Before version 10 of Stata, a nonnormalized version of the nested logit model was fit, which you can request by specifying the nonnormalized option.

You must use nlogitgen to generate a new categorical variable to specify the branches of the nested logit tree before calling nlogit.

Quick start

Create variables identifying alternatives at higher levels

For a three-level nesting structure, create 12alt identifying four alternatives at level two based on the variable balt, which identifies eight bottom-level alternatives

Same as above, defining 12alt from values of balt rather than from value labels

```
nlogitgen 12alt = balt(12alt1: 1|2, 12alt2: 3|4, 12alt3: 5|6, /// 12alt4: 7|8)
```

Create talt identifying top-level alternatives based on the four alternatives in 12alt

```
nlogitgen talt = 12alt(talt1: 12alt1 | 12alt2, talt2: 12alt3 | 12alt4)
```

Examine tree structure

Display three-level nesting structure

```
nlogittree balt 12alt talt
```

Also report choice frequencies of indicator chosen for each bottom-level alternative nlogittree balt 12alt talt, choice(chosen)

Identify potentially problematic observations before fitting the model by specifying case identifier casevar

```
nlogittree balt 12alt talt, choice(chosen) case(casevar)
```

Same as above, and generate prob indicating problematic observations nlogittree balt 12alt talt, choice(chosen) case(casevar) generate(prob)

Fit nested logit model

Three-level model with alternative-specific covariate x1, case-specific covariate x2 modeling top-level choice, and case-specific covariate x3 modeling level-two choice

```
nlogit chosen x1 || talt: x2 || 12alt: x3 || balt:, case(casevar)
```

Same as above, but do not estimate intercepts for bottom-level alternatives

```
nlogit chosen x1 || talt: x2 || 12alt: x3 || balt:, noconstant ///
     case(casevar)
```

Same as above, but estimate intercepts for top-level alternatives

```
nlogit chosen x1 || talt: x2, estconst || 12alt: x3 ///
     || balt:, noconstant case(casevar)
```

Specify the base alternative at each level

```
nlogit chosen x1 || talt: x2, base(talt2) || 12alt: x3, base(12alt4)
     || balt:, base(balt8) case(casevar)
```

Use nonnormalized parameterization

```
nlogit chosen x1 || talt: x2 || 12alt: x3 || balt:, case(casevar) ///
     nonnormalized
```

4 nlogit - Nested logit regression

nlogit_options	Description					
Model						
*case(varname)	use varname to identify cases					
$base(\# \mathit{lbl})$	use the specified level or label of <i>altvar</i> as the base alternative the bottom level					
<u>nocons</u> tant	suppress the constant terms for the bottom-level alternatives					
<u>nonn</u> ormalized	use the nonnormalized parameterization					
altwise	use alternativewise deletion instead of casewise deletion					
<pre>constraints(constraints)</pre>	apply specified linear constraints					
SE/Robust						
vce(vcetype)	<pre>vcetype may be oim, robust, cluster clustvar, bootstrap, or jackknife</pre>					
Reporting						
$\underline{1}$ evel(#)	set confidence level; default is level(95)					
<u>notr</u> ee	suppress display of tree-structure output; see also nolabel and nobranches					
<u>nocnsr</u> eport	do not display constraints					
display_options	control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling					
Maximization						
maximize_options	control the maximization process; seldom used					
<u>col</u> linear	keep collinear variables					
*case(varname) is required.						
nlogittree_options	Description					
Main						
<pre>choice(depvar)</pre>	use depvar as the choice indicator variable					
case(varname)	use varname to identify cases					
<pre>generate(newvar)</pre>	create newvar to identify invalid observations					
<u>nolab</u> el	suppress the value labels in tree-structure output					
nobranches	suppress drawing branches in the tree-structure output					

byaltvarlist may contain factor variables; see [U] 11.4.3 Factor variables.

bootstrap, by, collect, fp, jackknife, and statsby are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

fweights, iweights, and pweights are allowed with nlogit, and fweights are allowed with nlogittree; see [U] 11.1.6 weight. Weights for nlogit must be constant within case.

collinear does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Options

Specification and options for lev#_equation

altvar is a variable identifying alternatives at this level of the hierarchy.

byaltvarlist specifies the variables to be used to compute the by-alternative regression coefficients for that level. For each variable specified in the variable list, there will be one regression coefficient for each alternative of that level of the hierarchy. If the variable is constant across each alternative (a case-specific variable), the regression coefficient associated with the base alternative is not identifiable. These regression coefficients are labeled as (base) in the regression table. If the variable varies among the alternatives, a regression coefficient is estimated for each alternative.

base (# | lbl) can be specified in each level equation where it identifies the base alternative to be used at that level. The default is the alternative that has the highest frequency.

If vce(bootstrap) or vce(jackknife) is specified, you must specify the base alternative for each level that has a *byaltvarlist* or whether the constants will be estimated. Doing so ensures that the same model is fit with each call to nlogit.

estconst applies to all the level equations except the bottom-level equation. Specifying estconst requests that constants for each alternative (except the base alternative) be estimated. By default, no constant is estimated at these levels. Constants can be estimated in only one level of the tree hierarchy. If you specify estconst for one of the level equations, you must specify noconstant for the bottom-level equation.

Options for nlogit

Model

case (varname) specifies the variable that identifies each case. case() is required.

base(#|lbl) can be specified in each level equation where it identifies the base alternative to be used at that level. The default is the alternative that has the highest frequency.

If vce(bootstrap) or vce(jackknife) is specified, you must specify the base alternative for each level that has a *byaltvarlist* or whether the constants will be estimated. Doing so ensures that the same model is fit with each call to nlogit.

- noconstant applies only to the equation defining the bottom level of the hierarchy. By default, constants are estimated for each alternative of *altvar*, less the base alternative. To suppress the constant terms for this level, specify noconstant. If you do not specify noconstant, you cannot specify estconst for the higher-level equations.
- nonnormalized requests a nonnormalized parameterization of the model that does not scale the inclusive values by the degree of dissimilarity of the alternatives within each nest. Use this option to replicate results from older versions of Stata. The default is to use the RUM-consistent parameterization.
- altwise specifies that alternativewise deletion be used when omitting observations because of missing values in your variables. The default is to use casewise deletion; that is, the entire group of observations making up a case is omitted if any missing values are encountered. This option does not apply to observations that are excluded by the if or in qualifier or the by prefix; these observations are always handled alternativewise regardless of whether altwise is specified.

6

constraints (constraints); see [R] Estimation options.

The inclusive-valued/dissimilarity parameters are parameterized as ml ancillary parameters. They are labeled as [alternative_tau]_const, where alternative is one of the alternatives defining a branch in the tree. To constrain the inclusive-valued/dissimilarity parameter for alternative al to be, say, equal to alternative a2, you would use the following syntax:

- . constraint 1 [a1_tau]_cons = [a2_tau]_cons
- . nlogit ..., constraints(1)

SE/Robust

vce(vcetype) specifies the type of standard error reported, which includes types that are derived
from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that
allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods
(bootstrap, jackknife); see [R] vce_option.

If vce(robust) or vce(cluster *clustvar*) is specified, the likelihood-ratio test for the independence of irrelevant alternatives (IIA) is not computed.

Reporting

level(#); see [R] Estimation options.

notree specifies that the tree structure of the nested logit model not be displayed. See also nolabel and nobranches below for when notree is not specified. cmd:notree may not be specified on replay.

nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels,
 allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt),
 sformat(%fmt), and nolstretch; see [R] Estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace,
 gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#),
 nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are
 seldom used.

The technique(bhhh) option is not allowed. The default optimization technique is technique(bfgs).

The following option is available with nlogit but is not shown in the dialog box:

collinear prevents collinear variables from being omitted. Use this option when you know that you have collinear variables and you are applying constraints() to handle the rank reduction. See [R] Estimation options for details on using collinear with constraints().

nlogit will not allow you to specify an independent variable in more than one level equation. Specifying the collinear option will allow execution to proceed in this case, but it is your responsibility to ensure that the parameters are identified.

Specification and options for nlogitgen

newaltvar and altvar are variables identifying alternatives at each level of the hierarchy.

label defines a label to associate with the branch. If no label is given, a numeric value is used.

alternative specifies an alternative, of altvar specified in the syntax, to be included in the branch. It is either a numeric value or the label associated with that value. An example of nlogitgen is

```
. nlogitgen type = restaurant(fast: 1 | 2,
> family: CafeEccell | LosNortenos | WingsNmore, fancy: 6 | 7)
```

log and nolog specify whether to display the iteration log. The iteration log is displayed by default unless you used set iterlog off to suppress it; see set iterlog in [R] set iter.

Specification and options for nlogittree

Main

altvarlist is a list of alternative variables that define the tree hierarchy. The first variable must define bottom-level alternatives, and the order continues to the variable defining the top-level alternatives.

choice (depvar) defines the choice indicator variable and forces nlogittree to compute and display choice frequencies for each bottom-level alternative.

case(varname) specifies the variable that identifies each case. When both case() and choice() are specified, nlogittree executes diagnostics on the tree structure and identifies observations that will cause nlogit to terminate execution or drop observations.

generate(newvar) generates a new indicator variable, newvar, that is equal to 1 for invalid observations. This option requires that both choice() and case() are also specified.

nolabel forces nlogittree to suppress value labels in tree-structure output.

nobranches forces nlogittree to suppress drawing branches in the tree-structure output.

Remarks and examples

stata.com

Remarks are presented under the following headings:

Introduction Data setup and the tree structure Estimation Testing for the IIA Nonnormalized model

Introduction

nlogit performs full information maximum-likelihood estimation for nested logit models. These models relax the assumption of independently distributed errors and the IIA inherent in conditional and multinomial logit models by clustering similar alternatives into nests. The nested logit model is a direct generalization of McFadden's choice model fit by cmclogit. You may want to read [CM] Intro 5, [CM] Intro 8, and [CM] cmclogit before continuing.

Although nlogit fits choice models, it is not a cm command, and you do not have to cmset your data. nlogit has its own data requirements for nested alternatives, which are detailed in the following examples.

By default, nlogit uses a RUM parameterization. Before version 10 of Stata, a nonnormalized version of the nested logit model was fit, which you can request by specifying the nonnormalized option. We recommend using the RUM parameterization for new projects because it is based on a sound model of consumer behavior.

McFadden (1977, 1981) showed how this model can be derived from a rational choice framework. Amemiya (1985, chap. 9) contains a nice discussion of how this model can be derived under the assumption of utility maximization. Hensher, Rose, and Greene (2015) provide a lucid introduction to choice models, including nested logit.

Throughout this entry, we consider a model of restaurant choice. We begin by introducing the data.

Example 1: Families choosing a restaurant

We have fictional data on 300 families and their choice of seven local restaurants. Freebirds and Mama's Pizza are fast food restaurants; Café Eccell, Los Norteños, and Wings 'N More are family restaurants; and Christopher's and Mad Cows are fancy restaurants. We want to model the decision of where to eat as a function of household income (income, in thousands of dollars), the number of children in the household (kids), the rating of the restaurant according to a local restaurant guide (rating, coded 0-5), the average meal cost per person (cost), and the distance between the household and the restaurant (distance, in miles). income and kids are attributes of the family, rating is an attribute of the alternative (the restaurant), and cost and distance are attributes of the alternative as perceived by the families—that is, each family has its own cost and distance for each restaurant.

We begin by loading the data and listing some of the variables for the first three families:

- . use https://www.stata-press.com/data/r18/restaurant
- . describe

Contains data from https://www.stata-press.com/data/r18/restaurant.dta 2,100 Observations:

Variables:

2 Dec 2022 15:07

Variable name	Storage type	Display format	Value label	Variable label
family_id	int	%9.0g		family ID
restaurant	byte	%12.0g	names	choices of restaurants
income	int	%9.0g		household income
cost	float	%9.0g		average meal cost per person
kids	byte	%9.0g		number of kids in the household
rating	byte	%9.0g		ratings in local restaurant guide
distance	float	%9.0g		distance between home and restaurant

20.	3	Christophers	0	3	4	9.551273
21.	3	MadCows	0	3	5	5.539806

Because each family chose among seven restaurants, there are 7 observations in the dataset for each family. The variable chosen is coded 0/1, with 1 indicating the chosen restaurant and 0 otherwise.

We could fit a conditional logit model to our data. Because income and kids are constant within each family, we would use the cmclogit command instead of clogit. However, the conditional logit may be inappropriate. That model assumes that the random errors are independent, and as a result, it forces the odds ratio of any two alternatives to be independent of the other alternatives, a property known as the IIA. We will discuss the IIA assumption in more detail later.

Assuming that unobserved shocks influencing a decision maker's attitude toward one alternative have no effect on his or her attitude toward the other alternatives may seem innocuous, but often this assumption is too restrictive. Suppose that when a family was deciding which restaurant to visit, they were pressed for time because of plans to attend a movie later. The unobserved shock (being in a hurry) would raise the likelihood that the family goes to either fast food restaurant (Freebirds or Mama's Pizza). Similarly, another family might be choosing a restaurant to celebrate a birthday and therefore be inclined to attend a fancy restaurant (Christopher's or Mad Cows).

Nested logit models relax the independence assumption and allow us to group alternatives for which unobserved shocks may have concomitant effects. Here we suspect that restaurants should be grouped by type (fast, family, or fancy). The tree structure of a family's decision about where to eat might look like this:

At the bottom of the tree are the individual restaurants, indicating that there are some random shocks that affect a family's decision to eat at each restaurant independently. Above the restaurants are the three types of restaurants, indicating that other random shocks affect the type of restaurant chosen. As is customary when drawing nested logit trees, at the top level is one box, representing the family making the decision.

We use the following terms to describe nested logit models.

level, or decision level, is the level or stage at which a decision is made. The example above has only two levels. In the first level, a type of restaurant is chosen—fast food, family, or fancy—and in the second level, a specific restaurant is chosen.

bottom level is the level where the final decision is made. In our example, this is when we choose a specific restaurant.

alternative set is the set of all possible alternatives at any given decision level.

bottom alternative set is the set of all possible alternatives at the bottom level. This concept is often referred to as the choice set in the economics-choice literature. In our example, the bottom alternative set is all seven of the specific restaurants.

alternative is a specific alternative within an alternative set. In the first level of our example, "fast food" is an alternative. In the second or bottom level, "Mad Cows" is an alternative. Not all alternatives within an alternative set are available to someone making a choice at a specific stage, only those that are nested within all higher-level decisions.

chosen alternative is the alternative from an alternative set that we observe someone having chosen.

□ Technical note

Although the trees in nested logit analysis are often interpreted as implying that the highest-level decisions are made first, followed by decisions at lower levels, and finally the decision among alternatives at the bottom level, no such temporal ordering is implied. See Hensher, Rose, and Greene (2015, chap. 14). In our example, we are not assuming that families first choose whether to attend a fast, family, or fancy restaurant and then choose the particular restaurant; we assume merely that they choose one of the seven restaurants.

Data setup and the tree structure

To fit a nested logit model, you must first create a variable that defines the structure of your nested logit tree.

Example 2: Identifying the first-level set of alternatives

To run nlogit, we need to generate a categorical variable that identifies the first-level set of alternatives: fast food, family restaurants, or fancy restaurants. We can do so easily by using nlogitgen.

```
. nlogitgen type = restaurant(fast: Freebirds | MamasPizza,
> family: CafeEccell | LosNortenos| WingsNmore, fancy: Christophers | MadCows)
New variable type is generated with 3 groups
label list lb_type
lb_type:
           1 fast
           2 family
           3 fancy
```

. nlogittree restaurant type, choice(chosen)

Tree structure specified for the nested logit model

type	N		restaurant	N	k
fast	600		Freebirds MamasPizza	300	12
		ᆫ	MamasPizza	300	15
family	900		CafeEccell	300	78
		-	CafeEccell LosNortenos WingsNmore	300	75
		ᆫ	WingsNmore	300	69
fancy	600		Christophers MadCows	300	27
-		L_	MadCows	300	24

2100 300 Total

k = number of times alternative is chosen N = number of observations at each level

The new categorical variable is type, which takes on value 1 (fast) if restaurant is Freebirds or Mama's Pizza; value 2 (family) if restaurant is Café Eccell, Los Norteños, or Wings 'N More; and value 3 (fancy) otherwise. nlogittree displays the tree structure. 4

□ Technical note

We could also use values instead of value labels of restaurant in nlogitgen. Value labels are optional, and the default value labels for type are type1, type2, and type3. The vertical bar is also optional.

```
. use https://www.stata-press.com/data/r18/restaurant, clear
. nlogitgen type = restaurant(1 2, 3 4 5, 6 7)
New variable type is generated with 3 groups
label list lb_type
lb_type:
           1 type1
           2 type2
           3 type3
```

. nlogittree restaurant type

Tree structure specified for the nested logit model

type	N	rest	aurant	N
type1	600	Free Mama	birds	300
				300
type2	900	— Cafe	Eccell	300
		Cafe LosN Wing	ortenos	300
		L Wing	sNmore	300
type3	600	T Chri	stopher	s 300
		└ MadC	ows	300
			Total	2100

N = number of observations at each level

In our dataset, every family was able to choose among all seven restaurants. However, in other applications some decision makers may not have been able to choose among all possible alternatives. For example, two cases may have choice hierarchies of

cas	se 1	cas	se 2
type	restaurant	type	restaurant
fast -	Freebirds MamasPizza	fast -	⊤ Freebirds MamasPizza
family -	CafeEccell LosNortenos WingsNmore	family -	LosNortenos WingsNmore
	Christophers MadCows	fancy -	Christophers

where the second case does not have the restaurant alternatives Café Eccell or Mad Cows available to them. The only restriction is that the relationships between higher- and lower-level alternative sets be the same for all decision makers. In this two-level example, Freebirds and Mama's Pizza are classified as fast food restaurants for both cases; Café Eccell, Los Norteños, and Wings 'N More are family restaurants; and Christopher's and Mad Cows are fancy restaurants. nlogit requires only that hierarchy be maintained for all cases.

Estimation

Example 3: Fitting the model

With our type variable created that defines the three types of restaurants, we can now examine how the alternative-specific attributes (cost, rating, and distance) apply to the bottom alternative set (the seven restaurants) and how family-specific attributes (income and kid) apply to the alternative set at the first decision level (the three types of restaurants).

- . use https://www.stata-press.com/data/r18/restaurant, clear
- . quietly nlogitgen type = restaurant(fast: Freebirds | MamasPizza,
- > family: CafeEccell | LosNortenos| WingsNmore, fancy: Christophers | MadCows)
- . nlogit chosen cost rating distance || type: income kids, base(family) ||
- > restaurant:, noconstant case(family_id)

Tree structure specified for the nested logit model

First, let's examine how we called nlogit. The delimiters (||) separate equations. The first equation specifies the dependent variable, chosen, and three alternative-specific variables, cost, rating, and distance. We refer to these variables as alternative specific because they vary among the bottom-level alternatives, the restaurants. We obtain one parameter estimate for each variable. These estimates are listed in the equation subtable labeled restaurant.

For the second equation, we specify the type variable. It identifies the first-level alternatives, the restaurant types. Following the colon after type, we specify two case-specific variables, income and kids. Here we obtain a parameter estimate for each variable for each alternative at this level. That is why we call these variable lists "by-alternative" variables. Because income and kids do not vary within each case, to identify the model, one must specify the alternative set of parameters as zero. We specified the base(family) option with this equation to restrict the parameters for the family alternative.

The variable identifying the bottom-level alternatives, restaurant, is specified after the second equation delimiter. We do not specify any variables after the colon delimiter at this level. Had we specified variables here, we would have obtained an estimate for each variable in each equation. As we will see below, these variables parameterize the constant term in the utility equation for each bottom-level alternative. The noconstant option suppresses bottom-level alternative-specific constant terms.

Near the bottom of the output are the dissimilarity parameters, which measure the degree of correlation of random shocks within each of the three types of restaurants. Dissimilarity parameters greater than one imply that the model is inconsistent with random utility maximization; Hensher, Rose, and Greene (2005, sec. 13.6) discuss this in detail. We will ignore the fact that all our dissimilarity parameters exceed one.

The conditional logit model is a special case of nested logit in which all the dissimilarity parameters are equal to one. At the bottom of the output, we find a likelihood-ratio test of this hypothesis. Here we have mixed evidence of the null hypothesis that all the parameters are one. Equivalently, the property known as the IIA imposed by the conditional logit model holds if and only if all dissimilarity parameters are equal to one. We discuss the IIA in more detail now.

Testing for the IIA

The IIA is a property of the multinomial and conditional logit models that forces the odds of choosing one alternative over another to be independent of the other alternatives. For simplicity, suppose that a family was choosing only between Freebirds and Mama's Pizza, and the family was equally likely to choose either of the restaurants. The probability of going to each restaurant is 50%. Now suppose that Bill's Burritos opens up next door to Freebirds, which is also a burrito restaurant. If the IIA holds, then the probability of going to each restaurant must now be 33.33% so that the family remains equally likely to go to Mama's Pizza or Freebirds.

The IIA may sometimes be a plausible assumption. However, a more likely scenario would be for the probability of going to Mama's Pizza to remain at 50% and the probabilities of going to Freebirds and Bill's Burritos to be 25% each, because the two restaurants are next door to each other and serve the same food. Nested logit analysis would allow us to relax the IIA assumption of conditional logit. We could group Bill's Burritos and Freebirds into one nest that encompasses all burrito restaurants and create a second nest for pizzerias.

The IIA is a consequence of assuming that the errors are independent and identically distributed (i.i.d.). Because the errors are i.i.d., they cannot contain any alternative-specific unobserved information, and therefore adding a new alternative cannot affect the relationship between a pair of existing alternatives.

4

In the previous example, we saw that a joint test that the dissimilarity parameters were equal to one is one way to test for IIA. However, that test required us to specify a tree for the nested logit model, and different specifications could lead to conflicting results of the test. Hausman and McFadden (1984) suggest that if part of the choice set truly is irrelevant with respect to the other alternatives, omitting that subset from the conditional logit model will not lead to inconsistent estimates. Therefore, Hausman's (1978) specification test can be used to test for IIA, and this test will not be sensitive to the tree structure we specify for a nested logit model.

Example 4: Testing the IIA assumption

We want to test the IIA for the subset of family restaurants against the alternatives of fast food and fancy restaurants. To do so, we need to use Stata's hausman command; see [R] hausman.

We first run the estimation on the full bottom alternative set, store the results by using estimates store, and then run the estimation on the bottom alternative set, excluding the alternatives of family restaurants. We then run the hausman test.

B = Inconsistent under Ha, efficient under HO; obtained from clogit.

Test of HO: Difference in coefficients not systematic

 $chi2(5) = (b-B)'[(V_b-V_B)^(-1)](b-B)$

= 10.70Prob > chi2 = 0.0577

(V_b-V_B is not positive definite)

Similar to our findings in example 3, the results of the test of the IIA are mixed. We cannot reject the IIA at the commonly used 5% significance level, but we could at the 10% level. Substantively, a significant test result suggests that the odds of going to one of the fancy restaurants versus going to one of the fast food restaurants change if we include the family restaurants in the alternative set and that a nested logit specification may be warranted.

1

Nonnormalized model

Previous versions of Stata fit a nonnormalized nested logit model that is available via the nonnormalized option. The nonnormalized version is presented in, for example, Greene (2018, 837–839). Here we outline the differences between the nonnormalized model and the random utility parameterization of the model. Our discussion follows Heiss (2002) and assumes the nested logit tree has two levels, with M alternatives at the upper level and a total of J alternatives at the bottom level.

In a RUM framework, by consuming alternative j, decision maker i obtains utility

$$U_{ij} = V_{ij} + \epsilon_{ij} = \alpha_j + \mathbf{x}_{ij}\boldsymbol{\beta}_j + \mathbf{z}_i\boldsymbol{\gamma}_j + \epsilon_{ij}$$

where V_{ij} is the deterministic part of utility and ϵ_{ij} is the random part. \mathbf{x}_{ij} are alternative-specific variables and \mathbf{z}_i are case-specific variables. The set of errors $\epsilon_{i1}, \ldots, \epsilon_{iJ}$ are assumed to follow the generalized extreme-value (GEV) distribution, which is a generalization of the type 1 extreme-value distribution that allows for alternatives within nests of the tree structure to be correlated. Let ρ_m denote the correlation in nest m, and define the dissimilarity parameter $\tau_m = \sqrt{1-\rho_m}$. $\tau_m = 0$ implies that the alternatives in nest m are perfectly correlated, whereas $\tau_m=1$ implies independence.

The inclusive value for the mth nest corresponds to the expected value of the utility that decision maker i obtains by consuming an alternative in nest m. Denote this value by IV_m ,

$$IV_m = \ln \sum_{j \in B_m} \exp(V_k/\tau_m) \tag{1}$$

where B_m denotes the set of alternatives in nest m. Given the inclusive values, we can show that the probability that random-utility-maximizing decision maker i chooses alternative j is

$$\Pr_{j} = \frac{\exp\{V_{j}/\tau(j)\}}{\exp\{\text{IV}(j)\}} \frac{\exp\{\tau(j)\text{IV}(j)\}}{\sum_{m} \exp(\tau_{m}\text{IV}_{m})}$$

where $\tau(j)$ and $\mathrm{IV}(j)$ are the dissimilarity parameter and inclusive value for the nest in which alternative j lies.

In contrast, for the nonnormalized model, we have a latent variable

$$\widetilde{V}_{i,j} = \widetilde{\alpha}_j + \mathbf{x}_{i,j}\widetilde{\boldsymbol{\beta}}_j + \mathbf{z}_i\widetilde{\boldsymbol{\gamma}}_j$$

and corresponding inclusive values

$$\widetilde{\mathrm{IV}}_m = \ln \sum_{j \in B_m} \exp(\widetilde{V}_k) \tag{2}$$

The probability of choosing alternative j is

$$\mathrm{Pr}_j = \frac{\exp(\widetilde{V}_j)}{\exp\{\widetilde{\mathrm{r}}\widetilde{\mathrm{V}}(j)\}} \frac{\exp\{\tau(j)\widetilde{\mathrm{r}}\widetilde{\mathrm{V}}(j)\}}{\sum_m \exp(\tau_m\widetilde{\mathrm{r}}\widetilde{\mathrm{V}}_m)}$$

Equations (1) and (2) represent the key difference between the random utility and the nonnormalized models. By scaling the V_{ij} within each nest, the RUM parameterization allows utilities to be compared across nests. Without the rescaling, utilities can be compared only for goods within the same nest. Moreover, adding a constant to each V_{ij} for consumer i will not affect the probabilities of the RUM, but adding a constant to each \widetilde{V}_{ij} will affect the probabilities from the nonnormalized model. Decisions based on utility maximization can depend only on utility differences and not the scale or zero point of the utility function because utility is an ordinal concept, so the nonnormalized model cannot be consistent with utility maximization.

Heiss (2002) showed that the nonnormalized model can be consistent with a random utility parameterization in the special case where all the variables are specified in the bottom-level equation. Then multiplying the nonnormalized coefficients by the respective dissimilarity parameters results in the coefficients that are consistent with a RUM.

□ Technical note

Degenerate nests occur when there is only one alternative in a branch of the tree hierarchy. The associated dissimilarity parameter of the RUM is not defined. The inclusive-valued parameter of the nonnormalized model will be identifiable if there are alternative-specific variables specified in (1) of the model specification (the *indepvars* in the model syntax). Numerically, you can skirt the issue of nonidentifiable/undefined parameters by setting constraints on them. For the RUM constraint, set the dissimilarity parameter to 1. See the description of constraints() in *Options* for details on setting constraints on the dissimilarity parameters.

Methods and formulas

Methods and formulas are presented under the following headings:

Two-level nested logit model Three-level nested logit model

Two-level nested logit model

Consider our two-level nested logit model for restaurant choice. We define $T=\{1,2,3\}$ to be the set of indices denoting the three restaurant types and $R_1=\{1,2\}$, $R_2=\{3,4,5\}$, and $R_3=\{6,7\}$ to be the set of indices representing each restaurant within type $t\in T$. Let C_1 and C_2 be the random variables that represent the choices made for the first level, restaurant type, and second level, restaurant, of the hierarchy, where we observe the choices $C_1=t,t\in T$, and $C_2=j,j\in R_t$. Let \mathbf{z}_t and \mathbf{x}_{tj} , for $t\in T$ and $j\in R_t$, refer to the row vectors of explanatory variables for the first-level alternatives and bottom-level alternatives for one case, respectively. We write the utilities (latent variables) as $U_{tj}=\mathbf{z}_t\alpha_t+\mathbf{x}_{tj}\beta_j+\epsilon_{tj}=\eta_{tj}+\epsilon_{tj}$, where α_t and β_j are column vectors and the ϵ_{tj} are random disturbances. When the \mathbf{x}_{tj} are alternative specific, we can drop the indices from β , where we estimate one coefficient for each alternative in R_t , $t\in T$. These variables are specified in the first equation of the nlogit syntax (see example 3).

When the random-utility framework is used to describe the choice behavior, the alternative that is chosen is the alternative that has the highest utility. Assume for our restaurant example that we choose restaurant type $t \in T$. For the RUM parameterization of nlogit, the conditional distribution of ϵ_{tj} given choice of restaurant type t is a multivariate version of Gumbel's extreme-value distribution,

$$F_{R|T}(\epsilon \mid t) = \exp\left[-\left\{\sum_{m \in R_t} \exp(\epsilon_{tm}/\tau_t)\right\}^{\tau_t}\right]$$
 (3)

where it has been shown that the ϵ_{tj} , $j \in R_t$, are exchangeable with correlation $1 - \tau_t^2$, for $\tau_t \in (0, 1]$ (Kotz and Nadarajah 2000). For example, the probability of choosing Christopher's, j = 6 given type t = 3, is

$$\begin{split} \Pr(C_2 = 6 \,|\, C_1 = 3) &= \, \Pr\left(U_{36} - U_{37} > 0\right) \\ &= \, \Pr\left(\epsilon_{37} \leq \epsilon_{36} + \eta_{36} - \eta_{37}\right) \\ &= \int_{-\infty}^{\infty} \left\{ \int_{-\infty}^{\epsilon_{36} + \eta_{36} - \eta_{37}} f_{R|T}\left(\epsilon_{36}, \epsilon_{37}\right) d\epsilon_{37} \right\} d\epsilon_{36} \end{split}$$

where $f = \frac{\partial F}{\partial \epsilon_{36} \partial \epsilon_{37}}$ is the joint density function of ϵ given t. U_{37} is the utility of eating at Mad Cows, the other fancy (t=3) restaurant. Amemiya (1985) demonstrates that this integral evaluates to the logistic function

$$\begin{aligned} \Pr(C_2 = 6 \,|\, C_1 = 3) &= \frac{\exp(\eta_{36}/\tau_3)}{\exp(\eta_{36}/\tau_3) + \exp(\eta_{37}/\tau_3)} \\ &= \frac{\exp(\mathbf{x}_{36}\beta_6/\tau_3)}{\exp(\mathbf{x}_{36}\beta_6/\tau_3) + \exp(\mathbf{x}_{37}\beta_7/\tau_3)} \end{aligned}$$

and in general

$$\Pr(C_2 = j \mid C_1 = t) = \frac{\exp(\mathbf{x}_{tj}\boldsymbol{\beta}_j/\tau_t)}{\sum_{m \in R_t} \exp(\mathbf{x}_{tm}\boldsymbol{\beta}_m/\tau_t)}$$
(4)

Letting $\tau_t = 1$ in (3) reduces to the product of independent extreme-value distributions, and (4) reduces to the multinomial logistic function.

For the logistic function in (4), we scale the linear predictors by the dissimilarity parameters. Another formulation of the conditional probability of choosing alternative $j \in R_t$ given choice $t \in T$ is the logistic function without this normalization,

$$Pr(C_2 = j \mid C_1 = t) = \frac{\exp(\mathbf{x}_{tj}\boldsymbol{\beta}_j)}{\sum_{m \in R_t} \exp(\mathbf{x}_{tm}\boldsymbol{\beta}_m)}$$

and this is what is used in nlogit's nonnormalized parameterization.

Amemiya (1985) defines the general form for the joint distribution of the ϵ 's as

$$F_{T,R}(\epsilon) = \, \exp\left\{-\sum_{k \in T} \theta_k \left(\sum_{m \in R_k} \, \exp(-\epsilon_{km}/\tau_k)\right)^{\tau_k}\right\}$$

from which the probability of choice $t, t \in T$ can be derived as

$$\Pr(C_1 = t) = \frac{\theta_t \left\{ \sum_{m \in R_t} \exp(\eta_{tm}/\tau_t) \right\}^{\tau_t}}{\sum_{k \in T} \theta_k \left\{ \sum_{m \in R_k} \exp(\eta_{km}/\tau_k) \right\}^{\tau_k}}$$
(5)

nlogit sets $\theta_t = 1$. Noting that

$$\begin{split} \left\{ \sum_{m \in R_t} \exp(\eta_{tm}/\tau_t) \right\}^{\tau_t} &= \left\{ \sum_{m \in R_t} \exp\left(\frac{\mathbf{z}_t \boldsymbol{\alpha}_t + \mathbf{x}_{tm} \boldsymbol{\beta}_m}{\tau_t}\right) \right\}^{\tau_t} \\ &= \exp(\mathbf{z}_t \boldsymbol{\alpha}_t) \left\{ \sum_{m \in R_t} \exp\left(\mathbf{x}_{tm} \boldsymbol{\beta}_m/\tau_t\right) \right\}^{\tau_t} \\ &= \exp(\mathbf{z}_t \boldsymbol{\alpha}_t + \tau_t I_t) \end{split}$$

we define the inclusive values I_t as

$$I_t = \ln \left\{ \sum_{m \in R_t} \exp(\mathbf{x}_{tm} oldsymbol{eta}_m / au_t)
ight\}$$

and we can view

$$\exp(\tau_t I_t) = \left\{ \sum_{m \in R_t} \exp(x_{tm} \beta_m)^{1/\tau_t} \right\}^{\tau_t}$$

as a weighted average of the $\exp(x_{tm}\beta_m)$, for $m \in R_t$. For the nlogit RUM parameterization, we can express (5) as

$$\Pr(C_1 = t) = \frac{\exp(\mathbf{z}_t \boldsymbol{\alpha}_t + \tau_t I_t)}{\sum_{k \in T} \exp(\mathbf{z}_k \boldsymbol{\alpha}_k + \tau_k I_k)}$$

Next, we define inclusive values for the nonnormalized model to be

$$\widetilde{I}_t = \ln \left\{ \sum_{m \in R_t} \exp(\mathbf{x}_{tm} \boldsymbol{\beta}_m) \right\}$$

and we express $Pr(C_1 = t)$ as

$$\Pr(C_1 = t) = \frac{\exp(\mathbf{z}_t \alpha_t + \tau_t \widetilde{I}_t)}{\sum_{k \in T} \exp(\mathbf{z}_k \alpha_k + \tau_k \widetilde{I}_k)}$$
(6)

Equation (5) is consistent with (6) only when $\eta_{ij} = \mathbf{x}_{ij}\beta_j$, so in general the nlogit nonnormalized model is not consistent with the RUM.

Now assume that we have N cases where we add a third subscript, i, to denote case i, i = 1, ..., N. Denote y_{itj} to be a binary variable indicating the choice made by case i so that for each i only one y_{itj} is 1 and the rest are 0 for all $t \in T$ and $j \in R_t$. The log likelihood for the two-level RUM is

$$\log \ell = \sum_{i=1}^{N} \sum_{k \in T} \sum_{m \in R_k} y_{itj} \log \left\{ \Pr(C_{i1} = k) \Pr(C_{i2} = m | C_{i1} = k) \right\}$$

$$= \sum_{i=1}^{N} \sum_{k \in T} \sum_{m \in R_k} y_{itj} \left[\mathbf{z}_{ik} \boldsymbol{\alpha}_k + \tau_k I_{ik} - \log \left\{ \sum_{l \in T} \exp(\mathbf{z}_{il} \boldsymbol{\alpha}_l + \tau_l I_{il}) \right\} + \mathbf{x}_{itj} \boldsymbol{\beta}_m / \tau_k - \log \left\{ \sum_{l \in R_k} \exp(\mathbf{x}_{ikl} \boldsymbol{\beta}_l / \tau_k) \right\} \right]$$

The likelihood for the nonnormalized model has a similar form, replacing I with \tilde{I} and by not scaling $\mathbf{x}_{ikj}\boldsymbol{\beta}_i$ by τ_k .

Three-level nested logit model

Here we define a three-level nested logit model that can be generalized to the four-level and higher models. As before, let the integer set T be the indices for the first level of choices. Let sets S_t , $t \in T$, be mutually exclusive sets of integers representing the choices of the second level of the hierarchy. Finally, let R_j , $j \in S_t$, be the bottom-level choices. Let $U_{tjk} = \eta_{tjk} + \epsilon_{tjk}$, $k \in R_j$, and the distribution of ϵ_{tjk} be Gumbel's multivariate extreme value of the form

$$F(\epsilon) = \exp\left(-\sum_{t \in T} \left[\sum_{j \in S_t} \left\{\sum_{k \in R_j} \exp(-\eta_{tjk}/\tau_j)\right\}^{\tau_j/\upsilon_t}\right]^{\upsilon_j}\right)$$

Let C_1 , C_2 , and C_3 represent the choice random variables for levels 1, 2, and the bottom, respectively. Then the set of conditional probabilities is

$$\begin{split} & \Pr(C_3 = k \,|\, C_1 = t, C_2 = j) = \frac{\exp(\eta_{tjk}/\tau_j)}{\sum_{l \in R_j} \, \exp(\eta_{tjl}/\tau_j)} \\ & \Pr(C_2 = j \,|\, C_1 = t) = \frac{\left\{\sum_{k \in R_j} \, \exp(\eta_{tjk}/\tau_j)\right\}^{\tau_j/\upsilon_t}}{\sum_{l \in S_t} \left\{\sum_{k \in R_l} \, \exp(\eta_{tlk}/\tau_l)\right\}^{\tau_l/\upsilon_t}} \\ & \Pr(C_1 = t) = \frac{\left[\sum_{j \in S_t} \left\{\sum_{k \in R_j} \, \exp(\eta_{tjk}/\tau_j)\right\}^{\tau_j/\upsilon_t}\right]^{\upsilon_t}}{\sum_{l \in T} \left[\sum_{j \in S_l} \left\{\sum_{k \in R_j} \, \exp(\eta_{ljk}/\tau_j)\right\}^{\tau_j/\upsilon_l}\right]^{\upsilon_l}} \end{split}$$

Assume that we can decompose the linear predictor as $\eta_{tjk} = \mathbf{z}_t \alpha_t + \mathbf{u}_{tj} \gamma_j + \mathbf{x}_{tjk} \beta_k$. Here \mathbf{z}_t , \mathbf{u}_{tj} , and \mathbf{x}_{tjk} are the row vectors of explanatory variables for the first, second, and bottom levels of the hierarchy, respectively, and α_t , γ_j , and β_k are the corresponding column vectors of regression coefficients for $t \in T$, $j \in S_t$, and $k \in R_j$. We then can define the inclusive values for the first and second levels as

$$\begin{split} I_{tj} &= \log \sum_{k \in R_j} \, \exp(\mathbf{x}_{tjk} \boldsymbol{\beta}_k / \tau_j) \\ J_t &= \, \log \sum_{j \in S_t} \, \exp(\mathbf{u}_{tj} \boldsymbol{\gamma}_j / \upsilon_t + \frac{\tau_j}{\upsilon_t} I_{tj}) \end{split}$$

and rewrite the probabilities

$$\begin{aligned} \Pr(C_3 = k \mid C_1 = t, C_2 = j) &= \frac{\exp(\mathbf{x}_{tjk}\boldsymbol{\beta}_k/\tau_j)}{\sum_{l \in R_j} \exp(\mathbf{x}_{tjl}\boldsymbol{\beta}_l/\tau_j)} \\ \Pr(C_2 = j \mid C_1 = t) &= \frac{\exp(\mathbf{u}_{tj}\boldsymbol{\gamma}_j/\upsilon_t + \frac{\tau_j}{\upsilon_t}I_{tj})}{\sum_{l \in S_t} \exp(\mathbf{u}_{tl}\boldsymbol{\gamma}_l/\upsilon_t + \frac{\tau_l}{\upsilon_t}I_{tl})} \\ \Pr(C_1 = t) &= \frac{\exp(\mathbf{z}_t\boldsymbol{\alpha}_t + \upsilon_tJ_t)}{\sum_{l \in T} \exp(\mathbf{z}_l\boldsymbol{\alpha}_l + \upsilon_lJ_l)} \end{aligned}$$

We add a fourth index, i, for case and define the indicator variable y_{itjk} , $i=1,\ldots,N$, to indicate the choice made by case i, $t \in T$, $j \in S_t$, and $k \in R_j$. The log likelihood for the nlogit RUM is

$$\begin{split} \ell &= \sum_{i=1}^{N} \sum_{t \in T} \sum_{j \in S_{t}} \sum_{k \in R_{j}} y_{itjk} \left\{ \mathbf{z}_{it} \alpha_{t} + \upsilon_{t} J_{it} - \log \left(\sum_{m \in T} \mathbf{z}_{im} \alpha_{m} + \upsilon_{m} J_{im} \right) + \right. \\ &\left. \mathbf{u}_{itj} \gamma_{j} / \upsilon_{t} + \frac{\tau_{j}}{\upsilon_{t}} I_{itj} - \log \left(\sum_{m \in S_{t}} \mathbf{u}_{itm} \gamma_{m} / \upsilon_{t} + \frac{\tau_{m}}{\upsilon_{t}} I_{itm} \right) + \right. \\ &\left. \mathbf{x}_{itjk} \beta_{k} / \tau_{k} - \sum_{m \in R_{t}} \exp(\mathbf{x}_{itjm} \beta_{m} / \tau_{k}) \right\} \end{split}$$

and for the nonnormalized nlogit model, the log likelihood is

$$\begin{split} \ell &= \sum_{i=1}^{N} \sum_{t \in T} \sum_{j \in S_{t}} \sum_{k \in R_{j}} y_{itjk} \left\{ \mathbf{z}_{it} \boldsymbol{\alpha}_{t} + \upsilon_{t} J_{it} - \log \left(\sum_{m \in T} \mathbf{z}_{im} \boldsymbol{\alpha}_{m} + \upsilon_{m} J_{im} \right) + \right. \\ &\left. \mathbf{u}_{itj} \boldsymbol{\gamma}_{j} + \tau_{j} I_{itj} - \log \left(\sum_{m \in S_{t}} \mathbf{u}_{itm} \boldsymbol{\gamma}_{m} + \tau_{m} I_{itm} \right) + \right. \\ &\left. \mathbf{x}_{itjk} \boldsymbol{\beta}_{k} - \sum_{m \in R_{t}} \exp(\mathbf{x}_{itjm} \boldsymbol{\beta}_{m}) \right\} \end{split}$$

Extending the model to more than three levels is straightforward, albeit notationally cumbersome.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using vce(robust) and vce(cluster clustvar), respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.
