

meqrlogit — Multilevel mixed-effects logistic regression (QR decomposition)

Description	Quick start	Menu	Syntax
Options	Remarks and examples	Stored results	Methods and formulas
References	Also see		

Description

`meqrlogit`, like `melogit`, fits mixed-effects models for binary or binomial responses. The conditional distribution of the response given the random effects is assumed to be Bernoulli, with success probability determined by the logistic cumulative distribution function.

`meqrlogit` provides an alternative estimation method, which uses the QR decomposition of the variance-components matrix. This method may aid convergence when variance components are near the boundary of the parameter space.

Quick start

Two-level logistic regression of y on x with random intercepts by `lev2` using QR decomposition

```
meqrlogit y x || lev2:
```

Add random coefficients for x

```
meqrlogit y x || lev2: x
```

As above, but allow the random effects to be correlated

```
meqrlogit y x || lev2: x, covariance(unstructured)
```

Three-level random-intercept model of y on x with `lev2` nested within `lev3`

```
meqrlogit y x || lev3: || lev2:
```

Crossed-effects model of y on x with two-way crossed random effects by factors `a` and `b`

```
meqrlogit y x || _all:R.a || b:
```

Menu

Statistics > Multilevel mixed-effects models > Estimation by QR decomposition > Logistic regression

Syntax

```
meqrlogit depvar fe_equation || re_equation [ || re_equation ... ] [ , options ]
```

where the syntax of *fe_equation* is

```
[ indepvars ] [ if ] [ in ] [ , fe_options ]
```

and the syntax of *re_equation* is one of the following:

for random coefficients and intercepts

```
levelvar: [ varlist ] [ , re_options ]
```

for random effects among the values of a factor variable

```
levelvar: R.varname [ , re_options ]
```

levelvar is a variable identifying the group structure for the random effects at that level or is `_all` representing one group comprising all observations.

<i>fe_options</i>	Description
<code>Model</code>	
<code>noconstant</code>	suppress constant term from the fixed-effects equation
<code>offset(<i>varname</i>)</code>	include <i>varname</i> in model with coefficient constrained to 1

<i>re_options</i>	Description
<code>Model</code>	
<code>covariance(<i>vartype</i>)</code>	variance–covariance structure of the random effects
<code>noconstant</code>	suppress constant term from the random-effects equation
<code>collinear</code>	keep collinear variables

<i>options</i>	Description
Model	
<u>binomial</u> (<i>varname</i> #)	set binomial trials if data are in binomial form
Reporting	
<u>level</u> (#)	set confidence level; default is <code>level(95)</code>
or	report fixed-effects coefficients as odds ratios
<u>variance</u>	show random-effects parameter estimates as variances and covariances; the default
<u>stddeviations</u>	show random-effects parameter estimates as standard deviations and correlations
<u>noretale</u>	suppress random-effects table
<u>nofetable</u>	suppress fixed-effects table
<u>estmetric</u>	show parameter estimates in the estimation metric
<u>noheader</u>	suppress output header
<u>nogroup</u>	suppress table summarizing groups
<i>display_options</i>	control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Integration	
<u>intpoints</u> (# [<i># ...</i>])	set the number of integration (quadrature) points; default is <code>intpoints(7)</code>
<u>laplace</u>	use Laplacian approximation; equivalent to <code>intpoints(1)</code>
Maximization	
<i>maximize_options</i>	control the maximization process; seldom used
<u>retolerance</u> (#)	tolerance for random-effects estimates; default is <code>retolerance(1e-8)</code> ; seldom used
<u>reiterate</u> (#)	maximum number of iterations for random-effects estimation; default is <code>reiterate(50)</code> ; seldom used
<u>matsqrt</u>	parameterize variance components using matrix square roots; the default
<u>matlog</u>	parameterize variance components using matrix logarithms
<u>refineopts</u> (<i>maximize_options</i>)	control the maximization process during refinement of starting values
<u>coeflegend</u>	display legend instead of statistics
<i>vartype</i>	Description
<u>independent</u>	one unique variance parameter per random effect, all covariances 0; the default unless the R. notation is used
<u>exchangeable</u>	equal variances for random effects, and one common pairwise covariance
<u>identity</u>	equal variances for random effects, all covariances 0; the default if the R. notation is used
<u>unstructured</u>	all variances and covariances to be distinctly estimated

indepvars may contain factor variables; see [U] 11.4.3 Factor variables.

indepvars and *varlist* may contain time-series operators; see [U] 11.4.4 Time-series varlists.

bootstrap, *by*, *jackknife*, *mi estimate*, *rolling*, and *statsby* are allowed; see [U] 11.1.10 Prefix commands.

coeflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Options

Model

noconstant suppresses the constant (intercept) term and may be specified for the fixed-effects equation and for any of or all the random-effects equations.

offset(varname) specifies that *varname* be included in the fixed-effects portion of the model with the coefficient constrained to be 1.

covariance(vartype) specifies the structure of the covariance matrix for the random effects and may be specified for each random-effects equation. *vartype* is one of the following: *independent*, *exchangeable*, *identity*, and *unstructured*.

covariance(independent) covariance structure allows for a distinct variance for each random effect within a random-effects equation and assumes that all covariances are 0. The default is *covariance(independent)*, except when the *R.* notation is used, in which case the default is *covariance(identity)* and only *covariance(identity)* and *covariance(exchangeable)* are allowed.

covariance(exchangeable) structure specifies one common variance for all random effects and one common pairwise covariance.

covariance(identity) is short for “multiple of the identity”; that is, all variances are equal and all covariances are 0.

covariance(unstructured) allows for all variances and covariances to be distinct. If an equation consists of p random-effects terms, the unstructured covariance matrix will have $p(p+1)/2$ unique parameters.

collinear specifies that *meqrlogit* not omit collinear variables from the random-effects equation. Usually, there is no reason to leave collinear variables in place; in fact, doing so usually causes the estimation to fail because of the matrix singularity caused by the collinearity. However, with certain models (for example, a random-effects model with a full set of contrasts), the variables may be collinear, yet the model is fully identified because of restrictions on the random-effects covariance structure. In such cases, using the *collinear* option allows the estimation to take place with the random-effects equation intact.

binomial(varname | #) specifies that the data are in binomial form; that is, *devar* records the number of successes from a series of binomial trials. This number of trials is given either as *varname*, which allows this number to vary over the observations, or as the constant *#*. If *binomial()* is not specified (the default), *devar* is treated as Bernoulli, with any nonzero, nonmissing values indicating positive responses.

Reporting

level(#); see [R] estimation options.

or reports estimated fixed-effects coefficients transformed to odds ratios, that is, $\exp(\beta)$ rather than β . Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. *or* may be specified either at estimation or upon replay.

`variance`, the default, displays the random-effects parameter estimates as variances and covariances. `stddeviations` displays the random-effects parameter estimates as standard deviations and correlations.

`norettable` suppresses the random-effects table.

`nofetable` suppresses the fixed-effects table.

`estmetric` displays all parameter estimates in the estimation metric. Fixed-effects estimates are unchanged from those normally displayed, but random-effects parameter estimates are displayed as log-standard deviations and hyperbolic arctangents of correlations, with equation names that organize them by model level.

`noheader` suppresses the output header, either at estimation or upon replay.

`nogroup` suppresses the display of group summary information (number of groups, average group size, minimum, and maximum) from the output header.

display_options: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] [estimation options](#).

Integration

`intpoints(#[# ...])` sets the number of integration points for adaptive Gaussian quadrature. The more integration points, the more accurate the approximation to the log likelihood. However, computation time increases with the number of quadrature points, and in models with many levels or many random coefficients, this increase can be substantial.

You may specify one number of integration points applying to all levels of random effects in the model, or you may specify distinct numbers of points for each level. `intpoints(7)` is the default; that is, by default seven quadrature points are used for each level.

`laplace` specifies that log likelihoods be calculated using the Laplacian approximation, equivalent to adaptive Gaussian quadrature with one integration point for each level in the model; `laplace` is equivalent to `intpoints(1)`. Computation time increases as a function of the number of quadrature points raised to a power equaling the dimension of the random-effects specification. The computational time saved by using `laplace` can thus be substantial, especially when you have many levels or random coefficients.

The Laplacian approximation has been known to produce biased parameter estimates, but the bias tends to be more prominent in the estimates of the variance components rather than in the estimates of the fixed effects. If your interest lies primarily with the fixed-effects estimates, the Laplace approximation may be a viable faster alternative to adaptive quadrature with multiple integration points.

When the R.*varname* notation is used, the dimension of the random effects increases by the number of distinct values of *varname*. Even when this number is small to moderate, it increases the total random-effects dimension to the point where estimation with more than one quadrature point is prohibitively intensive.

For this reason, when you use the R. notation in your random-effects equations, the `laplace` option is assumed. You can override this behavior by using the `intpoints()` option, but doing so is not recommended.

maximize_options: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] [maximize](#). Those that require special mention for `meqrlogit` are listed below.

For the `technique()` option, the default is `technique(nr)`. The `bhhh` algorithm may not be specified.

`from(init_specs)` is particularly useful when combined with `refineopts(iterate(0))` (see the description [below](#)), which bypasses the initial optimization stage.

`retolerance(#)` specifies the convergence tolerance for the estimated random effects used by adaptive Gaussian quadrature. Although not estimated as model parameters, random-effects estimators are used to adapt the quadrature points. Estimating these random effects is an iterative procedure, with convergence declared when the maximum relative change in the random effects is less than `retolerance()`. The default is `retolerance(1e-8)`. You should seldom have to use this option.

`reiterate(#)` specifies the maximum number of iterations used when estimating the random effects to be used in adapting the Gaussian quadrature points; see the `retolerance()` option. The default is `reiterate(50)`. You should seldom have to use this option.

`matsqrt` (the default), during optimization, parameterizes variance components by using the matrix square roots of the variance–covariance matrices formed by these components at each model level.

`matlog`, during optimization, parameterizes variance components by using the matrix logarithms of the variance–covariance matrices formed by these components at each model level.

The `matsqrt` parameterization ensures that variance–covariance matrices are positive semidefinite, while `matlog` ensures matrices that are positive definite. For most problems, the matrix square root is more stable near the boundary of the parameter space. However, if convergence is problematic, one option may be to try the alternate `matlog` parameterization. When convergence is not an issue, both parameterizations yield equivalent results.

`refineopts(maximize_options)` controls the maximization process during the refinement of starting values. Estimation in `meqrlogit` takes place in two stages. In the first stage, starting values are refined by holding the quadrature points fixed between iterations. During the second stage, quadrature points are adapted with each evaluation of the log likelihood. Maximization options specified within `refineopts()` control the first stage of optimization; that is, they control the refining of starting values.

maximize_options specified outside `refineopts()` control the second stage.

The one exception to the above rule is the `nolog` option, which when specified outside `refineopts()` applies globally.

`from(init_specs)` is not allowed within `refineopts()` and instead must be specified globally.

Refining starting values helps make the iterations of the second stage (those that lead toward the solution) more numerically stable. In this regard, of particular interest is `refineopts(iterate(#))`, with two iterations being the default. Should the maximization fail because of instability in the Hessian calculations, one possible solution may be to increase the number of iterations here.

The following option is available with `meqrlogit` but is not shown in the dialog box:

`coeflegend`; see [R] [estimation options](#).

Remarks and examples

Mixed-effects logistic regression is logistic regression containing both fixed effects and random effects. In longitudinal data and panel data, random effects are useful for modeling intraclass correlation; that is, observations in the same cluster are correlated because they share common cluster-level random effects.

`meqrlogit` allows for many levels of random effects. For example, in a three-level model you can specify random effects for schools and then random effects for classes nested within schools. In this model, the observations (presumably, the students) comprise the first level, the classes comprise the second level, and the schools comprise the third.

However, for simplicity, for now we consider the two-level model, where for a series of M independent clusters, and conditional on a set of random effects \mathbf{u}_j ,

$$\Pr(y_{ij} = 1 | \mathbf{u}_j) = H(\mathbf{x}_{ij}\boldsymbol{\beta} + \mathbf{z}_{ij}\mathbf{u}_j) \quad (1)$$

for $j = 1, \dots, M$ clusters, with cluster j consisting of $i = 1, \dots, n_j$ observations. The responses are the binary-valued y_{ij} , and we follow the standard Stata convention of treating $y_{ij} = 1$ if `depvarij ≠ 0` and treating $y_{ij} = 0$ otherwise. The $1 \times p$ row vector \mathbf{x}_{ij} are the covariates for the fixed effects, analogous to the covariates you would find in a standard logistic regression model, with regression coefficients (fixed effects) $\boldsymbol{\beta}$.

The $1 \times q$ vector \mathbf{z}_{ij} are the covariates corresponding to the random effects and can be used to represent both random intercepts and random coefficients. For example, in a random-intercept model, \mathbf{z}_{ij} is simply the scalar 1. The random effects \mathbf{u}_j are M realizations from a multivariate normal distribution with mean $\mathbf{0}$ and $q \times q$ variance matrix $\boldsymbol{\Sigma}$. The random effects are not directly estimated as model parameters but are instead summarized according to the unique elements of $\boldsymbol{\Sigma}$, known as variance components. One special case of (1) places $\mathbf{z}_{ij} = \mathbf{x}_{ij}$ so that all covariate effects are essentially random and distributed as multivariate normal with mean $\boldsymbol{\beta}$ and variance $\boldsymbol{\Sigma}$.

Finally, because this is logistic regression, $H(\cdot)$ is the logistic cumulative distribution function, which maps the linear predictor to the probability of a success ($y_{ij} = 1$), with $H(v) = \exp(v) / \{1 + \exp(v)\}$.

Model (1) may also be stated in terms of a latent linear response, where only $y_{ij} = I(y_{ij}^* > 0)$ is observed for the latent

$$y_{ij}^* = \mathbf{x}_{ij}\boldsymbol{\beta} + \mathbf{z}_{ij}\mathbf{u}_j + \epsilon_{ij}$$

The errors ϵ_{ij} are distributed as logistic with mean 0 and variance $\pi^2/3$ and are independent of \mathbf{u}_j .

Model (1) is an example of a generalized linear mixed model (GLMM), which generalizes the linear mixed-effects (LME) model to non-Gaussian responses. You can fit LMEs in Stata by using `mixed` and fit GLMMs by using `meqglm`. Because of the relationship between LMEs and GLMMs, there is insight to be gained through examination of the linear mixed model. This is especially true for Stata users because the terminology, syntax, options, and output for fitting these types of models are nearly identical. See [ME] `mixed` and the references therein, particularly in [Introduction](#), for more information.

Multilevel models with binary responses have been used extensively in the health and social sciences. As just one example, [Leyland and Goldstein \(2001, sec. 3.6\)](#) describe a study of equity of healthcare in Great Britain. Multilevel models with binary and other limited dependent responses also have a long history in econometrics; [Rabe-Hesketh, Skrondal, and Pickles \(2005\)](#) provide an excellent survey.

Log-likelihood calculations for fitting any generalized mixed-effects model require integrating out the random effects. One widely used modern method is to directly estimate the integral required to calculate the log likelihood by Gauss–Hermite quadrature or some variation thereof. The estimation method

used by `meqrlogit` is a multicoefficient and multilevel extension of one of these quadrature types, namely, adaptive Gaussian quadrature (AGQ) based on conditional modes, with the multicoefficient extension from [Pinheiro and Bates \(1995\)](#) and the multilevel extension from [Pinheiro and Chao \(2006\)](#); see [Methods and formulas](#).

► Example 1: Two-level random-intercept model

[Ng et al. \(2006\)](#) analyze a subsample of data from the 1989 Bangladesh fertility survey ([Huq and Cleland 1990](#)), which polled 1,934 Bangladeshi women on their use of contraception.

```
. use http://www.stata-press.com/data/r15/bangladesh
(Bangladesh Fertility Survey, 1989)
. describe
Contains data from http://www.stata-press.com/data/r15/bangladesh.dta
  obs:      1,934      Bangladesh Fertility Survey, 1989

variable name	storage type	display format	value label	variable label
district	byte	%9.0g		District
c_use	byte	%9.0g	yesno	Use contraception
urban	byte	%9.0g	urban	Urban or rural
age	float	%6.2f		Age, mean centered
child1	byte	%9.0g		1 child
child2	byte	%9.0g		2 children
child3	byte	%9.0g		3 or more children

Sorted by: district

The women sampled were from 60 districts, identified by the variable `district`. Each district contained either urban or rural areas (variable `urban`) or both. The variable `c_use` is the binary response, with a value of 1 indicating contraceptive use. Other covariates include mean-centered `age` and three indicator variables recording number of children.

Consider a standard logistic regression model, amended to have random effects for each district. Defining $\pi_{ij} = \Pr(c_use_{ij} = 1)$, we have

$$\text{logit}(\pi_{ij}) = \beta_0 + \beta_1 \text{urban}_{ij} + \beta_2 \text{age}_{ij} + \beta_3 \text{child1}_{ij} + \beta_4 \text{child2}_{ij} + \beta_5 \text{child3}_{ij} + u_j \quad (2)$$

for $j = 1, \dots, 60$ districts, with $i = 1, \dots, n_j$ women in district j .

```

Notes:

- The estimation log consists of two parts:
 - A set of iterations aimed at refining starting values. These are designed to be relatively quick iterations aimed at getting the parameter estimates within a neighborhood of the eventual solution, making the iterations in (b) more numerically stable.
 - A set of gradient-based iterations. By default, these are Newton–Raphson iterations, but other methods are available by specifying the appropriate *maximize_options*; see [R] [maximize](#).
- The first estimation table reports the fixed effects, and these can be interpreted just as you would the output from `logit`. You can also specify the `or` option at estimation or on replay to display the fixed effects as odds ratios instead.

If you did display results as odds ratios, you would find urban women to have roughly double the odds of using contraception as that of their rural counterparts. Having any number of children will increase the odds from three- to fourfold when compared with the base category of no children. Contraceptive use also decreases with age.

- The second estimation table shows the estimated variance components. The first section of the table is labeled `district: Identity`, meaning that these are random effects at the `district` level and that their variance–covariance matrix is a multiple of the identity matrix; that is, $\Sigma = \sigma_u^2 \mathbf{I}$.

Because we have only one random effect at this level, meqrlogit knew that Identity is the only possible covariance structure. In any case, σ_u^2 was estimated as 0.22 with standard error 0.07.

4. A likelihood-ratio test comparing the model to ordinary logistic regression, (2) without u_j , is provided and is highly significant for these data.

◀

The above extends to models with more than two levels of nesting by adding more random-effects equations, each separated by `||`.

Stored results

meqrlogit stores the following in `e()`:

Scalars

<code>e(N)</code>	number of observations
<code>e(k)</code>	number of parameters
<code>e(k_f)</code>	number of fixed-effects parameters
<code>e(k_r)</code>	number of random-effects parameters
<code>e(k_rs)</code>	number of variances
<code>e(k_rc)</code>	number of covariances

Methods and formulas

Model (1) assumes Bernoulli data, a special case of the binomial. Because binomial data are also supported by meqrlglit (option binomial()), the methods presented below are in terms of the more general binomial mixed-effects model.

For a two-level binomial model, consider the response y_{ij} as the number of successes from a series of r_{ij} Bernoulli trials (replications). For cluster j , $j = 1, \dots, M$, the conditional distribution of $\mathbf{y}_j = (y_{j1}, \dots, y_{jn_j})'$, given a set of cluster-level random effects \mathbf{u}_j , is

$$\begin{aligned} f(\mathbf{y}_j | \mathbf{u}_j) &= \prod_{i=1}^{n_j} \left[\binom{r_{ij}}{y_{ij}} \{H(\mathbf{x}_{ij}\boldsymbol{\beta} + \mathbf{z}_{ij}\mathbf{u}_j)\}^{y_{ij}} \{1 - H(\mathbf{x}_{ij}\boldsymbol{\beta} + \mathbf{z}_{ij}\mathbf{u}_j)\}^{r_{ij} - y_{ij}} \right] \\ &= \exp \left(\sum_{i=1}^{n_j} \left[y_{ij}(\mathbf{x}_{ij}\boldsymbol{\beta} + \mathbf{z}_{ij}\mathbf{u}_j) - r_{ij} \log \{1 + \exp(\mathbf{x}_{ij}\boldsymbol{\beta} + \mathbf{z}_{ij}\mathbf{u}_j)\} + \log \binom{r_{ij}}{y_{ij}} \right] \right) \end{aligned}$$

for $H(v) = \exp(v) / \{1 + \exp(v)\}$.

Defining $\mathbf{r}_j = (r_{j1}, \dots, r_{jn_j})'$ and

$$c(\mathbf{y}_j, \mathbf{r}_j) = \sum_{i=1}^{n_j} \log \binom{r_{ij}}{y_{ij}}$$

where $c(\mathbf{y}_j, \mathbf{r}_j)$ does not depend on the model parameters, we can express the above compactly in matrix notation,

$$f(\mathbf{y}_j | \mathbf{u}_j) = \exp \left[\mathbf{y}'_j (\mathbf{X}_j \boldsymbol{\beta} + \mathbf{Z}_j \mathbf{u}_j) - \mathbf{r}'_j \log \{1 + \exp(\mathbf{X}_j \boldsymbol{\beta} + \mathbf{Z}_j \mathbf{u}_j)\} + c(\mathbf{y}_j, \mathbf{r}_j) \right]$$

where \mathbf{X}_j is formed by stacking the row vectors \mathbf{x}_{ij} and \mathbf{Z}_j is formed by stacking the row vectors \mathbf{z}_{ij} . We extend the definitions of the functions $\log(\cdot)$ and $\exp(\cdot)$ to be vector functions where necessary.

Because the prior distribution of \mathbf{u}_j is multivariate normal with mean $\mathbf{0}$ and $q \times q$ variance matrix $\boldsymbol{\Sigma}$, the likelihood contribution for the j th cluster is obtained by integrating \mathbf{u}_j out of the joint density $f(\mathbf{y}_j, \mathbf{u}_j)$,

$$\begin{aligned} \mathcal{L}_j(\boldsymbol{\beta}, \boldsymbol{\Sigma}) &= (2\pi)^{-q/2} |\boldsymbol{\Sigma}|^{-1/2} \int f(\mathbf{y}_j | \mathbf{u}_j) \exp(-\mathbf{u}'_j \boldsymbol{\Sigma}^{-1} \mathbf{u}_j / 2) d\mathbf{u}_j \\ &= \exp \{c(\mathbf{y}_j, \mathbf{r}_j)\} (2\pi)^{-q/2} |\boldsymbol{\Sigma}|^{-1/2} \int \exp \{h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j)\} d\mathbf{u}_j \end{aligned} \tag{5}$$

where

$$h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j) = \mathbf{y}'_j (\mathbf{X}_j \boldsymbol{\beta} + \mathbf{Z}_j \mathbf{u}_j) - \mathbf{r}'_j \log \{1 + \exp(\mathbf{X}_j \boldsymbol{\beta} + \mathbf{Z}_j \mathbf{u}_j)\} - \mathbf{u}'_j \boldsymbol{\Sigma}^{-1} \mathbf{u}_j / 2$$

and for convenience, in the arguments of $h(\cdot)$ we suppress the dependence on the observable data $(\mathbf{y}_j, \mathbf{r}_j, \mathbf{X}_j, \mathbf{Z}_j)$.

The integration in (5) has no closed form and thus must be approximated. The Laplacian approximation (Tierney and Kadane 1986; Pinheiro and Bates 1995) is based on a second-order Taylor expansion of $h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j)$ about the value of \mathbf{u}_j that maximizes it. Taking first and second derivatives, we obtain

$$\begin{aligned} h'(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j) &= \frac{\partial h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j)}{\partial \mathbf{u}_j} = \mathbf{Z}'_j \{\mathbf{y}_j - \mathbf{m}(\boldsymbol{\beta}, \mathbf{u}_j)\} - \boldsymbol{\Sigma}^{-1} \mathbf{u}_j \\ h''(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j) &= \frac{\partial^2 h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j)}{\partial \mathbf{u}_j \partial \mathbf{u}'_j} = -\{\mathbf{Z}'_j \mathbf{V}(\boldsymbol{\beta}, \mathbf{u}_j) \mathbf{Z}_j + \boldsymbol{\Sigma}^{-1}\} \end{aligned}$$

where $\mathbf{m}(\boldsymbol{\beta}, \mathbf{u}_j)$ is the vector function with the i th element equal to the conditional mean of y_{ij} given \mathbf{u}_j , that is, $r_{ij} H(\mathbf{x}_{ij} \boldsymbol{\beta} + \mathbf{z}_{ij} \mathbf{u}_j)$. $\mathbf{V}(\boldsymbol{\beta}, \mathbf{u}_j)$ is the diagonal matrix whose diagonal entries v_{ij} are the conditional variances of y_{ij} given \mathbf{u}_j , namely,

$$v_{ij} = r_{ij} H(\mathbf{x}_{ij} \boldsymbol{\beta} + \mathbf{z}_{ij} \mathbf{u}_j) \{1 - H(\mathbf{x}_{ij} \boldsymbol{\beta} + \mathbf{z}_{ij} \mathbf{u}_j)\}$$

The maximizer of $h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j)$ is $\hat{\mathbf{u}}_j$ such that $h'(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j) = \mathbf{0}$. The integrand in (5) is proportional to the posterior density $f(\mathbf{u}_j | \mathbf{y}_j)$, so $\hat{\mathbf{u}}_j$ also represents the posterior mode, a plausible estimator of \mathbf{u}_j in its own right.

Given the above derivatives, the second-order Taylor approximation then takes the form

$$h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j) \approx h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j) + \frac{1}{2} (\mathbf{u}_j - \hat{\mathbf{u}}_j)' h''(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j) (\mathbf{u}_j - \hat{\mathbf{u}}_j) \quad (6)$$

The first-derivative term vanishes because $h'(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j) = \mathbf{0}$. Therefore,

$$\begin{aligned} \int \exp\{h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j)\} d\mathbf{u}_j &\approx \exp\{h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j)\} \\ &\quad \times \int \exp\left[-\frac{1}{2} (\mathbf{u}_j - \hat{\mathbf{u}}_j)' \{-h''(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j)\} (\mathbf{u}_j - \hat{\mathbf{u}}_j)\right] d\mathbf{u}_j \quad (7) \\ &= \exp\{h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j)\} (2\pi)^{q/2} | -h''(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j) |^{-1/2} \end{aligned}$$

because the latter integrand can be recognized as the “kernel” of a multivariate normal density.

Combining the above with (5) (and taking logs) gives the Laplacian log-likelihood contribution of the j th cluster,

$$\mathcal{L}_j^{\text{Lap}}(\boldsymbol{\beta}, \boldsymbol{\Sigma}) = -\frac{1}{2} \log |\boldsymbol{\Sigma}| - \log |\mathbf{R}_j| + h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j) + c(\mathbf{y}_j, \mathbf{r}_j)$$

where \mathbf{R}_j is an upper-triangular matrix such that $-h''(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j) = \mathbf{R}_j \mathbf{R}'_j$. Pinheiro and Chao (2006) show that $\hat{\mathbf{u}}_j$ and \mathbf{R}_j can be efficiently computed as the iterative solution to a least-squares problem by using matrix decomposition methods similar to those used in fitting LME models (Bates and Pinheiro 1998; Pinheiro and Bates 2000; [ME] mixed).

The fidelity of the Laplacian approximation is determined wholly by the accuracy of the approximation in (6). An alternative that does not depend so heavily on this approximation is integration via AGQ (Naylor and Smith 1982; Liu and Pierce 1994).

The application of AGQ to this particular problem is from Pinheiro and Bates (1995). When we reexamine the integral in question, a transformation of integration variables yields

$$\begin{aligned} \int \exp \{h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j)\} d\mathbf{u}_j &= |\mathbf{R}_j|^{-1} \int \exp \{h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j + \mathbf{R}_j^{-1}\mathbf{t})\} dt \\ &= (2\pi)^{q/2} |\mathbf{R}_j|^{-1} \int \exp \{h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j + \mathbf{R}_j^{-1}\mathbf{t}) + \mathbf{t}'\mathbf{t}/2\} \phi(\mathbf{t}) dt \end{aligned} \quad (8)$$

where $\phi(\cdot)$ is the standard multivariate normal density. Because the integrand is now expressed as some function multiplied by a normal density, it can be estimated by applying the rules of standard Gauss–Hermite quadrature. For a predetermined number of quadrature points N_Q , define $a_k = \sqrt{2}a_k^*$ and $w_k = w_k^*/\sqrt{\pi}$, for $k = 1, \dots, N_Q$, where (a_k^*, w_k^*) are a set of abscissas and weights for Gauss–Hermite quadrature approximations of $\int \exp(-x^2)f(x)dx$, as obtained from Abramowitz and Stegun (1964, 924).

Define $\mathbf{a}_k = (a_{k_1}, a_{k_2}, \dots, a_{k_q})'$; that is, \mathbf{a}_k is a vector that spans the N_Q abscissas over the dimension q of the random effects. Applying quadrature rules to (8) yields the AGQ approximation,

$$\begin{aligned} \int \exp \{h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \mathbf{u}_j)\} d\mathbf{u}_j &\approx (2\pi)^{q/2} |\mathbf{R}_j|^{-1} \sum_{k_1=1}^{N_Q} \cdots \sum_{k_q=1}^{N_Q} \left[\exp \{h(\boldsymbol{\beta}, \boldsymbol{\Sigma}, \hat{\mathbf{u}}_j + \mathbf{R}_j^{-1}\mathbf{a}_k) + \mathbf{a}_k'\mathbf{a}_k/2\} \prod_{p=1}^q w_{k_p} \right] \\ &\equiv (2\pi)^{q/2} \widehat{G}_j(\boldsymbol{\beta}, \boldsymbol{\Sigma}) \end{aligned}$$

resulting in the AGQ log-likelihood contribution of the i th cluster,

$$\mathcal{L}_j^{\text{AGQ}}(\boldsymbol{\beta}, \boldsymbol{\Sigma}) = -\frac{1}{2} \log |\boldsymbol{\Sigma}| + \log \left\{ \widehat{G}_j(\boldsymbol{\beta}, \boldsymbol{\Sigma}) \right\} + c(\mathbf{y}_j, \mathbf{r}_j)$$

The “adaptive” part of adaptive Gaussian quadrature lies in the translation and rescaling of the integration variables in (8) by using $\hat{\mathbf{u}}_j$ and \mathbf{R}_j^{-1} , respectively. This transformation of quadrature abscissas (centered at 0 in standard form) is chosen to better capture the features of the integrand, which through (7) can be seen to resemble a multivariate normal distribution with mean $\hat{\mathbf{u}}_j$ and variance $\mathbf{R}_j^{-1}\mathbf{R}_j^{-T}$. AGQ is therefore not as dependent as the Laplace method upon the approximation in (6). In AGQ, (6) serves merely to redirect the quadrature abscissas, with the AGQ approximation improving as the number of quadrature points N_Q increases. In fact, Pinheiro and Bates (1995) point out that AGQ with only one quadrature point ($a = 0$ and $w = 1$) reduces to the Laplacian approximation.

The log likelihood for the entire dataset is then simply the sum of the contributions of the M individual clusters, namely, $\mathcal{L}(\boldsymbol{\beta}, \boldsymbol{\Sigma}) = \sum_{j=1}^M \mathcal{L}_j^{\text{Lap}}(\boldsymbol{\beta}, \boldsymbol{\Sigma})$ for Laplace and $\mathcal{L}(\boldsymbol{\beta}, \boldsymbol{\Sigma}) = \sum_{j=1}^M \mathcal{L}_j^{\text{AGQ}}(\boldsymbol{\beta}, \boldsymbol{\Sigma})$ for AGQ.

Maximization of $\mathcal{L}(\boldsymbol{\beta}, \boldsymbol{\Sigma})$ is performed with respect to $(\boldsymbol{\beta}, \boldsymbol{\theta})$, where $\boldsymbol{\theta}$ is a vector comprising the unique elements of the matrix square root of $\boldsymbol{\Sigma}$. This is done to ensure that $\boldsymbol{\Sigma}$ is always positive semidefinite. If the `matlog` option is specified, then $\boldsymbol{\theta}$ instead consists of the unique elements of the matrix logarithm of $\boldsymbol{\Sigma}$. For well-conditioned problems, both methods produce equivalent results, yet our experience deems the former as more numerically stable near the boundary of the parameter space.

Once maximization is achieved, parameter estimates are mapped from $(\widehat{\beta}, \widehat{\theta})$ to $(\widehat{\beta}, \widehat{\gamma})$, where $\widehat{\gamma}$ is a vector containing the unique (estimated) elements of Σ , expressed as logarithms of standard deviations for the diagonal elements and hyperbolic arctangents of the correlations for off-diagonal elements. This last step is necessary to (a) obtain a parameterization under which parameter estimates can be displayed and interpreted individually, rather than as elements of a matrix square root (or logarithm), and (b) parameterize these elements such that their ranges each encompass the entire real line.

Parameter estimates are stored in `e(b)` as $(\widehat{\beta}, \widehat{\gamma})$, with the corresponding variance–covariance matrix stored in `e(V)`. Parameter estimates can be displayed in this metric by specifying the `estmetric` option. However, in `meqrlgit` output, variance components are displayed as variances and covariances.

The approach outlined above can be extended from two-level models to higher-level models; see [Pinheiro and Chao \(2006\)](#) for details.
