> **testnl** — Test nonlinear hypotheses after estimation

Syntax	Menu	Description	Options
Remarks and examples	Stored results	Methods and formulas	References
Also see			

Syntax

> testnl *exp* = *exp* $\big[$ = *exp* ... $\big]$ $\big[$, *options* $\big]$

> testnl (*exp* = *exp* $\big[$ = *exp* ... $\big]$) $\big[$ (*exp* = *exp* $\big[$ = *exp* ... $\big]$) ... $\big]$ $\big[$, *options* $\big]$

options	Description
<u>m</u>test $\big[$(*opt*)$\big]$	test each condition separately
<u>iterate</u>(#)	use maximum # of iterations to find the optimal step size
df(#)	use F distribution with # denominator degrees of freedom for the reference distribution of the test statistic
<u>nosvy</u>adjust	carry out the Wald test as $W/k \sim F(k,d)$; for use with svy estimation commands when the df() option is also specified

df(#) and nosvyadjust do not appear in the dialog box.

The second syntax means that if more than one expression is specified, each must be surrounded by parentheses.

exp is a possibly nonlinear expression containing

> _b[*coef*]
> _b[*eqno*:*coef*]
> [*eqno*]*coef*
> [*eqno*]_b[*coef*]

eqno is

> ##
> *name*

coef identifies a coefficient in the model. *coef* is typically a variable name, a level indicator, an interaction indicator, or an interaction involving continuous variables. Level indicators identify one level of a factor variable and interaction indicators identify one combination of levels of an interaction; see [U] **11.4.3 Factor variables**. *coef* may contain time-series operators; see [U] **11.4.4 Time-series varlists**.

Distinguish between [], which are to be typed, and $\big[\ \big]$, which indicate optional arguments.

Menu

Statistics > Postestimation > Tests > Test nonlinear hypotheses

Description

testnl tests (linear or nonlinear) hypotheses about the estimated parameters from the most recently fit model.

testnl produces Wald-type tests of smooth nonlinear (or linear) hypotheses about the estimated parameters from the most recently fit model. The p-values are based on the delta method, an approximation appropriate in large samples.

testnl can be used with svy estimation results; see [SVY] **svy postestimation**.

The format (exp_1=exp_2=exp_3...) for a simultaneous-equality hypothesis is just a convenient shorthand for a list (exp_1=exp_2) (exp_1=exp_3), etc.

testnl may also be used to test linear hypotheses. test is faster if you want to test only linear hypotheses; see [R] **test**. testnl is the only option for testing linear and nonlinear hypotheses simultaneously.

Options

mtest $\big[$(*opt*)$\big]$ specifies that tests be performed for each condition separately. *opt* specifies the method for adjusting p-values for multiple testing. Valid values for *opt* are

<u>b</u>onferroni	Bonferroni's method
holm	Holm's method
<u>s</u>idak	Šidák's method
<u>noad</u>just	no adjustment is to be made

Specifying mtest without an argument is equivalent to specifying mtest(noadjust).

iterate(#) specifies the maximum number of iterations used to find the optimal step size in the calculation of numerical derivatives of the test expressions. By default, the maximum number of iterations is 100, but convergence is usually achieved after only a few iterations. You should rarely have to use this option.

The following options are available with testnl but are not shown in the dialog box:

df(#) specifies that the F distribution with # denominator degrees of freedom be used for the reference distribution of the test statistic. With survey data, # is the design degrees unless nosvyadjust is specified.

nosvyadjust is for use with svy estimation commands when the df() option is also specified; see [SVY] **svy estimation**. It specifies that the Wald test be carried out without the default adjustment for the design degrees of freedom. That is, the test is carried out as $W/k \sim F(k, d)$ rather than as $(d - k + 1)W/(kd) \sim F(k, d - k + 1)$, where $k =$ the dimension of the test and $d =$ the design degrees of freedom specified in the df() option.

Remarks and examples

stata.com

Remarks are presented under the following headings:

Introduction

▷ Example 1

We have just estimated the parameters of an earnings model on cross-sectional time-series data using one of Stata's more sophisticated estimators:

```
. use http://www.stata-press.com/data/r13/earnings
(NLS Women 14-24 in 1968)

. xtgee ln_w grade age c.age#c.age, corr(exchangeable) nolog
GEE population-averaged model             Number of obs      =        1326
Group variable:                  idcode   Number of groups   =         269
Link:                          identity   Obs per group: min =           1
Family:                        Gaussian                  avg =         4.9
Correlation:               exchangeable                  max =           9
                                          Wald chi2(3)       =      327.33
Scale parameter:                .0976738   Prob > chi2        =      0.0000
```

ln_wage	Coef.	Std. Err.	z	P>|z|	[95% Conf. Interval]	
grade	.0749686	.0066111	11.34	0.000	.062011	.0879261
age	.1080806	.0235861	4.58	0.000	.0618526	.1543086
c.age#c.age	−.0016253	.0004739	−3.43	0.001	−.0025541	−.0006966
_cons	−.8788933	.2830899	−3.10	0.002	−1.433739	−.3240473

An implication of this model is that peak earnings occur at age -_b[age]/(2*_b[c.age#c.age]), which here is equal to 33.2. Say that we have a theory that peak earnings should occur at age 16 + 1/_b[grade].

```
. testnl -_b[age]/(2*_b[c.age#c.age]) = 16 + 1/_b[grade]
  (1)  -_b[age]/(2*_b[c.age#c.age]) = 16 + 1/_b[grade]
              chi2(1) =        1.71
          Prob > chi2 =      0.1914
```

These data do not reject our theory.

◁

Using testnl to perform linear tests

testnl may be used to test linear constraints, but test is faster; see [R] **test**. You could type

```
. testnl _b[x4] = _b[x1]
```

but it would take less computer time if you typed

```
. test _b[x4] = _b[x1]
```

Specifying constraints

The constraints to be tested can be formulated in many different ways. You could type

```
. testnl _b[mpg]*_b[weight] = 1
```

or

```
. testnl _b[mpg] = 1/_b[weight]
```

or you could express the constraint any other way you wished. (To say that testnl allows constraints to be specified in different ways does not mean that the test itself does not depend on the formulation. This point is briefly discussed later.) In formulating the constraints, you must, however, exercise one caution: users of test often refer to the coefficient on a variable by specifying the variable name. For example,

```
. test mpg = 0
```

More formally, they should type

```
. test _b[mpg] = 0
```

but test allows the _b[] surrounding the variable name to be omitted. testnl does not allow this shorthand. Typing

```
. testnl mpg=0
```

specifies the constraint that the value of variable mpg in the first observation is zero. If you make this mistake, sometimes testnl will catch it:

```
. testnl mpg=0
equation (1) contains reference to X rather than _b[X]
r(198);
```

In other cases, testnl may not catch the mistake; then the constraint will be dropped because it does not make sense:

```
. testnl mpg=0
  Constraint (1) dropped
```

(There are reasons other than this for constraints being dropped.) The worst case, however, is

```
. testnl _b[weight]*mpg = 1
```

when what you mean is not that _b[weight] equals the reciprocal of the value of mpg in the first observation, but rather that

```
. testnl _b[weight]*_b[mpg] = 1
```

Sometimes this mistake will be caught by the "contains reference to X rather than _b[X]" error, and sometimes it will not. Be careful.

testnl, like test, can be used after any Stata estimation command, including the survey estimators. When you use it after a multiple-equation command, such as mlogit or heckman, you refer to coefficients by using Stata's standard syntax: [*eqname*]_b[*varname*].

Stata's single-equation estimation output looks like this:

	Coef	...	
weight	12.27	...	<- coefficient is _b[weight]
mpg	3.21	...	

Stata's multiple-equation output looks like this:

	Coef	...	
cat1		...	
weight	12.27	...	<- coefficient is [cat1]_b[weight]
mpg	3.21	...	
8		...	
weight	5.83	...	<- coefficient is [8]_b[weight]
mpg	7.43	...	

Dropped constraints

testnl automatically drops constraints when

- They are nonbinding, for example, _b[mpg]=_b[mpg]. More subtle cases include

      _b[mpg]*_b[weight] = 4
      _b[weight] = 2
      _b[mpg] = 2

  In this example, the third constraint is nonbinding because it is implied by the first two.

- They are contradictory, for example, _b[mpg]=2 and _b[mpg]=3. More subtle cases include

      _b[mpg]*_b[weight] = 4
      _b[weight] = 2
      _b[mpg] = 3

  The third constraint contradicts the first two.

Multiple constraints

▷ Example 2

We illustrate the simultaneous test of a series of constraints using simulated data on labor-market promotion in a given year. We fit a probit model with separate effects for education, experience, and experience-squared for men and women.

```
. use http://www.stata-press.com/data/r13/promotion
. probit promo male male#c.(yedu yexp yexp2), nolog
```

Probit regression

				Number of obs	=	775
				LR chi2(7)	=	424.42
				Prob > chi2	=	0.0000
Log likelihood = −245.42768				Pseudo R2	=	0.4637

promo	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
male	.6489974	.203739	3.19	0.001	.2496763	1.048318
male#c.yedu						
0	.9730237	.1056136	9.21	0.000	.7660248	1.180023
1	1.390517	.1527288	9.10	0.000	1.091174	1.68986
male#c.yexp						
0	.4559544	.0901169	5.06	0.000	.2793285	.6325803
1	1.422539	.1544255	9.21	0.000	1.11987	1.725207
male#c.yexp2						
0	−.1027149	.0573059	−1.79	0.073	−.2150325	.0096026
1	−.3749457	.1160113	−3.23	0.001	−.6023236	−.1475677
_cons	.9872018	.1148215	8.60	0.000	.7621559	1.212248

Note: 1 failure and 2 successes completely determined.

The effects of human capital seem to differ between men and women. A formal test confirms this.

```
. test (yedu#0.male = yedu#1.male) (yexp#0.male = yexp#1.male)
> (yexp2#0.male = yexp2#1.male)
 ( 1)  [promo]0b.male#c.yedu - [promo]1.male#c.yedu = 0
 ( 2)  [promo]0b.male#c.yexp - [promo]1.male#c.yexp = 0
 ( 3)  [promo]0b.male#c.yexp2 - [promo]1.male#c.yexp2 = 0
            chi2(  3) =    35.43
          Prob > chi2 =    0.0000
```

How do we interpret this gender difference? It has repeatedly been stressed (see, for example, Long [1997, 47–50]; Allison [1999]) that comparison of groups in binary response models, and similarly in other latent-variable models, is hampered by an identification problem: with β the regression coefficients for the latent variable and σ the standard deviation of the latent residual, only the β/σ are identified. In fact, in terms of the latent regression, the probit coefficients should be interpreted as β/σ, not as the β. If we cannot claim convincingly that the residual standard deviation σ does not vary between the sexes, equality of the regression coefficients β implies that the coefficients of the probit model for men and women are *proportional* but not necessarily equal. This is a nonlinear hypothesis in terms of the probit coefficients, not a linear one.

```
. testnl _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
> = _b[yexp2#1.male]/_b[yexp2#0.male]
  (1)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
  (2)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp2#1.male]/_b[yexp2#0.male]
            chi2(2) =      9.21
          Prob > chi2 =    0.0100
```

We conclude that we find fairly strong evidence against the proportionality of the coefficients, and hence we have to conclude that success in the labor market is produced in different ways by men and women. (But remember, these were simulated data.)

◁

▷ Example 3

The syntax for specifying the equality of multiple expressions is just a convenient shorthand for specifying a series of constraints, namely, that the first expression equals the second expression, the first expression also equals the third expression, etc. The Wald test performed and the output of testnl are the same whether we use the shorthand or we specify the series of constraints. The lengthy specification as a series of constraints can be simplified using the continuation symbols ///.

```
. testnl (_b[yedu#1.male]/_b[yedu#0.male] = ///
>         _b[yexp#1.male]/_b[yexp#0.male])  ///
>         (_b[yedu#1.male]/_b[yedu#0.male] = ///
>         _b[yexp2#1.male]/_b[yexp2#0.male])
 (1)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
 (2)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp2#1.male]/_b[yexp2#0.male]

            chi2(2) =        9.21
        Prob > chi2 =      0.0100
```

Having established differences between men and women, we would like to do multiple testing between the ratios. Because we did not specify hypotheses in advance, we prefer to adjust the p-values of tests using, here, Bonferroni's method.

```
. testnl _b[yedu#1.male]/_b[yedu#0.male] = ///
>        _b[yexp#1.male]/_b[yexp#0.male] = ///
>        _b[yexp2#1.male]/_b[yexp2#0.male], mtest(b)
 (1)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
 (2)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp2#1.male]/_b[yexp2#0.male]
```

	chi2	df	p
(1)	6.89	1	0.0173 #
(2)	0.93	1	0.6713 #
all	9.21	2	0.0100

 # Bonferroni-adjusted p-values

◁

Manipulability

Although testnl allows you to specify constraints in different ways that are mathematically equivalent, as noted above, this does not mean that the tests are the same. This difference is known as the manipulability of the Wald test for nonlinear hypotheses; also see [R] **boxcox**. The test might even be significant for one formulation but not significant for another formulation that is mathematically equivalent. Trying out different specifications to find a formulation with the desired p-value is totally inappropriate, though it may actually be fun to try. There is no variance under representation because the nonlinear Wald test is actually a standard Wald test for a linearization of the constraint, which depends on the particular specification. We note that the likelihood-ratio test is not manipulable in this sense.

From a statistical point of view, it is best to choose a specification of the constraints that is as linear is possible. Doing so usually improves the accuracy of the approximation of the null-distribution of the test by a χ^2 or an F distribution. The example above used the nonlinear Wald test to test whether the coefficients of human capital variables for men were proportional to those of women. A specification of proportionality of coefficients in terms of ratios of coefficients is fairly nonlinear if the coefficients in the denominator are close to 0. A more linear version of the test results from a bilinear formulation. Thus instead of

```
. testnl _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]

 (1)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]

              chi2(1) =        6.89
            Prob > chi2 =      0.0087
```

perhaps

```
. testnl _b[yedu#1.male]*_b[yexp#0.male] = _b[yedu#0.male]*_b[yexp#1.male]

 (1)  _b[yedu#1.male]*_b[yexp#0.male] = _b[yedu#0.male]*_b[yexp#1.male]

              chi2(1) =       13.95
            Prob > chi2 =      0.0002
```

is better, and in fact it has been suggested that the latter version of the test is more reliable. This assertion is confirmed by performing simulations and is in line with theoretical results of Phillips and Park (1988). There is strong evidence against the proportionality of human capital effects between men and women, implying for this example that differences in the residual variances between the sexes can be ruled out as the explanation of the sex differences in the analysis of labor market participation.

Stored results

testnl stores the following in r():

Scalars
r(df)	degrees of freedom
r(df_r)	residual degrees of freedom
r(chi2)	χ^2
r(p)	significance
r(F)	F statistic

Macros
r(mtmethod)	method specified in mtest()

Matrices
r(G)	derivatives of $R(\mathbf{b})$ with respect to $\mathbf{b}$; see *Methods and formulas* below
r(R)	$R(\mathbf{b})-\mathbf{q}$; see *Methods and formulas* below
r(mtest)	multiple test results

Methods and formulas

After fitting a model, define $\mathbf{b}$ as the resulting $1 \times k$ parameter vector and $\mathbf{V}$ as the $k \times k$ covariance matrix. The (linear or nonlinear) hypothesis is given by $R(\mathbf{b}) = \mathbf{q}$, where R is a function returning a $j \times 1$ vector. The Wald test formula is (Greene 2012, 528)

$$W = \left\{ R(\mathbf{b}) - \mathbf{q} \right\}' \left(\mathbf{G}\mathbf{V}\mathbf{G}' \right)^{-1} \left\{ R(\mathbf{b}) - \mathbf{q} \right\}$$

where $\mathbf{G}$ is the derivative matrix of $R(\mathbf{b})$ with respect to $\mathbf{b}$. W is distributed as χ^2 if $\mathbf{V}$ is an asymptotic covariance matrix. $F = W/j$ is distributed as F for linear regression.

The adjustment methods for multiple testing are described in [R] test. The adjustment for survey design effects is described in [SVY] svy postestimation.
