Description Remarks and examples Also see

Description

We model a binary outcome that depends on a continuous endogenous covariate and has an endogenous treatment by using eprobit with the endogenous() and entreat() options.

Remarks and examples

Continuing from [ERM] **Example 3a**, State U administrators have implemented a voluntary program to increase retention freshman year. Whether a student chose to participate is stored in the indicator variable program. They are concerned that unobservable factors that influence a student's decision to participate in the college retention program also influence the probability of graduation. For example, students who have higher self-motivation may be more likely to join and also more likely to graduate without the program. Thus, they are concerned that participation in the program may be an endogenously chosen treatment. Further, they would like to control for the possibility that the unobserved factors affecting graduation have different relationships with the unobserved factors that affect participation and high school GPA for those who participated and those who did not.

The researchers believe the program was easier to access for students who lived on campus freshman year. They also think students who had scholarships may have been more motivated to attend the program. However, they do not believe either of these variables independently affects the probability of graduation after controlling for other covariates in the model. They use an indicator for on-campus residence during the freshman year (campus), having a scholarship of any kind (scholar), and parents' income in the treatment assignment model. . eprobit graduate income i.roommate, endogenous(hsgpa = income i.hscomp)

corr(e.hsgpa, e.program)	0206714	.0264813	-0.78	0.435	0724717	.03124

The main equation output is slightly different from that in [ERM] **Example 3a**. Because program was specified as a treatment, it was automatically interacted with each of the other covariates in the graduate equation.

We specified the pocorrelation suboption in entreat() so that we estimate separate correlation parameters for the two potential outcomes—for those who participated and those who did not. In the treated group, the correlation of the errors from the graduation equation and those from the program participation equation corr(e.program, e.graduate) is estimated to be 0.43 and is significantly different from zero. The researchers conclude that unobservable factors that increase the chance of participating in the program also increase the chance of graduating among the individuals that participate in the program.

Now, we use estat teffects to estimate the ATE of program participation on college graduation. We specified vce(robust) when we fit the model, so estat teffects reports standard errors and tests for the population ATE.

. estat teffects Predictive margins Number of obs = 2,500						
	Margin	Unconditional std. err.	z	P> z	[95% conf.	interval]
ATE program (1 vs 0)	.1053155	.0491882	2.14	0.032	.0089083	.2017226

We estimate that the ATE is 0.11. In other words, the average probability of graduating increases by 0.11 when all students participate in the program versus when no students participate in the program.

We might be interested if those students who self-selected into the program increased their graduation probability by more than 0.11. We estimate the average treatment effect on the treated (ATET).

. estat terre	cts, atet					
Predictive ma	rgins				Number of obs Subpop. no. c	s = 2,500 bbs = 1,352
	Margin	Unconditional std. err.	z	P> z	[95% conf.	interval]
ATET program (1 vs 0)	. 1255127	.0674688	1.86	0.063	0067236	.2577491

In this case, the program is only a little more effective on average for those who chose to participate than it would have been for everyone. The ATET is 0.13, only 0.02 higher than the ATE.

Those are the overall averages. Do graduation rates for participants and nonparticipants differ by high school GPA and parents' income? Our dataset has grouping variables, so we can let margins estimate graduation rates for subpopulations defined by all three covariates.

. margins, over(program incomegrp hsgpagrp) vce(unconditional)
 (output omitted)

The output is copious. You can type the command and see it if you like. The patterns are easier to see on a marginsplot.

```
. marginsplot, plot(program) xlabels(0 4 8 12)
```

The red line shows expected graduation rates for those who participated in the program. The blue line shows rates for nonparticipants. Clearly, the differences between the groups in the program and those out of the program differ dramatically across GPA and family income. For GPAs at or above 3.5, the graduation rates are so high that there was no room for differences. For those with GPAs below 2.5, we see differences, with participation graduation rates being higher than nonparticipation, but lots of variation as income increases. For the other groups, the graduation rates are estimated to be substantially higher among those who participated.

We were careful not to call the comparisons above effects or attribute them directly to the program. They are indeed expected rates for the groups, but the students self-selected into program participation groups. If we want to compare graduation rates assuming all students do not participate and then assuming all students do participate, we type

```
. margins r.program, over(incomegrp hsgpagrp) vce(unconditional)
> contrast(nowald)
(output omitted)
```

(output omitted)

The output is again long, so we leave you to see it for yourself. The graphs reveal the patterns across groups.

. marginsplot, by(hsgpagrp) xlabels(0 4 8 12)

Contrasts of predictive margins of program with 95% CIs

These differences are close to what we would have seen had we differenced the red and blue lines of the first graph. In this graph, each point is an estimate of the average treatment effect for a subpopulation defined by a range of GPAs and a range of family income. We note that the confidence intervals, as represented by the capped lines, are fairly wide.
