These functions compute derivatives of the real function \( f(p) \) at the real parameter values \( p \).

derv_init() begins the definition of a problem and returns \( D \), a problem-description handle set that contains default values.

The deriv_init_*\((D, \ldots)\) functions then allow you to modify those defaults. You use these functions to describe your particular problem: to set the identity of function \( f() \), to set parameter values, and the like.

derv\((D, todo)\) then computes derivatives depending upon the value of \( todo \).

\[
derv(D, 0) \text{ returns the function value without computing derivatives.}
\]

\[
derv(D, 1) \text{ returns the first derivatives, also known as the gradient vector for scalar-valued functions (type d and v) or the Jacobian matrix for vector-valued functions (type t).}
\]

\[
derv(D, 2) \text{ returns the matrix of second derivatives, also known as the Hessian matrix; the gradient vector is also computed. This syntax is not allowed for type t evaluators.}
\]

The deriv_result_*\((D)\) functions can then be used to access other values associated with the solution.

Usually you would stop there. In other cases, you could compute derivatives at other parameter values:

\[
derv_init_params(D, p_{alt})
\]

\[
derv(D, todo)
\]

Aside: The deriv_init_*\((D, \ldots)\) functions have two modes of operation. Each has an optional argument that you specify to set the value and that you omit to query the value. For instance, the full syntax of deriv_init_params() is

\[
void \ deriv_init_params(D, \ real \ rowvector \ parameters)
\]

\[
real \ rowvector \ deriv_init_params(D)
\]

The first syntax sets the parameter values and returns nothing. The second syntax returns the previously set (or default, if not set) parameter values.

All the deriv_init_*\((D, \ldots)\) functions work the same way.
Syntax

Remarks and examples

Remarks are presented under the following headings:

First example
Notation and formulas
Type d evaluators
Example of a type d evaluator
Type v evaluators
User-defined arguments
Example of a type v evaluator
Type t evaluators
Example of a type t evaluator
Functions

The derivative functions may be used interactively.

Below we use the functions to compute \( f'(x) \) at \( x = 0 \), where the function is

\[
f(x) = \exp(-x^2 + x - 3)
\]

```c
: void myeval(x, y)
> { y = exp(-x^2 + x - 3) }
```

```c
: D = deriv_init()
: deriv_init_evaluator(D, &myeval())
: deriv_init_params(D, 0)
: dydx = deriv(D, 1)
: dydx .0497870683
: exp(-3) .0497870684
```

The derivative, given the above function, is \( f'(x) = (-2x+1) \times \exp(-x^2+x-3) \), so \( f'(0) = \exp(-3) \).
Notation and formulas

We wrote the above in the way that mathematicians think, that is, differentiate \( y = f(x) \). Statisticians, on the other hand, think differentiate \( s = f(b) \). To avoid favoritism, we will write \( v = f(p) \) and write the general problem with the following notation:

Differentiate \( v = f(p) \) with respect to \( p \), where

\[
\begin{align*}
    v &: \text{ a scalar} \\
    p &: 1 \times np
\end{align*}
\]

The gradient vector is \( g = f'(p) = df/dp \), where

\[
\begin{align*}
    g &: 1 \times np
\end{align*}
\]

and the Hessian matrix is \( H = f''(p) = d^2f/dpdp' \), where

\[
\begin{align*}
    H &: np \times np
\end{align*}
\]

deriv() can also work with vector-valued functions. Here is the notation for vector-valued functions:

Differentiate \( v = f(p) \) with respect to \( p \), where

\[
\begin{align*}
    v &: 1 \times nv, \text{ a vector} \\
    p &: 1 \times np
\end{align*}
\]

The Jacobian matrix is \( J = f'(p) = df/dp \), where

\[
\begin{align*}
    J &: nv \times np
\end{align*}
\]

and where

\[
J[i, j] = dv[i]/dp[j]
\]

Second-order derivatives are not computed by deriv() when used with vector-valued functions.

deriv() uses the following formula for computing the numerical derivative of \( f() \) at \( p \)

\[
f'(p) = \frac{f(p + d) - f(p - d)}{2d}
\]

where we refer to \( d \) as the delta used for computing numerical derivatives. To search for an optimal delta, we decompose \( d \) into two parts.

\[
d = h \times scale
\]

By default, \( h \) is a fixed value that depends on the parameter value.

\[
h = (\text{abs}(p)+1e-3)*1e-3
\]

deriv() searches for a value of \( scale \) that will result in an optimal numerical derivative, that is, one where \( d \) is as small as possible subject to the constraint that \( f(x + d) - f(x - d) \) will be calculated to at least half the accuracy of a double-precision number. This is accomplished by searching for \( scale \) such that \( |f(x) - f(x - d)| \) falls between \( v_0 \) and \( v_1 \), where

\[
\begin{align*}
    v_0 &= (\text{abs}(f(x))+1e-8)*1e-8 \\
    v_1 &= (\text{abs}(f(x))+1e-7)*1e-7
\end{align*}
\]

Use deriv_init_h() to change the default \( h \) values. Use deriv_init_scale() to change the default initial \( scale \) values. Use deriv_init_bounds() to change the default bounds \((1e-8, 1e-7)\) used for determining the optimal \( scale \).
Type d evaluators

You must write an evaluator function to calculate $f()$ before you can use the derivative functions. The example we showed above was of what is called a type d evaluator. Let’s stay with that.

The evaluator function we wrote was

```c
void myeval(x, y)
{
    y = exp(-x^2 + x - 3)
}
```

All type d evaluators open the same way,

```c
void evaluator(x, y)
```

although what you name the arguments is up to you. We named the arguments the way that mathematicians think, although we could just as well have named them the way that statisticians think:

```c
void evaluator(b, s)
```

To avoid favoritism, we will write them as

```c
void evaluator(p, v)
```

That is, we will think in terms of computing the derivative of $v = f(p)$ with respect to the elements of $p$.

Here is the full definition of a type d evaluator:

```c
void evaluator(real rowvector p, v)
```

where $v$ is the value to be returned:

$v$: real scalar

evaluator() is to fill in $v$ given the values in $p$.

evaluator() may return $v = .$ if $f()$ cannot be evaluated at $p$.

Example of a type d evaluator

We wish to compute the gradient of the following function at $p_1 = 1$ and $p_2 = 2$:

$v = \exp(-p_1^2 - p_2^2 - p_1p_2 + p_1 - p_2 - 3)$

Our numerical solution to the problem is

```c
: void eval_d(p, v)
  > {
  > }
  :
  : D = deriv_init()
  : deriv_init_evaluator(D, &eval_d())
```
For this problem, the elements of the gradient function are given by the following formulas, and we see that deriv() computed values that are in agreement with the analytical results (to the number of significant digits being displayed).

\[
\frac{dv}{dp_1} = (-2p_1 - p_2 + 1) \exp(-p_1^2 - p_2^2 - p_1 p_2 + p_1 - p_2 - 3)
\]

\[
\frac{dv}{dp_2} = (-2p_2 - p_1 - 1) \exp(-p_1^2 - p_2^2 - p_1 p_2 + p_1 - p_2 - 3)
\]

Type v evaluators

In some statistical applications, you will find type v evaluators more convenient to code than type d evaluators.

In statistical applications, one tends to think of a dataset of values arranged in matrix X, the rows of which are observations. The function \( h(p, X[i, .]) \) can be calculated for each row separately, and it is the sum of those resulting values that forms the function \( f(p) \) from which we would like to compute derivatives.

Type v evaluators are for such cases.

In a type d evaluator, you return scalar \( v = f(p) \).

In a type v evaluator, you return a column vector, \( v \), such that \( \text{colsum}(v) = f(p) \).

The code outline for type v evaluators is the same as those for d evaluators. All that differs is that \( v \), which is a real scalar in the d case, is now a real colvector in the v case.

User-defined arguments

The type v evaluators arise in statistical applications and, in such applications, there are data; that is, just knowing \( p \) is not sufficient to calculate \( v, g, \) and \( H \). Actually, that same problem can also arise when coding type d evaluators.

You can pass extra arguments to evaluators. The first line of all evaluators, regardless of type, is

\[
\text{void evaluator}(p, v)
\]

If you code

\[
\text{deriv_init_argument}(D, 1, X)
\]
the first line becomes

```c
void evaluator(p, X, v)
```

If you code

```c
deriv_init_argument(D, 1, X)
deriv_init_argument(D, 2, Y)
```

the first line becomes

```c
void evaluator(p, X, Y, v)
```

and so on, up to nine extra arguments. That is, you can specify extra arguments to be passed to your function.

**Example of a type v evaluator**

You have the following data:

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0.35</td>
</tr>
<tr>
<td>2</td>
<td>0.29</td>
</tr>
<tr>
<td>3</td>
<td>0.3</td>
</tr>
<tr>
<td>4</td>
<td>0.3</td>
</tr>
<tr>
<td>5</td>
<td>0.65</td>
</tr>
<tr>
<td>6</td>
<td>0.56</td>
</tr>
<tr>
<td>7</td>
<td>0.37</td>
</tr>
<tr>
<td>8</td>
<td>0.16</td>
</tr>
<tr>
<td>9</td>
<td>0.26</td>
</tr>
<tr>
<td>10</td>
<td>0.19</td>
</tr>
</tbody>
</table>

You believe that the data are the result of a beta distribution process with fixed parameters alpha and beta, and you wish to compute the gradient vector and Hessian matrix associated with the log likelihood at some values of those parameters alpha and beta (a and b in what follows). The formula for the density of the beta distribution is

\[
density(x) = \frac{\Gamma(a + b)}{\Gamma(a)\Gamma(b)} x^{a-1} (1 - x)^{b-1}
\]

In our type v solution to this problem, we compute the gradient and Hessian at \( a = 0.5 \) and \( b = 2 \).

```c
: void lnbetaden_v(p, x, lnf)
> {  
>     a = p[1]
>     b = p[2]
>     lnf = lngamma(a+b) :- lngamma(a) :- lngamma(b) :+  
>     (a-1)*log(x) :+ (b-1)*log(1:-x)
> }
```

```c
: D = deriv_init()
: deriv_init_evaluator(D, &lnbetaden_v())
: deriv_init_evaluatorytype(D, "v")
: deriv_init_params(D, (0.5, 2))
: deriv_init_argument(D, 1, x) ← important
Note the following:

1. Rather than calling the returned value v, we called it lnf. You can name the arguments as you please.

2. We arranged for an extra argument to be passed by coding deriv_init_argument(D, 1, x). The extra argument is the vector x, which we listed previously for you. In our function, we received the argument as x, but we could have used a different name just as we used lnf rather than v.

3. We set the evaluator type to "t".

Type t evaluators

Type t evaluators are for when you need to compute the Jacobian matrix from a vector-valued function.

Type t evaluators are different from type v evaluators in that the resulting vector of values should not be summed. One example is when the function f() performs a nonlinear transformation from the domain of p to the domain of v.

Example of a type t evaluator

Let’s compute the Jacobian matrix for the following transformation:

\[ v_1 = p_1 + p_2 \]

\[ v_2 = p_1 - p_2 \]

Here is our numerical solution, evaluating the Jacobian at \( p = (0, 0) \):

```c
: void eval_t1(p, v)
> {
>     v = J(1,2,)
> }
: D = deriv_init()
: deriv_init_evaluator(D, &eval_t1())
: deriv_init_evaluators_type(D, "t")
: deriv_init_params(D, (0,0))
```
Now let’s compute the Jacobian matrix for a less trivial transformation:

\[ v_1 = p_1^2 \]

\[ v_2 = p_1 p_2 \]

Here is our numerical solution, evaluating the Jacobian at \( p = (1, 2) \):

\[
\begin{array}{c}
1 & 2 \\
1 & 1.999999998 & 0 \\
2 & 2 & 1 \\
\end{array}
\]

Functions

**deriv_init()**

*transmorphic* deriv_init()

deriv_init() is used to begin a derivative problem. Store the returned result in a variable name of your choosing; we have used \( D \) in this documentation. You pass \( D \) as the first argument to the other deriv*() functions.

deriv_init() sets all deriv_init_*() values to their defaults. You may use the query form of deriv_init_*() to determine an individual default, or you can use deriv_query() to see them all.

The query form of deriv_init_*() can be used before or after calling deriv().
deriv_init_evaluator() and deriv_init_evaluatortype()

```c
void deriv_init_evaluator(D, pointer(function) scalar fptr)
void deriv_init_evaluatortype(D, evaluatortype)
pointer(function) scalar deriv_init_evaluator(D)
string scalar deriv_init_evaluatortype(D)
```

derv_init_evaluator(D, fptr) specifies the function to be called to evaluate f(p). Use of this function is required. If your function is named myfcn(), you code deriv_init_evaluator(D, &myfcn()).

derv_init_evaluatortype(D, evaluatortype) specifies the capabilities of the function that has been set using deriv_init_evaluator(). Alternatives for evaluatortype are "d", "v", and "t". The default is "d" if you do not invoke this function.

derv_init_evaluator(D) returns a pointer to the function that has been set.

derv_init_evaluatortype(D) returns the evaluator type currently set.

deriv_init_argument() and deriv_init_narguments()

```c
void deriv_init_argument(D, real scalar k, X)
void deriv_init_narguments(D, real scalar K)
pointer scalar deriv_init_argument(D, real scalar k)
real scalar deriv_init_narguments(D)
```

deriv_init_argument(D, k, X) sets the kth extra argument of the evaluator function to be X. X can be anything, including a view matrix or even a pointer to a function. No copy of X is made; it is a pointer to X that is stored, so any changes you make to X between setting it and X being used will be reflected in what is passed to the evaluator function.

deriv_init_narguments(D, K) sets the number of extra arguments to be passed to the evaluator function. This function is useless and included only for completeness. The number of extra arguments is automatically set when you use deriv_init_argument().

deriv_init_argument(D, k) returns a pointer to the object that was previously set.

deriv_init_narguments(D) returns the number of extra arguments that were passed to the evaluator function.

deriv_init_weights()

```c
void deriv_init_weights(D, real colvector weights)
pointer scalar deriv_init_weights(D)
```

deriv_init_weights(D, weights) sets the weights used with type v evaluators to produce the function value. By default, deriv() with a type v evaluator uses colsum(v) to compute the function value. With weights, deriv() uses cross(weights, v). weights must be row conformable with the column vector returned by the evaluator.

deriv_init_weights(D) returns a pointer to the weight vector that was previously set.
**deriv_init_params()**

```cpp
type void deriv_init_params(D, real rowvector params)

real rowvector deriv_init_params(D)
```

derv_init_params(D, params) sets the parameter values at which the derivatives will be computed. Use of this function is required.

derv_init_params(D) returns the parameter values at which the derivatives were computed.

**Advanced init functions**

The rest of the deriv_init_*() functions provide finer control of the numerical derivative taker.

**deriv_init_h(), . . . scale(), . . . bounds(), . . . search()**

```cpp
type void deriv_init_h(D, real rowvector h)

type void deriv_init_scale(D, real rowvector s)

type void deriv_init_bounds(D, real rowvector minmax)

type void deriv_init_search(D, search)

real rowvector deriv_init_h(D)

real rowvector deriv_init_scale(D)

real rowvector deriv_init_bounds(D)

string scalar deriv_init_search(D)
```

derv_init_h(D, h) sets the h values used to compute numerical derivatives.

derv_init_scale(D, s) sets the starting scale values used to compute numerical derivatives.

derv_init_bounds(D, minmax) sets the minimum and maximum values used to search for optimal scale values. The default is minmax = (1e-8, 1e-7).

derv_init_search(D, "interpolate") causes deriv() to use linear and quadratic interpolation to search for an optimal delta for computing the numerical derivatives. This is the default search method.

derv_init_search(D, "bracket") causes deriv() to use a bracketed quadratic formula to search for an optimal delta for computing the numerical derivatives.

derv_init_search(D, "off") prevents deriv() from searching for an optimal delta.

derv_init_h(D) returns the user-specified h values.

derv_init_scale(D) returns the user-specified starting scale values.

derv_init_bounds(D) returns the user-specified search bounds.

derv_init_search(D) returns the currently set search method.
deriv_init_verbose()

    void deriv_init_verbose(D, verbose)
    string scalar deriv_init_verbose(D)

derv_init verbose(D, verbose) sets whether error messages that arise during the execution of deriv() or _deriv() are to be displayed. Setting verbose to "on" means that they are displayed; "off" means that they are not displayed. The default is "on". Setting verbose to "off" is of interest only to users of _deriv().

derv_init verbose(D) returns the current value of verbose.

deriv()

     (varies) deriv(D, todo)

deriv(D, todo) invokes the derivative process. If something goes wrong, deriv() aborts with error.

    deriv(D, 0) returns the function value without computing derivatives.
    deriv(D, 1) returns the gradient vector; the Hessian matrix is not computed.
    deriv(D, 2) returns the Hessian matrix; the gradient vector is also computed.

Before you can invoke deriv(), you must have defined your evaluator function, evaluator(), and you must have set the parameter values at which deriv() is to compute derivatives:

    D = deriv_init()
    deriv_init_evaluator(D, &evaluator())
    deriv_init_params(D, (...))

The above assumes that your evaluator function is type d. If your evaluator function type is v (that is, it returns a column vector of values instead of a scalar value), you will also have coded

    deriv_init_evaluatorytype(D, "v")

and you may have coded other deriv_init_*() functions as well.

Once deriv() completes, you may use the deriv_result_*() functions. You may also continue to use the deriv_init_*() functions to access initial settings, and you may use them to change settings and recompute derivatives (that is, invoke deriv() again) if you wish.

_deriv()

     real scalar _deriv(D, todo)

_deriv(D) performs the same actions as deriv(D) except that, rather than returning the requested derivatives, _deriv() returns a real scalar and, rather than aborting if numerical issues arise, _deriv() returns a nonzero value. _deriv() returns 0 if all went well. The returned value is called an error code.

deriv() returns the requested result. It can work that way because the numerical derivative calculation must have gone well. Had it not, deriv() would have aborted execution.
deriv() returns an error code. If it is 0, the numerical derivative calculation went well, and you can obtain the gradient vector by using deriv_result_gradient(). If things did not go well, you can use the error code to diagnose what went wrong and take the appropriate action.

Thus _deriv(D) is an alternative to deriv(D). Both functions do the same thing. The difference is what happens when there are numerical difficulties.

deriv() and _deriv() work around most numerical difficulties. For instance, the evaluator function you write is allowed to return v equal to missing if it cannot calculate the f() at p + d. If that happens while computing the derivative, deriv() and _deriv() will search for a better d for taking the derivative. deriv(), however, cannot tolerate that happening at p (the parameter values you set using deriv_init_params()) because the function value must exist at the point when you want deriv() to compute the numerical derivative. deriv() issues an error message and aborts, meaning that execution is stopped. There can be advantages in that. The calling program need not include complicated code for such instances, figuring that stopping is good enough because a human will know to address the problem.

_deriv(), however, does not stop execution. Rather than aborting, _deriv() returns a nonzero value to the caller, identifying what went wrong. The only exception is that _deriv() will return a zero value to the caller even when the evaluator function returns v equal to missing at p, allowing programmers to handle this special case without having to turn deriv_init_verbose() off.

Programmers implementing advanced systems will want to use _deriv() instead of deriv(). Everybody else should use deriv().

Programmers using _deriv() will also be interested in the functions deriv_init_verbose(), deriv_result_errorcode(), deriv_result_errortext(), and deriv_result_returncode().

The error codes returned by _deriv() are listed below, under the heading deriv_result_errorcode(), ..._errortext(), and ..._returncode().

deriv_result_value()

real scalar deriv_result_value(D)

deriv_result_value(D) returns the value of f() evaluated at p.

deriv_result_values() and _deriv_result_values()

real matrix deriv_result_values(D)

void _deriv_result_values(D, v)

deriv_result_values(D) returns the vector values returned by the evaluator. For type v evaluators, this is the column vector that sums to the value of f() evaluated at p. For type t evaluators, this is the rowvector returned by the evaluator.

_deriv_result_values(D, v) uses swap() (see [M-5] swap()) to interchange v with the vector values stored in D. This destroys the vector values stored in D.

These functions should be called only with type v evaluators.
**deriv_result_gradient() and _deriv_result_gradient()**

```
real rowvector deriv_result_gradient(D)
void _deriv_result_gradient(D, g)
```

derv_result_gradient(D) returns the gradient vector evaluated at p.

_deriv_result_gradient(D, g) uses swap() (see [M-5] swap()) to interchange g with the gradient vector stored in D. This destroys the gradient vector stored in D.

**deriv_result_scores() and _deriv_result_scores()**

```
real matrix deriv_result_scores(D)
void _deriv_result_scores(D, S)
```

derv_result_scores(D) returns the matrix of the scores evaluated at p. The matrix of scores can be summed over the columns to produce the gradient vector.

_deriv_result_scores(D, S) uses swap() (see [M-5] swap()) to interchange S with the scores matrix stored in D. This destroys the scores matrix stored in D.

These functions should be called only with type v evaluators.

**deriv_result_Jacobian() and _deriv_result_Jacobian()**

```
real matrix deriv_result_Jacobian(D)
void _deriv_result_Jacobian(D, J)
```

derv_result_Jacobian(D) returns the Jacobian matrix evaluated at p.

_deriv_result_Jacobian(D, J) uses swap() (see [M-5] swap()) to interchange J with the Jacobian matrix stored in D. This destroys the Jacobian matrix stored in D.

These functions should be called only with type t evaluators.

**deriv_result_Hessian() and _deriv_result_Hessian()**

```
real matrix deriv_result_Hessian(D)
void _deriv_result_Hessian(D, H)
```

derv_result_Hessian(D) returns the Hessian matrix evaluated at p.

_deriv_result_Hessian(D, H) uses swap() (see [M-5] swap()) to interchange H with the Hessian matrix stored in D. This destroys the Hessian matrix stored in D.

These functions should not be called with type t evaluators.
deriv_result_h(), ..._scale(), and ..._delta()  

real rowvector deriv_result_h(D)  
real rowvector deriv_result_scale(D)  
real rowvector deriv_result_delta(D)  

deriv_result_h(D) returns the vector of h values that was used to compute the numerical derivatives.  
deriv_result_scale(D) returns the vector of scale values that was used to compute the numerical derivatives.  
deriv_result_delta(D) returns the vector of delta values used to compute the numerical derivatives.  

deriv_result_errorcode(), ..._errortext(), and ..._returncode()  

real scalar deriv_result_errorcode(D)  
string scalar deriv_result_errortext(D)  
real scalar deriv_result_returncode(D)  

These functions are for use after _deriv().  
deriv_result_errorcode(D) returns the same error code as _deriv(). The value will be zero if there were no errors. The error codes are listed in the table directly below.  
deriv_result_errortext(D) returns a string containing the error message corresponding to the error code. If the error code is zero, the string will be "".  
deriv_result_returncode(D) returns the Stata return code corresponding to the error code. The mapping is listed in the table directly below.  

In advanced code, these functions might be used as  

(void) _deriv(D, todo)  
... if (ec = deriv_result_code(D)) {  
   printf("{p}\n")  
   printf("%s\n", deriv_result_errortext(D))  
   printf("{p_end}\n")  
   exit(deriv_result_returncode(D))  
   /*NOTREACHED*/  
}
The error codes and their corresponding Stata return codes are

<table>
<thead>
<tr>
<th>Error code</th>
<th>Return code</th>
<th>Error text</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>198</td>
<td>invalid todo argument</td>
</tr>
<tr>
<td>2</td>
<td>111</td>
<td>evaluator function required</td>
</tr>
<tr>
<td>3</td>
<td>459</td>
<td>parameter values required</td>
</tr>
<tr>
<td>4</td>
<td>459</td>
<td>parameter values not feasible</td>
</tr>
<tr>
<td>5</td>
<td>459</td>
<td>could not calculate numerical derivatives—discontinuous region with missing values encountered</td>
</tr>
<tr>
<td>6</td>
<td>459</td>
<td>could not calculate numerical derivatives—flat or discontinuous region encountered</td>
</tr>
<tr>

<td>function() not found</td>
</tr>
<tr>
<td>17</td>
<td>459</td>
<td>Hessian calculations not allowed with type t evaluators</td>
</tr>
</tbody>
</table>

Note: Error 4 can occur only when evaluating \( f() \) at the parameter values. This error occurs only with \( \text{deriv()} \).

\textbf{deriv\_query()}

\begin{verbatim}
void deriv_query(D)
\end{verbatim}

derv_query(D) displays a report on the current deriv_init_*() values and some of the deriv_result_*() values. deriv_query(D) may be used before or after deriv(), and it is useful when using deriv() interactively or when debugging a program that calls deriv() or _deriv().

\textbf{Conformability}

All functions have \( 1 \times 1 \) inputs and have \( 1 \times 1 \) or \textit{void} outputs, except the following:

\begin{verbatim}
derv_init_params(D, params):
    D:     transmorphic
    params: 1 \times np
    result: void

derv_init_params(D):
    D:     transmorphic
    result: 1 \times np

derv_init_argument(D, k, X):
    D:     transmorphic
    k:     1 \times 1
    X:     anything
    result: void

derv_init_weights(D, params):
    D:     transmorphic
    params: N \times 1
    result: void
\end{verbatim}
deriv\_init\_h(D, h):
    D: transmorphic
    h: 1 \times np
    result: void

deriv\_init\_h(D):
    D: transmorphic
    result: 1 \times np

deriv\_init\_scale(D, scale):
    D: transmorphic
    scale: 1 \times np \text{ (type d and v evaluator)}
    nv \times np \text{ (type t evaluator)}
    void: void

deriv\_init\_bounds(D, minmax):
    D: transmorphic
    minmax: 1 \times 2
    result: void

deriv\_init\_bounds(D):
    D: transmorphic
    result: 1 \times w

deriv(D, 0):
    D: transmorphic
    result: 1 \times 1
    1 \times nv \text{ (type t evaluator)}

deriv(D, 1):
    D: transmorphic
    result: 1 \times np
    nv \times np \text{ (type t evaluator)}

deriv(D, 2):
    D: transmorphic
    result: np \times np

deriv\_result\_values(D):
    D: transmorphic
    result: N \times 1
    1 \times nv \text{ (type t evaluator)}
    N \times 1 \text{ (type v evaluator)}

deriv\_result\_values(D, v):
    D: transmorphic
    v: N \times 1
    1 \times nv \text{ (type t evaluator)}
    N \times 1 \text{ (type v evaluator)}
    result: void
deriv_result_gradient(D):
    D: transmorphic
    result: 1 × np

_deriv_result_gradient(D, g):
    D: transmorphic
    g: 1 × np
    result: void

deriv_result_scores(D):
    D: transmorphic
    result: N × np

_deriv_result_scores(D, S):
    D: transmorphic
    S: N × np
    result: void

deriv_result_Jacobian(D):
    D: transmorphic
    result: nv × np

_deriv_result_Jacobian(D, J):
    D: transmorphic
    J: nv × np
    result: void

deriv_result_Hessian(D):
    D: transmorphic
    result: np × np

_deriv_result_Hessian(D, H):
    D: transmorphic
    H: np × np
    result: void

deriv_result_h(D):
    D: transmorphic
    result: 1 × np

deriv_result_scale(D):
    D: transmorphic
    result: 1 × np (type d and v evaluator)
           nv × np (type t evaluator)

deriv_result_delta(D):
    D: transmorphic
    result: 1 × np (type d and v evaluator)
           nv × np (type t evaluator)
Diagnostics

All functions abort with error when used incorrectly. 

deriv() aborts with error if it runs into numerical difficulties. _deriv() does not; it instead returns a nonzero error code.

Methods and formulas

See sections 1.3.4 and 1.3.5 of Gould, Pitblado, and Poi (2010) for an overview of the methods and formulas deriv() uses to compute numerical derivatives.

Carl Gustav Jacob Jacobi (1804–1851) was born in Potsdam, Prussia, which is now Germany. Jacobi demonstrated great potential at a young age, meeting the qualifications to enter university at the age of 12. He obtained his PhD from the University of Berlin in 1825. In 1829, Jacobi published a paper making significant contributions to elliptic functions, which were consequently named after him. He also published a paper on functional determinants, giving rise to the Jacobian matrix and Jacobian determinant. He made many contributions to number theory, including proofs of quadratic reciprocity and Fermat’s two-square theorem. In addition to the functions and equations named after him, Jacobi was honored with a crater in his name. In 1833, the Royal Society elected Jacobi to fellowship, as did the Royal Society of Edinburgh in 1845.

Jacobi spent 15 years teaching at Königsberg University, where he also supervised the doctoral work of Ludwig Otto Hesse. Because of health complications, he spent some time in Italy and later relocated to Berlin, where he gave some lectures. However, after making some unfavorable political statements, he was denied the opportunity to work at the University of Berlin. This decision was later retracted, and he left his position at the University of Vienna to lecture at the University of Berlin. Jacobi died of smallpox in 1851.
