

Description

`lusolve(A , B)` solves $AX=B$ and returns X . `lusolve()` returns a matrix of missing values if A is singular.

`lusolve(A , B , tol)` does the same thing but allows you to specify the tolerance for declaring that A is singular; see [Tolerance](#) under *Remarks and examples* below.

`_lusolve(A , B)` and `_lusolve(A , B , tol)` do the same thing except that, rather than returning the solution X , they overwrite B with the solution and, in the process of making the calculation, they destroy the contents of A .

`_lusolve_la(A , B)` and `_lusolve_la(A , B , tol)` are the interfaces to the [M-1] **LAPACK** routines that do the work. They solve $AX=B$ for X , returning the solution in B and, in the process, using as workspace (overwriting) A . The routines return 1 if A was singular and 0 otherwise. If A was singular, B is overwritten with a matrix of missing values.

Syntax

numeric matrix `lusolve(numeric matrix A , numeric matrix B)`

numeric matrix `lusolve(numeric matrix A , numeric matrix B , real scalar tol)`

void `_lusolve(numeric matrix A , numeric matrix B)`

void `_lusolve(numeric matrix A , numeric matrix B , real scalar tol)`

real scalar `_lusolve_la(numeric matrix A , numeric matrix B)`

real scalar `_lusolve_la(numeric matrix A , numeric matrix B , real scalar tol)`

Remarks and examples

The above functions solve $AX=B$ via LU decomposition and are accurate. An alternative is `qrsolve()` (see [M-5] [qrsolve\(\)](#)), which uses QR decomposition. The difference between the two solutions is not, practically speaking, accuracy. When A is of full rank, both routines return equivalent results, and the LU approach is quicker, using approximately $O(2/3n^3)$ operations rather than $O(4/3n^3)$, where A is $n \times n$.

The difference arises when A is singular. Then the LU-based routines documented here return missing values. The QR-based routines documented in [M-5] [qrsolve\(\)](#) return a generalized (least squares) solution.

For more information on LU and QR decomposition, see [M-5] [lud\(\)](#) and see [M-5] [qrd\(\)](#).

Remarks are presented under the following headings:

Derivation
Relationship to inversion
Tolerance

Derivation

We wish to solve for X

$$AX = B \quad (1)$$

Perform LU decomposition on A so that we have $A = PLU$. Then (1) can be written as

$$PLUX = B$$

or, premultiplying by P' and remembering that $P'P = I$,

$$LUX = P'B \quad (2)$$

Define

$$Z = UX \quad (3)$$

Then (2) can be rewritten as

$$LZ = P'B \quad (4)$$

It is easy to solve (4) for Z because L is a lower-triangular matrix. Once Z is known, it is easy to solve (3) for X because U is upper triangular.

Relationship to inversion

Another way to solve

$$AX = B$$

is to obtain A^{-1} and then calculate

$$X = A^{-1}B$$

It is, however, better to solve $AX = B$ directly because fewer numerical operations are required, and the result is therefore more accurate and obtained in less computer time.

Indeed, rather than thinking about how solving a system of equations can be implemented via inversion, it is more productive to think about how inversion can be implemented via solving a system of equations. Obtaining A^{-1} amounts to solving

$$AX = I$$

Thus `lusolve()` (or any other solve routine) can be used to obtain inverses. The inverse of A can be obtained by coding

```
: Ainv = lusolve(A, I(rows(A)))
```

In fact, we provide `luinv()` (see [M-5] **luinv()**) for obtaining inverses via LU decomposition, but `luinv()` amounts to making the above calculation, although a little memory is saved because the matrix I is never constructed.

Hence, everything said about `lusolve()` applies equally to `luinv()`.

Tolerance

The default tolerance used is

$$\eta = (1e-13) * \text{trace}(\text{abs}(U)) / n$$

where U is the upper-triangular matrix of the LU decomposition of A : $n \times n$. A is declared to be singular if any diagonal element of U is less than or equal to η .

If you specify $\text{tol} > 0$, the value you specify is used to multiply η . You may instead specify $\text{tol} \leq 0$, and then the negative of the value you specify is used in place of η ; see [M-1] **Tolerance**.

So why not specify $\text{tol} = 0$? You do not want to do that because, as matrices become close to being singular, results can become inaccurate. Here is an example:

```
: rseed(12345)
: A = lowertriangle(runiform(4,4))
: A[3,3] = 1e-15
: trux = runiform(4,1)
: b = A*trux
: /* the above created an Ax=b problem, and we have placed the true
>   value of x in trux. We now obtain the solution via lusolve()
>   and compare trux with the value obtained:
> */
: x = lusolve(A, b, 0)
: trux, x
```

1	.260768733	.260768733
2	.0267289389	.0267289389
3	.1079423963	.0989119749
4	.3666839808	.3863636364

← The discussed numerical instability can cause this output to vary a little across different computers

We would like to see the second column being nearly equal to the first—the estimated x being nearly equal to the true x —but there are substantial differences.

Even though the difference between x and trux is substantial, the difference between them is small in the prediction space:

```
: A*trux-b, A*x-b
```

	1	2
1	0	0
2	0	0
3	0	-2.77556e-17
4	0	0

What made this problem so difficult was the line $A[3,3] = 1e-15$. Remove that and you would find that the maximum absolute difference between x and trux would be $-2.44249e-15$.

The degree to which the residuals $A*x-b$ are a reliable measure of the accuracy of x depends on the condition number of the matrix, which can be obtained by [M-5] **cond()**, which for A , is $4.47684e+15$. If the matrix is well conditioned, small residuals imply an accurate solution for x . If the matrix is ill conditioned, small residuals are not a reliable indicator of accuracy.

Another way to check the accuracy of x is to set $tol = 0$ and to see how well x could be obtained were $b = A*x$:

```
: x = lusolve(A, b, 0)
: x2 = lusolve(A, A*x, 0)
```

If x and $x2$ are virtually the same, then you can safely assume that x is the result of a numerically accurate calculation. You might compare x and $x2$ with `mreldif(x2,x)`; see [M-5] `rldif()`. In our example, `mreldif(x2,x)` is .03, a large difference.

If A is ill conditioned, then small changes in A or B can lead to radical differences in the solution for X .

Conformability

`lusolve(A, B, tol):`

input:

$A:$ $n \times n$
 $B:$ $n \times k$
 $tol:$ 1×1 (optional)

output:

result: $n \times k$

`_lusolve(A, B, tol):`

input:

$A:$ $n \times n$
 $B:$ $n \times k$
 $tol:$ 1×1 (optional)

output:

$A:$ 0×0
 $B:$ $n \times k$

`_lusolve_la(A, B, tol):`

input:

$A:$ $n \times n$
 $B:$ $n \times k$
 $tol:$ 1×1 (optional)

output:

$A:$ 0×0
 $B:$ $n \times k$
result: 1×1

Diagnostics

`lusolve(A, B, ...)`, `_lusolve(A, B, ...)`, and `_lusolve_la(A, B, ...)` return a result containing missing if A or B contain missing values. The functions return a result containing all missing values if A is singular.

`_lusolve(A, B, ...)` and `_lusolve_la(A, B, ...)` abort with error if A or B is a view.

`_lusolve_la(A, B, ...)` should not be used directly; use `_lusolve()`.
