Example 9 — Ordered probit regression with endogenous treatment and random effects

Description

In this example, we show how to estimate and interpret the results of an extended regression model with an ordinal outcome, an endogenous treatment, and random effects.

Remarks and examples

In [ERM] **Example 6a**, we examined fictional data on the health scores of women between the ages of 25 and 30. Each woman was observed at one time point. Our outcome was an ordinal health status ranging from 1 (poor) to 5 (excellent). We estimated the average treatment effect of having health insurance on the probabilities of having each health status.

Now suppose that we conduct a fictional study where we have collected data on 1,800 women between the ages of 25 and 30 annually from 2010 to 2013. We have measured the women's health status in each year. We want to estimate the average treatment effect (ATE) of having insurance on the probability of each of the five statuses. We suspect that our model needs to account for health insurance being an endogenous treatment. We also believe that unobserved characteristics of the individual might affect both health status and whether the woman has insurance, so we include random effects in both equations.

In addition to the insurance indicator, we include an indicator for whether the woman exercises regularly and the number of years of schooling she completed (grade) as exogenous covariates in the model for health status. For our treatment model, we use grade and an indicator for whether the woman is currently working or attending school (workschool), which is excluded from the outcome model.

Before we can fit our random-effects model, we need to specify the panel structure of the data using xtset. Our panel variable is personid, the identification code for the individual. The time variable is year, and it ranges from 2010 to 2013.

```
. use https://www.stata-press.com/data/r19/womenhlthre
(Women's health status panel)

. xtset personid year
Panel variable: personid (strongly balanced)
 Time variable: year, 2010 to 2013
        Delta: 1 unit
```

1

With the data xtset, we can estimate the parameters of the model.

```
. xteoprobit health exercise grade,
> entreat(insured = grade i.workschool) vce(robust)

(setting technique to bhhh)
Iteration 0:  Log pseudolikelihood = -12272.723
Iteration 1:  Log pseudolikelihood = -12256.949
Iteration 2:  Log pseudolikelihood = -12256.539
Iteration 3:  Log pseudolikelihood = -12256.478
Iteration 4:  Log pseudolikelihood = -12256.468
Iteration 5:  Log pseudolikelihood = -12256.466
Iteration 6:  Log pseudolikelihood = -12256.465
Iteration 7:  Log pseudolikelihood = -12256.465
Iteration 8:  Log pseudolikelihood = -12256.465
Iteration 9:  Log pseudolikelihood = -12256.465
```

Extended ordered probit regression   Number of obs   =   7,200
Group variable: personid   Number of groups =   1,800

                                      Obs per group:
                                            min =   4
                                            avg =   4.0
                                            max =   4
Integration method: mvaghermite   Integration pts. =   7

                                         Wald chi2(4)   = 404.14
Log pseudolikelihood = -12256.465   Prob > chi2   = 0.0000

                          (Std. err. adjusted for 1,800 clusters in personid)

The estimated correlation between the observation-level errors is 0.38. The estimated correlation between the individual-level random effects affecting health status and the individual-level random effects affecting insurance status is 0.33. Both are significantly different from zero. We conclude that insurance status is endogenous and that the unobserved person-specific factors that increase the chance of having health insurance also tend to increase the chance of being in a high health status. Additionally, the unobserved observation-level (time-varying) factors that increase the chance of having health insurance also tend to increase the chance of being in a high health status.

We see estimates of both the coefficients and the cutpoints for two equations, one for insured women (yes) and one for uninsured women (no). For both insured and uninsured, exercise and education have positive effects on health status.

We can use `estat teffects` to estimate the ATE of insurance on the probabilities of each health category.

```
. estat teffects
Predictive margins                                    Number of obs = 7,200
                          (Std. err. adjusted for 1,800 clusters in personid)
```

	Margin	Unconditional std. err.	z	P>|z|	[95% conf. interval]	
ATE_Pr1 insured (Yes vs No)	-.1761541	.0279001	-6.31	0.000	-.2308372	-.1214709

ATE_Pr3 insured (Yes vs No)	-.0607013	.0127344	-4.77	0.000	-.0856602	-.0357424
ATE_Pr4 insured (Yes vs No)	.1145319	.0214062	5.35	0.000	.0725765	.1564874
ATE_Pr5 insured (Yes vs No)	.2955128	.0345022	8.57	0.000	.2278897	.3631359

We see that the treatment effect is negative on the probability of being in poor health. The treatment effect becomes more positive for each successive health status. Looking at the last line, we see that the average probability of being in excellent health in the population of women aged 25 to 30 is 0.30 greater when all women have health insurance versus when no women have health insurance.
