fmm intro — Introduction to finite mixture models

Description Remarks and examples Acknowledgment References Also see

# Description

Finite mixture models (FMMs) are used to classify observations, to adjust for clustering, and to model unobserved heterogeneity. In finite mixture modeling, the observed data are assumed to belong to unobserved subpopulations called classes, and mixtures of probability densities or regression models are used to model the outcome of interest. After fitting the model, class membership probabilities can also be predicted for each observation. This entry discusses some fundamental and theoretical aspects of FMMs and illustrates these aspects with a worked example.

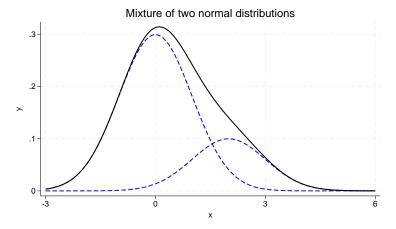

## **Remarks and examples**

Remarks are presented under the following headings:

Introduction Finite mixture models Mixture of normal distributions—FMM by example Beyond mixtures of distributions

### Introduction

The main concept in finite mixture modeling is that the observed data come from distinct, but unobserved, subpopulations. To illustrate, we plot the observed distribution of a whole population (solid line) and the unobserved densities of two underlying subpopulations (dashed lines).

The observed distribution looks approximately normal, with a slight asymmetry because of more values falling above zero than below. This asymmetry occurs because the distribution is a mixture of two normal densities; the right-hand density skews the distribution to the right. We can use FMMs to estimate the means and variances of the two underlying densities along with their proportions in the overall population.

More generally, we can use FMMs to model mixtures containing any number of subpopulations, and the subpopulation-specific models need not be limited to a mixture of normal densities. FMMs allow mixtures of linear and generalized linear regression models, including models for binary, ordinal, nominal, and count responses, and allow the inclusion of covariates with subpopulation-specific effects. We can also make inferences about each subpopulation and classify individual observations into a subpopulation.

Because of their flexibility, FMMs have been used extensively in various fields to classify observations, to adjust for clustering, and to model unobserved heterogeneity. Mixtures of normal densities with equal variances can be used to approximate any arbitrary continuous distribution, which makes FMMs a popular tool to model multimodal, skewed, or asymmetrical data. A mixture of regression models can be used to model phenomena such as clustering of internet traffic (Jorgensen 2004), demand for medical care (Deb and Trivedi 1997), disease risk (Schlattmann, Dietz, and Böhning 1996), and perceived consumer risk (Wedel and DeSarbo 1993). A mixture of a count model and a degenerate point mass distribution is often used for modeling zero-inflated and truncated count outcomes; see, for example, Jones et al. (2013, chap. 11). McLachlan and Peel (2000) and Frühwirth-Schnatter (2006) provide a comprehensive treatment of finite mixture modeling.

From a broader statistical perspective, FMMs are related to latent class analysis (LCA) models; both are used to identify classes using information from manifest (observed) variables. The difference is that FMMs allow parameters in a regression model for a single dependent variable to differ across classes while traditional LCA fits intercept-only models to multiple dependent variables. FMM is also a subset of structural equation modeling (SEM) where the latent variable is assumed to be categorical; see [SEM] Intro 1, [SEM] Intro 2, [SEM] gsem, and Skrondal and Rabe-Hesketh (2004, chap. 3) for a theoretical discussion. If your latent variable is continuous and your manifest variables are discrete, you can use item response theory models; see [IRT] irt. If both your latent variable and manifest variables are continuous, you can fit a structural equation model; see [SEM] sem.

Throughout this manual, we use the terms "class", "group", "type", or "component" to refer to an unobserved subpopulation. We use the terms "class probability" or "component probability" to refer to the probability of belonging to a given component in the mixture. Class probabilities are also referred to in the literature as "mixing weights" or "mixing proportions".

#### Finite mixture models

FMMs are probabilistic models that combine two or more density functions. In an FMM, the observed responses y are assumed to come from g distinct classes  $f_1, f_2, \ldots, f_g$  in proportions  $\pi_1, \pi_2, \ldots, \pi_g$ . In its simplest form, we can write the density of a g-component mixture model as

$$f(\boldsymbol{y}) = \sum_{i=1}^g \pi_i f_i(\boldsymbol{y} | \boldsymbol{x}' \boldsymbol{\beta}_i)$$

where  $\pi_i$  is the probability for the *i*th class,  $0 \le \pi_i \le 1$  and  $\sum \pi_i = 1$ , and  $f_i(\cdot)$  is the conditional probability density function for the observed response in the *i*th class model.

fmm uses the multinomial logistic distribution to model the probabilities for the latent classes. The probability for the *i*th latent class is given by

$$\pi_i = \frac{\exp(\gamma_i)}{\sum_{j=1}^g \exp(\gamma_j)}$$

where  $\gamma_i$  is the linear prediction for the *i*th latent class. By default, the first latent class is the base level so that  $\gamma_1 = 0$  and  $\exp(\gamma_1) = 1$ .

The likelihood is computed as the sum of the probability-weighted conditional likelihood from each latent class; see *Methods and formulas* in [FMM] **fmm** for details.

#### Mixture of normal distributions—FMM by example

The 1872 Hidalgo stamp of Mexico was printed on different paper types, which was typical of stamps of that era. For collectors, a stamp from a printing that used thicker paper is more valuable. We can use an FMM to predict the probability that a stamp is from a printing that used thick paper.

stamp.dta contains data on 485 measurements of stamp thickness, recorded to a thousandth of a millimeter. Here we plot the histogram of the measurements.

```

                                                                                     .14
                 .06
                                                                    .12
                                           Stamp thickness (mm)
```

At a minimum, the histogram suggests bimodality in the data, but we follow Izenman and Sommer (1988) and fit a mixture of three normal distributions to the data, each with its own mean and variance. We also estimate the proportion that each distribution contributes to the overall density. You can think of the three distributions as representing three different types of paper (thick, medium, thin) that the stamps were printed on. More specifically, our model is

$$f(\boldsymbol{y}) = \pi_1 N(\mu_1, \sigma_1^2) + \pi_2 N(\mu_2, \sigma_2^2) + \pi_3 N(\mu_3, \sigma_3^2)$$

The probability of being in each class is estimated using multinomial logistic regression

$$\begin{aligned} \pi_1 &= \frac{1}{1 + \exp(\gamma_2) + \exp(\gamma_3)} \\ \pi_2 &= \frac{\exp(\gamma_2)}{1 + \exp(\gamma_2) + \exp(\gamma_3)} \\ \pi_3 &= \frac{\exp(\gamma_3)}{1 + \exp(\gamma_2) + \exp(\gamma_3)} \end{aligned}$$

where the  $\gamma_i$  are intercepts in the multinomial logit model. By default, the first class is treated as the base, so  $\gamma_1 = 0$ .

To fit this model, we type

. fmm 3: regress thickness

We type fmm 3: because we have a mixture of three components. We type regress thickness to tell fmm to fit a linear regression model for each component. With no covariates, regress reduces to estimating the mean and variance of a Gaussian (normal) density for each component.

The result of typing our estimation command is

```

The output shows four iteration logs. The first three are for models that are fit to obtain starting values. Finding good starting values is often challenging for mixture models. fmm provides a variety of options for specifying and computing starting values; see *Options* in [FMM] fmm for more information.

The first output table presents the estimated class probabilities on a multinomial logistic scale. We can transform these estimates into probabilities as follows:

$$\begin{split} \pi_1 &= \frac{1}{1 + \exp(0.64) + \exp(0.81)} \approx 0.19 \\ \pi_2 &= \frac{\exp(0.64)}{1 + \exp(0.64) + \exp(0.81)} \approx 0.37 \\ \pi_3 &= \frac{\exp(0.81)}{1 + \exp(0.64) + \exp(0.81)} \approx 0.44 \end{split}$$

More conveniently, we can use the estat lcprob command, which calculates these probabilities and the associated standard errors and confidence intervals; see [FMM] estat lcprob.

tent class ma	arginal proba	abilities		Numbe	er of obs =

3	.4368286	.027885	.383149	.49203	

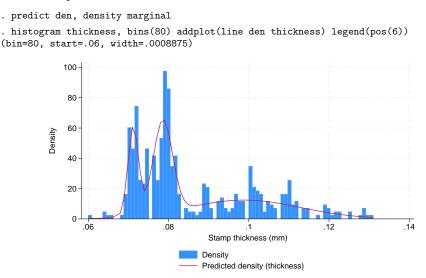

. estat lcprob

The three remaining tables of the fmm output show the estimated means and variances of each normal distribution.

The resulting mixture density, with maximum likelihood estimates of means, variances, and class probabilities, is given by

 $0.19 \times N(0.071, 0.0000017) + 0.37 \times N(0.079, 0.0000057) + 0.44 \times N(0.099, 0.0001967)$ 

This equation gives the predicted density of stamp thickness, and we can plot it against the empirical distribution of stamp thickness as follows:

We see that the first two components with small variances model the left-hand side of the empirical distribution, whereas the third component with much larger variance covers the long tail on the right-hand side of the empirical distribution.

We can use the predictions of the posterior probability of class membership to evaluate the probability of being in each class for each stamp. For the first stamp in our dataset, the probability of being in class 3, the thick paper type, is 1.

.089	0.000	0.001	0.999
.09131	0.000	0.000	1.000

Because there are no covariates in the model, the posterior probabilities are the same for any stamp with a given thickness and are as follows.

The third mixture component has a relatively large variance, so the four thinnest measures end up being incorrectly classified into the thick paper type. Because stamp thickness cannot be negative, we can improve the model fit if we use a density with support only on the positive real line, such as the lognormal distribution.

```
. fmm 3: glm thickness, family(lognormal)
 (output omitted)
```

We plot the predicted density from the mixture of normals with the density from the mixture of lognormals.

The mixture of lognormals correctly classifies the thinnest stamps into the thin paper type, which is confirmed by the predicted posterior probabilities.

#### Beyond mixtures of distributions

We have just scratched the surface of what can be done with fmm. We can fit mixtures of linear and generalized linear regression models where the effect of the covariates and the covariates themselves differ by class; see [FMM] **fmm estimation** for a list of supported outcome models. We can also model class probabilities with common or class-specific covariates.

More complicated FMMs can be fit using gsem within the LCA framework. gsem allows more than one response variable per component and more than one categorical latent variable; see, for instance, [SEM] **Example 54g**, where we fit a mixture of Poisson regression models to multiple responses. See *Latent class analysis (LCA)* in [SEM] **Intro 2** and *Latent class models* in [SEM] **Intro 5** for an overview of latent class modeling with gsem.
