

[Postestimation commands](#)[predict](#)[estat](#)[Remarks and examples](#)[Stored results](#)[Methods and formulas](#)[References](#)[Also see](#)

Postestimation commands

The following postestimation commands are of special interest after `didregress` and `xtdidregress`:

Command	Description
<code>estat trendplots</code>	graphical diagnostics for parallel trends
<code>estat ptrends</code>	parallel-trends test
<code>estat granger</code>	Granger causality test
<code>estat grangerplot</code>	time-specific treatment effects
<code>estat bdecomp</code>	treatment-effect decomposition

The following standard postestimation commands are also available:

Command	Description
<code>estat summarize</code>	summary statistics for the estimation sample
<code>estat vce</code>	variance–covariance matrix of the estimators (VCE)
<code>estimates</code>	cataloging estimation results
<code>etable</code>	table of estimation results
<code>forecast</code>	dynamic forecasts and simulations
<code>lincom</code>	point estimates, standard errors, testing, and inference for linear combinations of parameters
<code>nlcom</code>	point estimates, standard errors, testing, and inference for nonlinear combinations of parameters
<code>predict</code>	linear predictions and residuals
<code>predictnl</code>	point estimates, standard errors, testing, and inference for generalized predictions
<code>test</code>	Wald tests of simple and composite linear hypotheses
<code>testnl</code>	Wald tests of nonlinear hypotheses

predict

Description for predict

predict creates a new variable containing predictions such as linear predictors and residuals.

Menu for predict

Statistics > Postestimation

Syntax for predict

```
predict [type] newvar [if] [in] [ , statistic]
```

statistic	Description
Main	
xb	linear predictor; the default
residuals	residuals

Options for predict

Main

xb, the default, calculates the linear predictor. It excludes the effect of the first group or of the panel identifier. All other effects, including the time fixed effects, are included in the linear predictor.

residuals calculates the overall residuals. It is the difference of the outcome and the linear predictor, including all group, panel, and time effects. In other words, it is not just the difference of the outcome and the linear predictor.

estat

Description for estat

`estat trendplots` produces two diagnostic plots for assessing the parallel-trends assumption that is required for consistent estimation of the ATET using `didregress` or `xtdidregress`. The first plot consists of two lines showing the mean of the outcome over time for the treatment and the control groups. The second plot augments the DID model to include interactions of time with an indicator of treatment and plots the predicted values of this augmented model for the treatment and control groups. Both plots include a vertical line one period before treatment.

`estat ptrends` performs a test of whether the linear trends in the outcome variable are parallel between control and treatment groups during the pretreatment period.

`estat granger` performs a test of whether treatment effects can be observed in anticipation of the treatment.

`estat grangerplot` produces a graph of time-specific treatment effects by plotting coefficients from leads and lags of the treatment indicator variable.

`estat bdecomp` performs a treatment-effect (Bacon) decomposition into all 2-by-2 treatment-effect components when there are multiple cohorts, each with a different treatment timing. Optionally, the components can be plotted against their weights. `estat bdecomp` requires that the data be strongly balanced. That is, units defined by the group variable must have the same number of observations, and observation times must be the same across all units.

<i>trend_options</i>	Description
<code>omeans</code>	draw graph showing observed means
<code>omeans(<i>plot_options</i>)</code>	draw observed-means graph and affect its rendition
<code>ltrends</code>	draw graph showing linear trends
<code>ltrends(<i>plot_options</i>)</code>	draw linear-trends graph and affect its rendition
<code>notitle</code>	suppress overall title
<code>noxline</code>	suppress treatment-time reference line
<code>nocommonlegend</code>	display two individual legends
<code>legendfrom(#)</code>	specify which legend to use
<i>plot_options</i>	Description
Plot	
<i>cline_options</i>	affect rendition of the plotted trend lines; see [G-3] <i>cline_options</i>
<code>line1opts(<i>cline_options</i>)</code>	affect rendition of the line for controls
<code>line2opts(<i>cline_options</i>)</code>	affect rendition of the line for treated
Y axis, X axis, Titles, Legend, Overall	
<i>twoway_options</i>	any options other than <code>by()</code> documented in [G-3] <i>twoway_options</i>
<i>grangerplot_options</i>	Description
<code>nleads(#)</code>	number of leads
<code>nlags(#)</code>	number of lags
<code>baseline(#)</code>	baseline period
<code>lagview</code>	show lags instead of time units
<code>verbose</code>	display results of the underlying regression
<code>post</code>	post the results of the underlying regression in <code>e()</code>
<code>noci</code>	do not plot confidence intervals
<code>noyline</code>	suppress <i>y</i> -axis reference line
CI plot	
<code>recastci(<i>plotype</i>)</code>	plot confidence intervals using <i>plotype</i>
<code>ciopts(<i>rcap_options</i>)</code>	affect rendition of confidence intervals
<code>level(#)</code>	set confidence level; default is <code>level(95)</code>
Add plots	
<code>addplot(<i>plot</i>)</code>	add other plots to the graph
Y axis, X axis, Titles, Legend, Overall	
<i>twoway_options</i>	any options other than <code>by()</code> documented in [G-3] <i>twoway_options</i>

<i>bdecomp_options</i>	Description
<i>summaryonly</i>	show decomposition summary only
<i>fulldecomponly</i>	show full decomposition only
<i>noheader</i>	suppress the table header in the output
<i>notable</i>	suppress the table in the output
<i>graph</i>	plot individual components against their weights
Plot	
<i>copts(marker_options)</i>	change look of markers for cohorts
<i>tnopts(marker_options)</i>	change look of markers for treated versus never treated
<i>laopts(marker_options)</i>	change look of markers for later versus always treated
<i>leopts(marker_options)</i>	change look of markers for later versus earlier treated
<i>elopts(marker_options)</i>	change look of markers for earlier versus later treated
<i>atetlineopts(cline_options)</i>	change look of the ATET reference line
<i>noatetline</i>	suppress ATET reference line
Y axis, X axis, Titles, Legend, Overall	
<i>twoway_options</i>	any options other than <i>by()</i> documented in [G-3] <i>twoway_options</i>

Options for estat trendplots

omeans, *omeans(plot_options)*, *ltrends*, and *ltrends(plot_options)* specify which graphs are to be included and how they should be individually rendered. The default is *omeans ltrends*, meaning that both graphs are included without any modifications.

omeans specifies that the observed-means graph be included. Specifying *omeans* suppresses the linear-trends model graph unless *ltrends* or *ltrends(plot_options)* is also specified.

omeans(plot_options) specifies that the observed-means graph be included and affects its rendition. Specifying *omeans(plot_options)* suppresses the linear-trends model graph unless *ltrends* or *ltrends(plot_options)* is also specified.

ltrends specifies that the linear-trends model graph be included. Specifying *ltrends* suppresses the observed-means graph unless *omeans* or *omeans(plot_options)* is also specified.

ltrends(plot_options) specifies that the linear-trends model graph be included and affects its rendition. Specifying *ltrends(plot_options)* suppresses the observed-means graph unless *omeans* or *omeans(plot_options)* is also specified.

notitle suppresses the overall title of the rendered graph.

noxline suppresses rendering of the treatment-time reference line.

nocommonlegend suppresses the display of one common legend and renders two individual legends.

legendfrom(#) specifies which legend to use; the default is *legendfrom(1)*, which refers to the legend of the first plot (observed means). *legendfrom(#)* is not allowed with the *nocommonlegend* option.

Plot

cline_options affect the rendition of the plotted trend lines, including their style, size, and color; see [G-3] [cline_options](#).

line1opts(cline_options) affect the rendition of the plotted trend lines for the group of controls, including their style, size, and color; see [G-3] [cline_options](#).

line2opts(cline_options) affect the rendition of the plotted trend lines for the group of treated, including their style, size, and color; see [G-3] [cline_options](#).

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] [twoway_options](#), excluding *by()*. These include options for titling the graph (see [G-3] [title_options](#)) and for saving the graph to disk (see [G-3] [saving_option](#)).

Options for estat grangerplot

nleads(#) specifies the number of leads to be included in the model and plotted. By default, all available leads are included. The number of leads must be greater than 0.

nlags(#) specifies the number of lags to be included in the model and plotted. By default, all available lags are included. The number of lags must be greater than or equal to 0.

baseline(#) specifies the baseline period for which the corresponding lead or lag is omitted. By default, the first lead is omitted, which corresponds to the time period prior to intervention.

lagview specifies to show the values of the *x* axis in terms of lags. If this option is not specified, time values are shown.

verbose specifies to display the output of the underlying regression model.

post posts the results of the underlying regression as estimation results in *e()*.

noci removes the pointwise confidence intervals. The default is to plot the confidence intervals.

noyline suppresses rendering of the reference line.

CI plot

recastci(plotype) specifies that confidence intervals be plotted using *plotype*. *plotype* may be *rarea*, *rbar*, *rspike*, *rcap*, *rcapsym*, *rline*, *rconnected*, or *rscatter*; see [G-2] [graph twoway](#). When *recastci()* is specified, the plot-rendition options appropriate to the specified *plotype* may be used in lieu of *rcap_options*. For details on those options, follow the appropriate link from [G-2] [graph twoway](#).

ciopts(rcap_options) affects the rendition of confidence intervals; see [G-3] [rcap_options](#).

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is *level(95)* or as set by *set level*; see [U] [20.8 Specifying the width of confidence intervals](#).

Add plots

addplot(plot) provides a way to add other plots to the generated graph; see [G-3] [addplot_option](#).

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] *twoway_options*, excluding `by()`. These include options for titling the graph (see [G-3] *title_options*) and for saving the graph to disk (see [G-3] *saving_option*).

Options for estat bdecomp

`summaryonly` displays the decomposition summary only.

`fulldecomponly` displays the results of the full decomposition only.

`noheader` suppresses the table header in the output.

`notable` suppresses the results table in the output.

`graph` specifies to plot the treatment-effect components against their weights.

Plot

`copts` (*marker_options*) affect the rendition of the markers for the plotted cohort coefficients, including their style, size, and color; see [G-3] *marker_options*.

`tnopts` (*marker_options*) affect the rendition of the markers for the plotted coefficients for treated versus never treated, including their style, size, and color; see [G-3] *marker_options*.

`laopts` (*marker_options*) affect the rendition of the markers for the plotted coefficients for later versus always treated, including their style, size, and color; see [G-3] *marker_options*.

`leopts` (*marker_options*) affect the rendition of the markers for the plotted coefficients for later versus earlier treated, including their style, size, and color; see [G-3] *marker_options*.

`elopts` (*marker_options*) affect the rendition of the markers for the plotted coefficients for earlier versus later treated, including their style, size, and color; see [G-3] *marker_options*.

`atetlineopts` (*cline_options*) affect the rendition of the plotted ATET reference line, including its style, size, and color; see [G-3] *cline_options*.

`noatetline` suppresses rendering of the ATET reference line.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] *twoway_options*, excluding `by()`. These include options for titling the graph (see [G-3] *title_options*) and for saving the graph to disk (see [G-3] *saving_option*).

Remarks and examples

In the following, we discuss the treatment-effect decomposition approach implemented in `estat bdecomp`. To see examples of `estat trendplots`, `estat ptrends`, and `estat granger`, see examples 1, 4, 5, and 6 in [CAUSAL] [didregress](#). An example of `estat grangerplot` is shown in example 7 in [CAUSAL] [didregress](#).

A simple 2-by-2 DID design is characterized by two time periods (a period before and a period after a treatment or intervention occurs) and two groups (a treatment and a control group). Under this design, all treated units receive the treatment at the same time. A staggered DID design, on the other hand, involves multiple time points at which the treatment is administered. [Goodman-Bacon \(2021\)](#) has shown that, in this case, the ATET is a weighted average of all possible 2-by-2 DID estimators that compare treatment cohorts with each other. Decomposing an overall ATET into these 2-by-2 components provides a diagnostic tool to assess the validity of the two-way fixed-effects DID estimator implemented in `didregress` and `xtddidregress` when treatment timing varies.

Consider the case of a DID design with two treatment times so that the data consist of three groups: an earlier-treated group, a later-treated group, and a never-treated group. Under this scenario, there would be four 2-by-2 comparisons. Two of these come from comparing the group that was treated first with the never-treated group and comparing the group that was treated second with the never-treated group. The third compares the earlier-treated group with the later-treated group (before the later-treated group was treated). The fourth compares the later-treated group with the earlier-treated group (beginning at the point where the earlier-treated group received treatment). This fourth comparison is of particular concern if the 2-by-2 DID estimate substantially differs from the overall ATET estimate and if the corresponding weight is considerably large. In that case, this 2-by-2 estimate induces bias in the overall ATET estimate. The Bacon decomposition implemented in `estat bdecomp` offers insight into which 2-by-2 comparisons are driving the overall ATET estimate. With this decomposition, we can identify sources of variation that potentially bias the overall effect estimate. In cases of suspected bias, users may consider using `hddidregress` or `xthddidregress` to account for treatment-effect heterogeneity.

The decomposition requires that the data be strongly balanced with respect to the observed times per unit. Specifically, units defined by the group variable that is specified in the `group()` option of `didregress` or `xtddidregress` must have an equal number of observations, and observation times given by the variable specified in the `time()` option of `didregress` or `xtddidregress` must be the same across all units.

For further theoretical and empirical details, see [Goodman-Bacon \(2021\)](#). A summary of the Bacon treatment-effect decomposition is provided in [Baker, Larcker, and Wang \(2022\)](#). Applications of the Bacon decomposition can be found in [Rabideau et al. 2021](#) and [Strasser, Oggenfuss, and Wolter \(2022\)](#).

➤ Example 1: DID treatment-effect decomposition for designs with variation in treatment timing

We use a (fictional) dataset where the units are dog breeds for which registration numbers at the American Kennel Club are observed over the course of 10 years. We wish to find out whether the registration numbers change in response to a breed being featured in a widely shown movie. Here is an excerpt of the data:

```
. use https://www.stata-press.com/data/r19/akc
(Fictional dog breed and AKC registration data)
. list in 981/1000, sepby(breed) abbreviate(10) noobs
```

year	breed	movie	best	registered
2031	Old English Sheepdog	0	0	1324
2032	Old English Sheepdog	0	0	878
2033	Old English Sheepdog	0	0	699
2034	Old English Sheepdog	0	0	645
2035	Old English Sheepdog	0	0	1762
2036	Old English Sheepdog	0	0	1182
2037	Old English Sheepdog	1	0	1816
2038	Old English Sheepdog	1	0	4171
2039	Old English Sheepdog	1	0	3755
2040	Old English Sheepdog	1	0	4054
2031	Otterhound	0	0	692
2032	Otterhound	0	0	598
2033	Otterhound	0	0	670
2034	Otterhound	0	0	1642
2035	Otterhound	0	0	1311
2036	Otterhound	0	0	572
2037	Otterhound	0	0	1167
2038	Otterhound	0	0	620
2039	Otterhound	0	0	511
2040	Otterhound	0	0	1065

We list the data for two breeds, the Old English Sheepdog and the Otterhound. We can see that the Old English Sheepdog is featured in a movie that is released in the year 2037 and, thus, is a treated unit. The Otterhound breed has no such luck and belongs to the group that is never treated. Our outcome variable registered measures the number of registrations at the American Kennel Club. We use xtdidregress to fit a two-way fixed-effects DID model:

```
. xtset breed
Panel variable: breed (balanced)
. xtdidregress (registered) (movie), group(breed) time(year)
Treatment and time information
Time variable: year
Control:      movie = 0
Treatment:    movie = 1
```

	Control	Treatment
Group		
breed	119	22
Time		
Minimum	2031	2034
Maximum	2031	2037

Difference-in-differences regressionNumber of obs = 1,410

Data type: Longitudinal

(Std. err. adjusted for 141 clusters in breed)

registered	Coefficient	Robust std. err.	t	P> t	[95% conf. interval]	
ATET movie (1 vs 0)	2129.655	78.16241	27.25	0.000	1975.124	2284.186

Note: ATET estimate adjusted for panel effects and time effects.
Note: Treatment occurs at different times.

We can see that our overall ATET estimate is around 2,130, which is to say that we expect the number of dog registrations to increase by 2,130 if a member of their breed is featured as a movie protagonist. We can now use `estat bdecomp` to decompose this number into its constituent 2-by-2 parts:

```
. estat bdecomp
```

DID treatment-effect decomposition

ATET = 2129.655

Number of obs = 1,410

Number of groups = 141

Number of cohorts = 4

ATET decomposition summary	ATET component	Weight
Treated vs never treated	2166.021	0.970810
Treated earlier vs later	936.70729	0.013157
Treated later vs earlier	906.60588	0.016033

Full ATET decomposition	2x2 coefficient	Weight
Treated vs never treated		
2034 vs never treated	1673.5688	0.157125
2036 vs never treated	1999.2515	0.140290
2037 vs never treated	2315.6702	0.673394
Treated earlier vs later		
2034 vs 2036	580.59722	0.001132
2034 vs 2037	836.17778	0.008488
2036 vs 2037	1291.9333	0.003537
Treated later vs earlier		
2036 vs 2034	542.825	0.001886
2037 vs 2034	831.70833	0.011318
2037 vs 2036	1448.7167	0.002829

Note: Number of cohorts includes never treated.

Note: The ATET reported by `xtdidregress` is a weighted average of the ATET components. If any component is substantially different from the ATET reported by `xtdidregress` and the weight is large, consider accounting for treatment-effect heterogeneity by using `xthdidregress`.

In the table header, we see that we have 1,410 observations from 141 groups (breeds) and that we have four cohorts. The four cohorts consist of groups of breeds that are treated at three different times (2034, 2036, and 2037) and a group that is never treated. The first table shows a decomposition summary where the estimated ATET is decomposed into components due to comparisons between treated and never treated, between earlier treated and later treated, and between later treated and earlier treated. The results in the second table decompose the summary results further into the individual 2-by-2 comparisons.

From the summary results, we see that the component due to comparisons between treated and never treated is close to the overall effect estimate and that its weight is large. Specifically, the weight is around 0.97, which indicates that 97% of the overall ATET estimate is due to comparisons between treated and never treated. The other two components are not close to the overall effect. This would be a potential concern, especially for the later- versus earlier-treated comparisons, if the corresponding weight was considerably large. However, the weights are small here. The later- versus earlier-treated and earlier-versus later-treated components together account for only 3% of the overall ATET.

In the full decomposition results, we see the three components from the summary broken down further. For example, if we look at the treated versus never-treated component, we see that around two thirds of that component is driven by the group that received treatment last. We also see that the 2-by-2 coefficients are increasing, which provides some indication that the treatment effect may be changing over time.

In this example, the number of treatment times is relatively small. However, if that number is large, it can be instructive to plot the 2-by-2 coefficients against their weights. We do this by using the `graph` option of `estat bdecomp`. Because we do not need to see the numerical results again, we also specify the `notable` and `noheader` options:

```
. estat bdecomp, graph notable noheader
```

The blue circles are the 2-by-2 coefficients from the treated versus never-treated component; the red diamonds are the 2-by-2 coefficients from the earlier- versus later-treated component; and the green triangles are the 2-by-2 coefficients from the later- versus earlier-treated component. The triangles and diamonds, while being substantially different from the overall ATET (indicated by the dashed reference line), are all very close to zero weight. This indicates that the contribution of these coefficients to the overall ATET is negligible.

Stored results

`estat ptrends` stores the following results for the test of linear trends in `r()`:

Scalars

<code>r(N)</code>	number of observations
<code>r(F)</code>	test statistic
<code>r(df_r)</code>	number of degrees of freedom of the residuals for the F distribution under H_0
<code>r(p)</code>	p -value
<code>r(df_m)</code>	number of degrees of freedom of the test for the F distribution under H_0

`estat granger` stores the following results for the test of treatment anticipation in `r()`:

Scalars

<code>r(N)</code>	number of observations
<code>r(F)</code>	test statistic
<code>r(df_r)</code>	number of degrees of freedom of the residuals for the F distribution under H_0
<code>r(p)</code>	p -value
<code>r(df_m)</code>	number of degrees of freedom of the test for the F distribution under H_0

`estat grangerplot`, when used with option `post`, stores results from the underlying regression model in `e()` and `r()`.

`estat bdecomp` stores the following results in `r()`:

Scalars

<code>r(N_groups)</code>	number of panels
<code>r(N_obs)</code>	number of observations
<code>r(N_cohorts)</code>	number of cohorts
<code>r(atet)</code>	overall ATET
<code>r(atet_between_b)</code>	between component
<code>r(atet_within_b)</code>	within component
<code>r(atet_between_w)</code>	weight of between component
<code>r(atet_within_w)</code>	weight of within component

Macros

<code>r(ttimes)</code>	times of treatment
------------------------	--------------------

Matrices

<code>r(atet_comp_b)</code>	ATET components
<code>r(atet_comp_w)</code>	weights of ATET components
<code>r(coefs)</code>	individual 2-by-2 coefficients
<code>r(wgts)</code>	weights of individual 2-by-2 coefficients

Methods and formulas

The tests performed with `estat ptrends` and `estat granger` are based on augmented difference-in-differences (DID) models. With `estat ptrends`, we augment the DID model with terms that capture the differences in slopes between treated and controls. With `estat granger`, we augment the model by interacting the dummy variable that marks treated observations with dummy variables for time periods prior to the treatment to capture any potential anticipatory treatment effects.

Let's consider the case of panel data for individuals over time, in which individuals belong to a group s . Groups could be states, occupational categories, districts, etc. Let y_{its} be the outcome of individual i , who belongs to group s , at time t , where $i = 1, \dots, N$, $t = 1, \dots, T$, and $s = 1, \dots, S$.

We can write the DID model for such setups as follows:

$$y_{ist} = \gamma_i + \gamma_t + \mathbf{x}_{ist}\beta + D_{st}\delta + \epsilon_{ist}$$

Here γ_i are individual fixed effects, γ_t are time fixed effects, \mathbf{x}_{ist} are covariates, D_{st} is a variable that is 1 if an individual belongs to a group s that is treated at time t and is 0 otherwise, and ϵ_{ist} is an error term. The coefficient δ represents the average treatment effect on the treated (ATET).

To simplify the exposition below, we rewrite the model as follows:

$$\begin{aligned} y_{ist} &= \gamma_i + \gamma_t + \mathbf{x}_{ist}\beta + D_{st}\delta + \epsilon_{ist} \\ y_{ist} &= \text{DID}_{ist} + \epsilon_{ist} \end{aligned} \tag{1}$$

The linear-trends model that is used for the parallel-trends test with `estat ptrends` augments the above model with two more terms. Let $d_{t,0} = 1(d_t = 0)$ be a variable indicating pretreatment time periods, and let $d_{t,1} = 1(d_t = 1)$ be a variable indicating posttreatment time periods. Also, let w_i be a variable that is 1 if the individual belongs to a treated group and is 0 otherwise. The augmentation terms then consist of two 3-way interactions between $d_{t,0}$, w_i , and t , and $d_{t,1}$, w_i , and t :

$$y_{ist} = \text{DID}_{ist} + w_i d_{t,0} t \zeta_1 + w_i d_{t,1} t \zeta_2 + \epsilon_{ist} \tag{2}$$

Under this specification, the coefficient ζ_1 captures the differences in slopes between treatment group and control group in pretreatment periods, while ζ_2 captures the differences in slopes in posttreatment periods. If ζ_1 is 0, the linear trends in the outcome are parallel during pretreatment periods. The same is true for ζ_2 with respect to the posttreatment period; however, posttreatment differences in trends are not relevant for assessing the parallel-trends assumption. `estat ptrends` uses a Wald test of ζ_1 against 0 to assess whether the linear trends are parallel prior to treatment. Thus, the null hypothesis of this test is that the linear trends are parallel.

`estat granger` performs a Granger-type causality test to assess whether treatment effects are observed prior to the treatment. To illustrate this, suppose the treatment took place at time $t = j$. We could express D_{st} as $D_{st} = 1(t \geq j)w_i$. The Granger-type test augments the model with counterfactual treatment-time indicators. For example, if the treatment occurred at time $j - 1$, then we could construct a new treatment as $1(t_{it} \geq j - 1)w_i$, and if we have sufficient time points, we could construct another counterfactual treatment as $1(t_{it} \geq j - 2)w_i$, and so on. These terms are referred to as leads in the DID literature. The model used by `estat granger` uses the model in (1) and augments it with all leads leaving out one for identification purposes. Let J index the time at which the treatment occurs.

$$y_{ist} = \text{DID}_{ist} + \sum_{j=2}^{J-1} 1(t_{it} \geq j)w_i \lambda_j + \nu_{ist} \tag{3}$$

The test result is then obtained by performing a joint Wald test on the coefficients λ_j . Thus, the null hypothesis for this test is that the coefficients in λ_j are jointly 0, which is to say there are no anticipatory effects.

`estat grangerplot` fits a generalization of the DID model in (1) and plots the estimated coefficients from this model, including their 95% confidence intervals. The model is similar to (3), but this model parameterizes the leads differently and includes lags in addition to leads. Let I_s be the time of treatment, $m < 0$ be the number of time periods prior to I_s , $q \geq 0$ be the number of periods after I_s , and b be the baseline period. The model is

$$y_{ist} = \gamma_i + \gamma_t + \mathbf{x}_{ist}\boldsymbol{\beta} + \sum_{k=m, k \neq b}^q B_{st}^k w_i \lambda_k + \epsilon_{ist}$$

where

$$B_{st}^k = \begin{cases} 1(t_{it} \leq I_s + k), & \text{if } k = m \\ 1(t_{it} = I_s + k), & \text{if } m < k < q \\ 1(t_{it} \geq I_s + k), & \text{if } k = q \end{cases}$$

This yields a model with $|m|$ leads and q lags. By default, `estat grangerplot` uses all available leads and lags. If, without loss of generality, we set the base to the period prior to treatment, $b = -1$ (the default), then with $t = 1, \dots, T$ and $I_s = J$, a maximum of $n_{\text{leads}} = J - 2$ leads and $n_{\text{lags}} = T - J + 1$ lags is available. Notice that, if all available leads and lags are used, B_{st}^k reduces to $B_{st}^k = 1(t_{it} = I_s + k)$ because there are no periods before or after $I_s + k$. With fewer than available leads and lags, that is, $|m| < n_{\text{leads}}$ or $q < n_{\text{lags}}$, notice that the corresponding indicator variables capture the periods beyond the endpoints that correspond to m and q .

At a minimum, the model has to include a single lead. In that case, we have that $m = -1$ and $q = 0$. After omitting the base, we have that $k = 0$ and B_{st}^k reduces to $B_{st}^k = 1(t_{it} \geq I_s)$. Notice that $B_{st}^k w_i$ now yields our original treatment indicator D_{st} . In other words, the model with a single lead and no lags yields the special case of the DID model in (1). Notice also that the model in (3) is a special case, too. It is equivalent to the model fit by `estat grangerplot` with all available leads and no lags. However, (3) uses a different parameterization because the indicator variables are constructed differently. `estat grangerplot` plots the coefficients λ_k against the corresponding time periods.

The `estat trendplots` command produces two plots. The first plot is simply plotting the observed means for each treatment group at each point in time. The second plot is based on the model in (2), which is the model used for the parallel-trends test, but this model centers the continuous time variable around its minimum value:

$$y_{ist} = \text{DID}_{ist} + w_i d_{t,0} \{t - \min(t)\} \zeta_1 + w_i d_{t,1} \{t - \min(t)\} \zeta_2 + \mu_{ist}$$

Centering around the minimum time value provides a common reference point at the first observed time point such that deviations from parallelism are easily detectable. The graph then shows the predicted values from this model, evaluated at all observed time points for each of the treatment groups and at the means of the covariates.

While the formulas above are shown for the case of panel data, these methods work the same way for data that consist of repeated cross-sections.

The `estat bdecomp` command may be used in cases where units get treatment at different times. The command performs a decomposition of the estimated DID treatment effect into components that come from all possible 2-by-2 cohort comparisons. Cohorts are defined by the times of treatment administration and also include a group of never treated and potentially a group of always treated. Cohorts are also referred to as timing groups. `estat bdecomp` results are based on the derivation in [Goodman-Bacon \(2021\)](#).

For a DID model without covariates, we have the two-way fixed-effects model

$$y_{it} = \gamma_i + \gamma_t + D_{it}\delta^{\text{DD}} + \epsilon_{it}$$

where δ^{DD} is the overall treatment effect from the DID model. Let t_i denote the time when unit i receives treatment. If unit i was never treated, we set $t_i = U > T$ and say that the unit belongs to cohort U (where T is the latest time period for which we have data). If unit i was treated in period $k \in \{1, 2, \dots, T\}$, that is, $t_i = k$, we say that the unit belongs to cohort k . Let K denote the set of all cohorts (including U).

[Goodman-Bacon \(2021\)](#) show that we can decompose the estimated $\hat{\delta}^{\text{DD}}$ into the weighted sum of the DID coefficients that comes from all possible 2-by-2 cohort pairs,

$$\hat{\delta}^{\text{DD}} = \sum_{k \neq U} w_{kU} \hat{\delta}_{kU}^{2 \times 2} + \sum_{k \neq U} \sum_{l > k} \left[w_{kl}^k \hat{\delta}_{kl}^{2 \times 2, k} + w_{kl}^l \hat{\delta}_{kl}^{2 \times 2, l} \right]$$

where $\hat{\delta}_{kU}^{2 \times 2}$ is the coefficient from the 2-by-2 DID model that uses cohorts k and U as treatment and control, respectively, and $\hat{\delta}_{kl}^{2 \times 2, k}$ is the coefficient from the model that uses cohorts k and l as treatment and control, respectively. The weights w are given by

$$\begin{aligned} w_{kU} &= \frac{(s_k + s_U)^2 s_{kU} (1 - s_{kU}) \overline{D}_k (1 - \overline{D}_k)}{\hat{V}^D} \\ w_{kl}^k &= \frac{[(s_k + s_l)(1 - \overline{D}_l)]^2 s_{kl} (1 - s_{kl}) \frac{\overline{D}_k - \overline{D}_l}{1 - \overline{D}_l} \frac{1 - \overline{D}_k}{1 - \overline{D}_l}}{\hat{V}^D} \\ w_{kl}^l &= \frac{[(s_k + s_l) \overline{D}_k]^2 s_{kl} (1 - s_{kl}) \frac{\overline{D}_l}{\overline{D}_k} \frac{\overline{D}_k - \overline{D}_l}{\overline{D}_k}}{\hat{V}^D} \end{aligned}$$

where $s_j \equiv \sum_i 1(t_i = j)/N$ is the share of cohort $j \in K$, $s_{ab} \equiv s_a/(s_a + s_b)$ is the relative size of cohort a with respect to cohort b , $\overline{D}_j \equiv \sum_t 1(t \geq j)/T$ is the proportion of time spent in treatment by cohort $j \in K$, and \hat{V}^D is the sample variance of the treatment indicator demeaned with respect to both group and time fixed effects. The weights w sum to unity: $\sum_{k \neq U} w_{kU} + \sum_{k \neq U} \sum_{l > k} [w_{kl}^k + w_{kl}^l] = 1$.

For a model that includes time-varying covariates, \mathbf{x}_{it} , a similar decomposition result holds. Consider the model

$$y_{it} = \gamma_i + \gamma_t + \mathbf{x}_{it}\beta + D_{it}\delta^{\text{DD}|\mathbf{x}} + \epsilon_{it}$$

where $\delta^{\text{DD}|\mathbf{x}}$ denotes the covariate-adjusted ATET. In this case, we can decompose $\hat{\delta}^{\text{DD}|\mathbf{x}}$ into a within and a between component,

$$\hat{\delta}^{\text{DD}|\mathbf{x}} = \Omega \hat{\delta}_w^p + (1 - \Omega) \hat{\delta}_b^d$$

To estimate the within and between components, we first fit a linear model that partials the covariates out of D_{it} ; that is,

$$\widetilde{D}_{it} = \widetilde{\mathbf{x}}_{it} \widehat{\Gamma} + \widetilde{d}_{it} = \widetilde{p}_{it} + \widetilde{d}_{it} \quad (4)$$

where \widetilde{D}_{it} and $\widetilde{\mathbf{x}}_{it}$ are respectively the treatment indicator and the covariates demeaned with respect to both group and time fixed effects. The resulting residuals can then be separated into a within component, $\widetilde{d}_{i(k)t}$, and a between component, \widetilde{d}_{kt} , so that $\widetilde{d}_{it} = \widetilde{d}_{i(k)t} + \widetilde{d}_{kt}$.

The within component of \widetilde{d}_{it} is defined as $\widetilde{d}_{i(k)t} = (d_{it} - \bar{d}_i) - (\bar{d}_{kt} - \bar{d}_k)$, where $d_{it} = D_{it} - \widehat{\Gamma} \mathbf{x}_{it}$ is the treatment status adjusted by covariates only; and \bar{d}_i , \bar{d}_k , and \bar{d}_{kt} are respectively the averages of d_{it} by individual, cohort, and cohort by year. This component captures deviations of d_{it} from cohort averages and cohort-by-year averages.

The between component of \widetilde{d}_{it} is defined as $\widetilde{d}_{kt} = (\bar{d}_{kt} - \bar{d}_k) - (\bar{d}_t - \bar{\bar{d}})$, where \bar{d}_t and $\bar{\bar{d}}$ are the averages of d_{it} by year and in the whole sample, respectively.

The within and between components of the DID treatment effect, $\hat{\delta}_w^p$ and $\hat{\delta}_b^d$, can be obtained by separately regressing the outcome variable y_{it} on $\widetilde{d}_{i(k)t}$ and \widetilde{d}_{kt} , respectively. Thus, $y_{it} = a_w + \widetilde{d}_{i(k)t} \hat{\delta}_w^p + \nu_{it}$ and $y_{it} = a_b + \widetilde{d}_{kt} \hat{\delta}_b^d + \eta_{it}$. The weight Ω is given by the ratio of the variances $\Omega = \widehat{V}_w^d / \widehat{V}^d$, where \widehat{V}_w^d and \widehat{V}^d are the sample variances of $\widetilde{d}_{i(k)t}$ and \widetilde{d}_{it} , respectively.

The between component $\hat{\delta}_b^d$ can be decomposed further into 2-by-2 components

$$\hat{\delta}_b^d = \sum_k \sum_{l>k} w_{kl}^{b|\mathbf{x}} \hat{\delta}_{kl}^{2 \times 2|d}$$

where

$$\hat{\delta}_{kl}^{2 \times 2|d} = \frac{\widehat{V}_{kl}^D \hat{\delta}_{kl}^{2 \times 2} - \widehat{V}_{b,kl}^p \hat{\delta}_{b,kl}^p}{\widehat{V}_{b,kl}^d}$$

and

$$w_{kl}^{b|\mathbf{x}} = (s_k + s_l)^2 \frac{\widehat{V}_{b,kl}^d}{\widehat{V}_b^d}$$

In the formulas above, \widehat{V}_b^d and $\widehat{V}_{b,kl}^d$ are the sample variances of \widetilde{d}_{kt} in the whole sample and in the subsample consisting of cohorts k and l , respectively. \widehat{V}_{kl}^D and $\widehat{V}_{b,kl}^p$ are the sample variances of \widetilde{D}_{it} and \widetilde{p}_{it} , respectively, in the subsample consisting of cohorts k and l . Finally, $\hat{\delta}_{kl}^{2 \times 2}$ and $\hat{\delta}_{b,kl}^p$ are the coefficients from a regression of y_{it} on \widetilde{D}_{it} and from a regression of y_{it} on \widetilde{p}_{it} , respectively, in the subsample consisting of cohorts k and l .

Thus, the full decomposition for a DID specification with controls is

$$\hat{\delta}^{\text{DD}|\mathbf{x}} = \Omega \hat{\delta}_w^p + (1 - \Omega) \sum_k \sum_{l>k} w_{kl}^{b|\mathbf{x}} \hat{\delta}_{kl}^{2 \times 2|d}$$
