estat classification — Classification statistics and table

Description

estat classification reports various summary statistics, including the classification table.

estat classification requires that the current estimation results be from logistic, logit, probit, or ivprobit; see [R] logistic, [R] logit, [R] probit, or [R] ivprobit.

Quick start

Display classification table and related statistics for current estimation results

estat classification

Change probability threshold for assignment to positive outcome to 75%

estat classification, cutoff(.75)

Classification for observations with catvar = 2

estat classification if catvar==2

</thead>
<tbody>
<tr>
<td>all</td>
<td>display summary statistics for all observations in the data</td>
</tr>
<tr>
<td>cutoff(#)</td>
<td>positive outcome threshold; default is cutoff(0.5)</td>
</tr>
</tbody>
</table>

fweights are allowed; see [U] 11.1.6 weight.
estat classification is not appropriate after the svy prefix.

Options

all requests that the statistic be computed for all observations in the data, ignoring any if or in restrictions specified by the estimation command.
cutoff(#) specifies the value for determining whether an observation has a predicted positive outcome. An observation is classified as positive if its predicted probability is $\geq #$. The default is 0.5.

Remarks and examples

estat classification presents the classification statistics and classification table after logistic, logit, probit, or ivprobit.

Statistics are produced either for the estimation sample (the default) or for any set of observations. When weights, if, or in is used with the estimation command, it is not necessary to repeat the qualifier when you want statistics computed for the estimation sample. Specify if, in, or the all option only when you want statistics computed for a set of observations other than the estimation sample. Specify weights only when you want to use a different set of weights.
We illustrate `estat classification` after `logistic`; see [R] `logistic`.

</table>

Correctly classified 73.54%

The overall rate of correct classification is estimated to be 73.54, with 90.77% of the normal weight group correctly classified (specificity) and only 35.59% of the low weight group correctly classified (sensitivity). Classification is sensitive to the relative sizes of each component group, and always favors classification into the larger group. This phenomenon is evident here.

By default, `estat classification` uses a cutoff of 0.5, although you can vary this with the `cutoff()` option. You can use the `lsens` command to review the potential cutoffs; see [R] `lsens`.

### Stored results

`estat classification` stores the following in `r()`:

- **Scalars**
  - `r(P_corr)` percent correctly classified
  - `r(P_p1)` sensitivity
  - `r(P_n0)` specificity
  - `r(P_p0)` false-positive rate given true negative
  - `r(P_n1)` false-negative rate given true positive
  - `r(P_1p)` positive predictive value
  - `r(P_0n)` negative predictive value
  - `r(P_0p)` false-positive rate given classified positive
  - `r(P_in)` false-negative rate given classified negative

- **Matrices**
  - `r(ctype)` classification table
Methods and formulas

Let $j$ index observations. Define $c$ as the \texttt{cutoff()} specified by the user or, if not specified, as 0.5. Let $p_j$ be the predicted probability of a positive outcome and $y_j$ be the actual outcome, which we will treat as 0 or 1, although Stata treats it as 0 and non-0, excluding missing observations.

A prediction is classified as \textit{positive} if $p_j \geq c$ and otherwise is classified as \textit{negative}. The classification is \textit{correct} if it is positive and $y_j = 1$ or if it is negative and $y_j = 0$.

\textit{Sensitivity} is the fraction of $y_j = 1$ observations that are correctly classified. \textit{Specificity} is the percentage of $y_j = 0$ observations that are correctly classified.
