tssmooth dexp — Double-exponential smoothing

## Syntax

```
tssmooth dexp [type] newvar = exp [if] [in] [, options]
```

### options

You must `tsset` your data before using `tssmooth dexp`; see `[TS] tsset`. `exp` may contain time-series operators; see `[U] 11.4.4 Time-series varlists`.

## Menu

Statistics > Time series > Smoothers/univariate forecasters > Double-exponential smoothing

## Description

`tssmooth dexp` models the trend of a variable whose difference between changes from the previous values is serially correlated. More precisely, it models a variable whose second difference follows a low-order, moving-average process.

## Options

- **Main**
  - `replace` replaces `newvar` if it already exists.
  - `parms(#,)` specifies the parameter $\alpha$ for the double-exponential smoothers; $0 < #_\alpha < 1$. If `parms(#,)` is not specified, the smoothing parameter is chosen to minimize the in-sample sum-of-squared forecast errors.
  - `samp0(#)` and `s0(#1 #2)` are mutually exclusive ways of specifying the initial values for the recursion.
    - By default, initial values are obtained by fitting a linear regression with a time trend, using the first half of the observations in the dataset; see `Remarks and examples`.
    - `samp0(#)` specifies that the first `#` be used in that regression.
    - `s0(#1 #2)` specifies that `#1` `#2` be used as initial values.
forecast(#) specifies the number of periods for the out-of-sample prediction; \(0 \leq # \leq 500\). The default is forecast(0), which is equivalent to not performing an out-of-sample forecast.

**Remarks and examples**

The double-exponential smoothing procedure is designed for series that can be locally approximated as

\[
\hat{x}_t = m_t + b_t t
\]

where \(\hat{x}_t\) is the smoothed or predicted value of the series \(x\), and the terms \(m_t\) and \(b_t\) change over time. Abraham and Ledolter (1983), Bowerman, O’Connell, and Koehler (2005), and Montgomery, Johnson, and Gardiner (1990) all provide good introductions to double-exponential smoothing. Chatfield (2001, 2004) provides helpful discussions of how double-exponential smoothing relates to modern time-series methods.

The double-exponential method has been used both as a smoother and as a prediction method. [TS] tssmooth exponential shows that the single-exponential smoothed series is given by

\[
S_t = \alpha x_t + (1 - \alpha)S_{t-1}
\]

where \(\alpha\) is the smoothing constant and \(x_t\) is the original series. The double-exponential smoother is obtained by smoothing the smoothed series,

\[
S^{[2]}_t = \alpha S_t + (1 - \alpha)S^{[2]}_{t-1}
\]

Values of \(S_0\) and \(S^{[2]}_0\) are necessary to begin the process. Per Montgomery, Johnson, and Gardiner (1990), the default method is to obtain \(S_0\) and \(S^{[2]}_0\) from a regression of the first \(N_{\text{pre}}\) values of \(x_t\) on \(\tilde{t} = (1, \ldots, N_{\text{pre}} - t_0)'\). By default, \(N_{\text{pre}}\) is equal to one-half the number of observations in the sample. \(N_{\text{pre}}\) can be specified using the samp0() option.

The values of \(S_0\) and \(S^{[2]}_0\) can also be specified using the option s0().

> **Example 1: Smoothing a locally trending series**

Suppose that we had some data on the monthly sales of a book and that we wanted to smooth this series. The graph below illustrates that this series is locally trending over time, so we would not want to use single-exponential smoothing.
The following example illustrates that double-exponential smoothing is simply smoothing the
smoothed series. Because the starting values are treated as time-zero values, we actually lose 2
observations when smoothing the smoothed series.

\[
\begin{align*}
\text{. use http://www.stata-press.com/data/r13/sales2} \\
\text{. tssmooth exponential double sm1=sales, p(.7) s0(1031)} \\
\text{exponential coefficient = 0.7000} \\
\text{sum-of-squared residuals = 13923} \\
\text{root mean squared error = 13.192} \\
\text{. tssmooth exponential double sm2=sm1, p(.7) s0(1031)} \\
\text{exponential coefficient = 0.7000} \\
\text{sum-of-squared residuals = 7698.6} \\
\text{root mean squared error = 9.8098} \\
\text{. tssmooth dexponential double sm2b=sales, p(.7) s0(1031 1031)} \\
\text{double-exponential coefficient = 0.7000} \\
\text{sum-of-squared residuals = 3724.4} \\
\text{root mean squared error = 6.8231} \\
\text{. generate double sm2c = f2.sm2} \\
(2 missing values generated) \\
\text{. list sm2b sm2c in 1/10} \\
\hline 
\text{sm2b} & \text{sm2c} \\
\hline 
1. & 1031 \\
2. & 1028.3834 \\
3. & 1030.6306 \\
4. & 1017.8182 \\
5. & 1022.938 \\
6. & 1026.0752 \\
7. & 1041.8587 \\
8. & 1042.8341 \\
9. & 1035.9571 \\
10. & 1030.6651 \\
\hline 
\end{align*}
\]

The double-exponential method can also be viewed as a forecasting mechanism. The exponential
forecast method is a constrained version of the Holt–Winters method implemented in \texttt{tssmooth
hwinters} (as discussed by Gardner [1985] and Chatfield [2001]). Chatfield (2001) also notes that
the double-exponential method arises when the underlying model is an ARIMA(0,2,2) with equal
roots.

This method produces predictions \( \hat{x}_t \) for \( t = t_1, \ldots, T + \text{forecast()} \). These predictions
are obtained as a function of the smoothed series and the smoothed-smoothed series. For \( t \in [t_0, T] \),

\[
\hat{x}_t = \left( 2 + \frac{\alpha}{1-\alpha} \right) S_t - \left( 1 + \frac{\alpha}{1-\alpha} \right) S_t^{[2]}
\]

where \( S_t \) and \( S_t^{[2]} \) are as given above.

The out-of-sample predictions are obtained as a function of the constant term, the linear term of
the smoothed series at the last observation in the sample, and time. The constant term is \( a_T = 2S_T - S_T^{[2]} \),
and the linear term is \( b_T = \frac{\alpha}{1-\alpha}(S_T - S_T^{[2]} ) \). The \( \tau \)-th-step-ahead out-of-sample prediction is given by

\[
\hat{x}_t = a_t + \tau b_T
\]
Example 2: Forecasting a locally trending series

Specifying the forecast option puts the double-exponential forecast into the new variable instead of the double-exponential smoothed series. The code given below uses the smoothed series sm1 and sm2 that were generated above to illustrate how the double-exponential forecasts are computed.

```
. tssmooth dexponential double f1=sales, p(.7) s0(1031 1031) forecast(4)
double-exponential coefficient = 0.7000
sum-of-squared residuals = 20737
root mean squared error = 16.1

. generate double xhat = (2 + .7/.3) * sm1 - (1 + .7/.3) * f.sm2
   (5 missing values generated)
. list xhat f1 in 1/10
```

Example 3: Choosing an optimal parameter to forecast

Generally, when you are forecasting, you do not know the smoothing parameter. tssmooth dexponential computes the double-exponential forecasts of a series and obtains the optimal smoothing parameter by finding the smoothing parameter that minimizes the in-sample sum-of-squared forecast errors.

```
. tssmooth dexponential f2=sales, forecast(4)
computing optimal double-exponential coefficient (0,1)
optimal double-exponential coefficient = 0.3631
sum-of-squared residuals = 16075.805
root mean squared error = 14.175598
```

The following graph describes the fit that we obtained by applying the double-exponential forecast method to our sales data. The out-of-sample dynamic predictions are not constant, as in the single-exponential case.
\[ \text{tssmooth } \text{dexponential} \quad \text{Double-exponential smoothing} \]

\[ . \text{l} \text{ine } f2 \text{ sales } t, \text{ title(}"\text{Double exponential forecast with optimal alpha}\text{")} \]
\[ > \text{yt} \text{itle(Sales) xtitle(time)} \]

\[ \begin{array}{c}
\begin{array}{c}
\text{Double exponential forecast with optimal alpha}
\end{array}
\end{array} \]

\[ \begin{array}{c}
\begin{array}{c}
\text{950} \\
\text{1000} \\
\text{1050} \\
\text{1100} \\
\text{Sales}
\end{array}
\end{array} \]
\[ \begin{array}{c}
\begin{array}{c}
\text{0} \\
\text{20} \\
\text{40} \\
\text{60} \\
\text{80} \\
\text{time}
\end{array}
\end{array} \]

\[ \text{dexpc(0.3631) = sales} \]

\text{tssmooth dexponential} automatically detects panel data from the information provided when the dataset was \text{tsset}. The starting values are chosen separately for each series. If the smoothing parameter is chosen to minimize the sum-of-squared prediction errors, the optimization is performed separately on each panel. The stored results contain the results from the last panel. Missing values at the beginning of the sample are excluded from the sample. After at least one value has been found, missing values are filled in using the one-step-ahead predictions from the previous period.

**Stored results**

\text{tssmooth dexponential} stores the following in \text{r()}:

**Scalars**

- \text{r(N)} : number of observations
- \text{r(alpha)} : \(\alpha\) smoothing parameter
- \text{r(rss)} : sum-of-squared errors
- \text{r(rmse)} : root mean squared error
- \text{r(N_pre)} : number of observations used in calculating starting values, if starting values calculated
- \text{r(s2_0)} : initial value for linear term, i.e., \(S^2_0\)
- \text{r(s1_0)} : initial value for constant term, i.e., \(S_0\)
- \text{r(linear)} : final value of linear term
- \text{r(constant)} : final value of constant term
- \text{r(period)} : period, if filter is seasonal

**Macros**

- \text{r(method)} : smoothing method
- \text{r(exp)} : expression specified
- \text{r(timevar)} : time variable specified in \text{tsset}
- \text{r(panelvar)} : panel variable specified in \text{tsset}

**Methods and formulas**

A truncated description of the specified double-exponential filter is used to label the new variable. See \text{[D] label} for more information on labels.
An untruncated description of the specified double-exponential filter is saved in the characteristic \texttt{tssmooth} for the new variable. See \texttt{char} for more information on characteristics.

The updating equations for the smoothing and forecasting versions are as given previously.

The starting values for both the smoothing and forecasting versions of double-exponential are obtained using the same method, which begins with the model

$$x_t = \beta_0 + \beta_1 t$$

where $x_t$ is the series to be smoothed and $t$ is a time variable that has been normalized to equal 1 in the first period included in the sample. The regression coefficient estimates $\hat{\beta}_0$ and $\hat{\beta}_1$ are obtained via OLS. The sample is determined by the option \texttt{samp0()}. By default, \texttt{samp0()} includes the first half of the observations. Given the estimates $\hat{\beta}_0$ and $\hat{\beta}_1$, the starting values are

$$S_0 = \hat{\beta}_0 - \frac{(1 - \alpha)}{\alpha} \hat{\beta}_1$$
$$S_0^{[2]} = \hat{\beta}_0 - 2\frac{(1 - \alpha)}{\alpha} \hat{\beta}_1$$
