frontier fits stochastic production or cost frontier models; the default is a production frontier model. It provides estimators for the parameters of a linear model with a disturbance that is assumed to be a mixture of two components, which have a strictly nonnegative and symmetric distribution, respectively. frontier can fit models in which the nonnegative distribution component (a measurement of inefficiency) is assumed to be from a half-normal, exponential, or truncated-normal distribution. See Kumbhakar and Lovell (2000) for a detailed introduction to frontier analysis.

Quick start

Cobb–Douglas production frontier model of \( \ln y_1 \) as a function of \( \ln x_1 \) and \( \ln x_2 \)

\[
\text{frontier lny1 lnx1 lnx2}
\]

As above, but use exponential instead of half-normal distribution for the inefficiency term

\[
\text{frontier lny1 lnx1 lnx2, distribution(exponential)}
\]

Include \( x_3 \) as an explanatory variable in the idiosyncratic error variance function

\[
\text{frontier lny1 lnx1 lnx2, vhet(x3)}
\]

As above, and include \( x_4 \) as an explanatory variable in the technical inefficiency variance function

\[
\text{frontier lny1 lnx1 lnx2, vhet(x3) uhet(x4)}
\]

Conditional mean model with the mean modeled as a linear function of \( x_3 \)

\[
\text{frontier lny1 lnx1 lnx2, distribution(tnormal) cm(x3)}
\]

Cost frontier model of \( y_2 \) as a function of \( \ln x_1 \) and \( \ln x_2 \)

\[
\text{frontier y2 lnx1 lnx2, distribution(tnormal) cost}
\]
Syntax

| collinear        | keep collinear variables                                              |
| coeflegend       | display legend instead of statistics                                   |

* vce(robust) and vce(cluster clustvar) may not be specified with distribution(tnormal).
* indepvars and varlist may contain factor variables; see [U] 11.4.3 Factor variables.
* bootstrap, by, fp, jackknife, rolling, and statsby are allowed; see [U] 11.1.10 Prefix commands.
* Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
* fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.
* collinear and coeflegend do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
Options

---

**Model**

noconstant; see [R] Estimation options.

distribution(*distname*) specifies the distribution for the inefficiency term as half-normal (hnormal), exponential, or truncated-normal (tnormal). The default is hnormal.

ufrom(*matrix*) specifies a $1 \times K$ matrix of untransformed starting values when the distribution is truncated-normal (tnormal). frontier can estimate the parameters of the model by maximizing either the log likelihood or a transformed log likelihood (see Methods and formulas). frontier automatically transforms the starting values before passing them on to the transformed log likelihood. The matrix must have the same number of columns as there are parameters to estimate.

**Model 2**

constraints(*constraints*); see [R] Estimation options.

By default, when fitting the truncated-normal model or the conditional mean model, frontier maximizes a transformed log likelihood. When constraints are applied, frontier will maximize the untransformed log likelihood with constraints defined in the untransformed metric.

uhet(*varlist*, noconstant) specifies that the technical inefficiency component is heteroskedastic, with the variance function depending on a linear combination of $varlist_u$. Specifying noconstant suppresses the constant term from the variance function. This option may not be specified with distribution(tnormal).

vhet(*varlist*, noconstant) specifies that the idiosyncratic error component is heteroskedastic, with the variance function depending on a linear combination of $varlist_v$. Specifying noconstant suppresses the constant term from the variance function. This option may not be specified with distribution(tnormal).

cost specifies that frontier fit a cost frontier model.

---

**SE/Robust**

vce(*vcetype*) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

vce(robust) and vce(cluster clustvar) may not be specified with distribution(tnormal).

---

**Reporting**

level(#), nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabels, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.
Maximization

\[ \text{maximize} \]

\[ \text{options: difficult, technique(algorithm\_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init\_specs); see [R] Maximize. These options are seldom used.} \]

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following options are available with frontier but are not shown in the dialog box:
collinear, coeflegend; see [R] Estimation options.

Remarks and examples

Stochastic production frontier models were introduced by Aigner, Lovell, and Schmidt (1977) and Meeusen and van den Broeck (1977). Since then, stochastic frontier models have become a popular subfield in econometrics. Kumbhakar and Lovell (2000) provide a good introduction.

frontier fits three stochastic frontier models with distinct parameterizations of the inefficiency term and can fit stochastic production or cost frontier models.

Let’s review the nature of the stochastic frontier problem. Suppose that a producer has a production function \( f(z_i, \beta) \). In a world without error or inefficiency, the \( i \)th firm would produce

\[ q_i = f(z_i, \beta) \]

Stochastic frontier analysis assumes that each firm potentially produces less than it might due to a degree of inefficiency. Specifically,

\[ q_i = f(z_i, \beta) \xi_i \]

where \( \xi_i \) is the level of efficiency for firm \( i \); \( \xi_i \) must be in the interval \( (0, 1] \). If \( \xi_i = 1 \), the firm is achieving the optimal output with the technology embodied in the production function \( f(z_i, \beta) \). When \( \xi_i < 1 \), the firm is not making the most of the inputs \( z_i \) given the technology embodied in the production function \( f(z_i, \beta) \). Because the output is assumed to be strictly positive (that is, \( q_i > 0 \)), the degree of technical efficiency is assumed to be strictly positive (that is, \( \xi_i > 0 \)).

Output is also assumed to be subject to random shocks, implying that

\[ q_i = f(z_i, \beta) \xi_i \exp(v_i) \]

Taking the natural log of both sides yields

\[ \ln(q_i) = \ln\{ f(z_i, \beta) \} + \ln(\xi_i) + v_i \]

Assuming that there are \( k \) inputs and that the production function is linear in logs, defining \( u_i = -\ln(\xi_i) \) yields

\[ \ln(q_i) = \beta_0 + \sum_{j=1}^{k} \beta_j \ln(z_{ji}) + v_i - u_i \]

Because \( u_i \) is subtracted from \( \ln(q_i) \), restricting \( u_i \geq 0 \) implies that \( 0 < \xi_i \leq 1 \), as specified above.
Kumbhakar and Lovell (2000) provide a detailed version of the above derivation, and they show that performing an analogous derivation in the dual cost function problem allows us to specify the problem as

$$\ln(c_i) = \beta_0 + \beta_q \ln(q_i) + \sum_{j=1}^{k} \beta_j \ln(p_{ji}) + v_i + u_i$$

(2)

where $q_i$ is output, $z_{ji}$ are input quantities, $c_i$ is cost, and the $p_{ji}$ are input prices.

Intuitively, the inefficiency effect is required to lower output or raise expenditure, depending on the specification.

Technical note

The model that frontier actually fits is of the form

$$y_i = \beta_0 + \sum_{j=1}^{k} \beta_j x_{ji} + v_i - su_i$$

where

$$s = \begin{cases} 
1, & \text{for production functions} \\
-1, & \text{for cost functions}
\end{cases}$$

so, in the context of the discussion above, $y_i = \ln(q_i)$, and $x_{ji} = \ln(z_{ji})$ for a production function; and for a cost function, $y_i = \ln(c_i)$, and the $x_{ji}$ are the $\ln(p_{ji})$ and $\ln(q_i)$. You must take the natural logarithm of the data before fitting a stochastic frontier production or cost model. frontier performs no transformations on the data.

Different specifications of the $u_i$ and the $v_i$ terms give rise to distinct models. frontier provides estimators for the parameters of three basic models in which the idiosyncratic component, $v_i$, is assumed to be independently $N(0, \sigma^2_v)$ distributed over the observations. The basic models differ in their specification of the inefficiency term, $u_i$, as follows:

- **exponential**: the $u_i$ are independently exponentially distributed with variance $\sigma^2_u$
- **hnnormal**: the $u_i$ are independently half-normally $N^+(0, \sigma^2_u)$ distributed
- **tnormal**: the $u_i$ are independently $N^+(\mu, \sigma^2_u)$ distributed with truncation point at 0

For half-normal or exponential distributions, frontier can fit models with heteroskedastic error components, conditional on a set of covariates. For a truncated-normal distribution, frontier can also fit a conditional mean model in which the mean is modeled as a linear function of a set of covariates.

Example 1: The half-normal and the exponential models

For our first example, we demonstrate the half-normal and exponential models by reproducing a study found in Greene (2003, 505), which uses data originally published in Zellner and Revankar (1969). In this study of the transportation-equipment manufacturing industry, observations on value added, capital, and labor are used to estimate a Cobb–Douglas production function. The variable $\ln v$ is the log-transformed value added, $\ln k$ is the log-transformed capital, and $\ln l$ is the log-transformed labor. OLS estimates are compared with those from stochastic frontier models using both the half-normal and exponential distribution for the inefficiency term.

</table>
The parameter estimates and the estimates of the inefficiency terms closely match those published in Greene (2003, 505), but the standard errors of the parameter estimates are estimated differently (see the technical note below).

The output from \texttt{frontier} includes estimates of the standard deviations of the two error components, $\sigma_v$ and $\sigma_u$, which are labeled \texttt{sigma\_v} and \texttt{sigma\_u}, respectively. In the log likelihood, they are parameterized as $\ln \sigma_v^2$ and $\ln \sigma_u^2$, and these estimates are labeled /lnsig2v and /lnsig2u in the output. \texttt{frontier} also reports two other useful parameterizations. The estimate of the total error variance, $\sigma_S^2 = \sigma_v^2 + \sigma_u^2$, is labeled \texttt{sigma2}, and the estimate of the ratio of the standard deviation of the inefficiency component to the standard deviation of the idiosyncratic component, $\lambda = \sigma_u / \sigma_v$, is labeled \texttt{lambda}.

At the bottom of the output, \texttt{frontier} reports the results of a test that there is no technical inefficiency component in the model. This is a test of the null hypothesis $H_0 : \sigma_u^2 = 0$ against the alternative hypotheses $H_1 : \sigma_u^2 > 0$. If the null hypothesis is true, the stochastic frontier model reduces to an OLS model with normal errors. However, because the test lies on the boundary of the parameter space of $\sigma_u^2$, the standard likelihood-ratio test is not valid, and a one-sided generalized likelihood-ratio test must be constructed; see Gutierrez, Carter, and Drukker (2001). For this example, the output shows $LR = 0.43$ with a $p$-value of 0.256 for the half-normal model and $LR = 1.21$ with a $p$-value of 0.135 for the exponential model. There are several possible reasons for the failure to reject the null hypothesis, but the fact that the test is based on an asymptotic distribution and the sample size was 25 is certainly a leading candidate among those possibilities.

\textbf{Example 2: Models with heteroskedasticity}

Often the error terms may not have constant variance. \texttt{frontier} allows you to model heteroskedasticity in either error term as a linear function of a set of covariates. The variance of either the technical inefficiency or the idiosyncratic component may be modeled as

$$\sigma_i^2 = \exp(w_i \delta)$$

The default constant included in $w_i$ may be suppressed by appending a \texttt{noconstant} option to the list of covariates. Also, you can simultaneously specify covariates for both $\sigma_u_i$ and $\sigma_v_i$.

In this example, we use a sample of 756 observations of fictional firms producing a manufactured good by using capital and labor. The firms are hypothesized to use a constant returns-to-scale technology, but the sizes of the firms differ. Believing that this size variation will introduce heteroskedasticity into the idiosyncratic error term, we estimate the parameters of a Cobb–Douglas production function. To do this, we use a conditional heteroskedastic half-normal model, with the size of the firm as an explanatory variable in the variance function for the idiosyncratic error. We also perform a test of the hypothesis that the firms use a constant returns-to-scale technology.

          chi2(  1) =  0.03
          Prob > chi2 =  0.8622

The output above indicates that the variance of the idiosyncratic error term is a function of firm size. Also, we failed to reject the hypothesis that the firms use a constant returns-to-scale technology.

Technical note

In small samples, the conditional heteroskedastic estimators will lack precision for the variance parameters and may fail to converge altogether.

Example 3: The truncated-normal model

Let’s turn our attention to the truncated-normal model. Once again, we will use fictional data. For this example, we have 1,231 observations on the quantity of output, the total cost of production for each firm, the prices that each firm paid for labor and capital services, and a categorical variable measuring the quality of each firm’s management. After taking the natural logarithm of the costs (lncost), prices (lnp_k and lnp_l), and output (lnout), we fit a stochastic cost frontier model and specify the distribution for the inefficiency term to be truncated normal.

H0: No inefficiency component:  z = 5.595  Prob>=z = 0.000

In addition to the coefficients, the output reports estimates for several parameters. sigma_v2 is the estimate of \( \sigma^2_v \). sigma_u2 is the estimate of \( \sigma^2_u \). gamma is the estimate of \( \gamma = \sigma^2_u / \sigma^2_S \). sigma2 is the estimate of \( \sigma^2_S = \sigma^2_v + \sigma^2_u \). Because \( \gamma \) must be between 0 and 1, the optimization is parameterized in terms of the logit of \( \gamma \), and this estimate is reported as lgtgamma. Because \( \sigma^2_S \) must be positive, the optimization is parameterized in terms of \( \ln(\sigma^2_S) \), whose estimate is reported as lnsigma2. Finally, mu is the estimate of \( \mu \), the mean of the truncated-normal distribution.

In the output above, the generalized log-likelihood test for the presence of the inefficiency term has been replaced with a test based on the third moment of the OLS residuals. When \( \mu = 0 \) and \( \sigma_u = 0 \), the truncated-normal model reduces to a linear regression model with normally distributed errors. However, the distribution of the test statistic under the null hypothesis is not well established, because it becomes impossible to evaluate the log likelihood as \( \sigma_u \) approaches zero, prohibiting the use of the likelihood-ratio test.

However, Coelli (1995) noted that the presence of an inefficiency term would negatively skew the residuals from an OLS regression. By identifying negative skewness in the residuals with the presence of an inefficiency term, Coelli derived a one-sided test for the presence of the inefficiency term. The results of this test are given at the bottom of the output. For this example, the null hypothesis of no inefficiency component is rejected.

In the example below, we fit a truncated model and detect a statistically significant inefficiency term in the model. We might question whether the inefficiency term is identically distributed over all firms or whether there might be heterogeneity across firms. frontier provides an extension to the truncated normal model by allowing the mean of the inefficiency term to be modeled as a linear function of a set of covariates. In our dataset, we have a categorical variable that measures the quality of a firm’s management. We refit the model, including the cm() option, specifying a set of
binary indicator variables representing the different categories of the quality-measurement variable as covariates.

The conditional mean model was developed in the context of panel-data estimators, and we can apply frontier's conditional mean model to panel data.
frontier stores the following in e():

Scalars

- e(N): number of observations
- e(df_m): model degrees of freedom
- e(k): number of parameters
- e(k_eq): number of equations in e(b)
- e(k_eq_model): number of equations in overall model test
- e(k_dv): number of dependent variables
- e(chi2): $\chi^2$
- e(ll): log likelihood
- e(ll_c): log likelihood for $H_0: \sigma_u=0$
- e(z): test for negative skewness of OLS residuals
- e(sigma_u): standard deviation of technical inefficiency
- e(sigma_v): standard deviation of $v_i$
- e(p): $p$-value for model test
- e(chi2_c): LR test statistic
- e(p_z): $p$-value for $z$
- e(rank): rank of e(V)
- e(ic): number of iterations
- e(rc): return code
- e(converged): 1 if converged, 0 otherwise

Macros

- e(cmd): frontier
- e(cmdline): command as typed
- e(depvar): name of dependent variable
- e(function): production or cost
- e(wtype): weight type
- e(wexp): weight expression
- e(title): title in estimation output
- e(chi2type): Wald; type of model $\chi^2$ test
- e(dist): distribution assumption for $u_i$
- e(het): heteroskedastic components
- e(u_hetvar): varlist in uhet()
- e(v_hetvar): varlist in vhet()
- e(vce): vcetype specified in vce()
- e(vcetype): title used to label Std. Err.
- e(opt): type of optimization
- e(which): max or min; whether optimizer is to perform maximization or minimization
- e(ml_method): type of ml method
- e(user): name of likelihood-evaluator program
- e(technique): maximization technique
- e(properties): b V
- e(predict): program used to implement predict
- e(asbalanced): factor variables fvset as asbalanced
- e(asobserved): factor variables fvset as asobserved

Matrices

- e(b): coefficient vector
- e(Cns): constraints matrix
- e(ilog): iteration log (up to 20 iterations)
- e(gradient): gradient vector
- e(V): variance-covariance matrix of the estimators
- e(V_modelbased): model-based variance

Functions

- e(sample): marks estimation sample
Methods and formulas

Consider an equation of the form

\[ y_i = x_i \beta + v_i - su_i \]

where \( y_i \) is the dependent variable, \( x_i \) is a \( 1 \times k \) vector of observations on the independent variables included as indent covariates, \( \beta \) is a \( k \times 1 \) vector of coefficients, and

\[ s = \begin{cases} 
1, & \text{for production functions} \\
-1, & \text{for cost functions} 
\end{cases} \]

The log-likelihood functions are as follows.

Normal/half-normal model:

\[
\ln L = \sum_{i=1}^{N} \left\{ \frac{1}{2} \ln \left( \frac{2}{\pi} \right) - \ln \sigma_S + \ln \Phi \left( -\frac{s\epsilon_i \lambda}{\sigma_S} \right) - \frac{\epsilon_i^2}{2\sigma_S^2} \right\}
\]

Normal/exponential model:

\[
\ln L = \sum_{i=1}^{N} \left\{ -\ln \sigma_u + \frac{\sigma_v^2}{2\sigma_u^2} + \ln \Phi \left( \frac{-s\epsilon_i - \frac{\sigma_u^2}{\sigma_v}}{\sigma_u} \right) + \frac{s\epsilon_i}{\sigma_u} \right\}
\]

Normal/truncated-normal model:

\[
\ln L = \sum_{i=1}^{N} \left\{ -\frac{1}{2} \ln (2\pi) \right. \\
+ \ln \Phi \left[ \left( 1 - \gamma \right) \mu - s\gamma \epsilon_i \right] \\
- \frac{1}{2} \left( \frac{ \epsilon_i + s\mu }{\sigma_S} \right)^2 \left[ \frac{\sigma_S^2}{\gamma (1 - \gamma)} \right]^{1/2} \}
\]

where \( \sigma_S = \left( \sigma_u^2 + \sigma_v^2 \right)^{1/2} \), \( \lambda = \sigma_u / \sigma_v \), \( \gamma = \sigma_u^2 / \sigma_S^2 \), \( \epsilon_i = y_i - x_i \beta \), and \( \Phi() \) is the cumulative distribution function of the standard normal distribution.

To obtain estimation for \( u_i \), you can use either the mean or the mode of the conditional distribution \( f(u_i|\epsilon_i) \).

\[
E \left( u_i \mid \epsilon_i \right) = \mu_{*i} + \sigma_{*} \left\{ \frac{\phi(-\mu_{*i} / \sigma_{*})}{\Phi(\mu_{*i} / \sigma_{*})} \right\}
\]

\[
M \left( u_i \mid \epsilon_i \right) = \begin{cases} 
\mu_{*i}, & \text{if } \mu_{*i} \geq 0 \\
0, & \text{otherwise} 
\end{cases}
\]

Then, the technical efficiency \((s = 1)\) or cost efficiency \((s = -1)\) will be estimated by

\[
E_i = E \left\{ \exp(-su_i) \mid \epsilon_i \right\} \\
= \left\{ \frac{1 - \Phi \left( s\sigma_{*} - \mu_{*i} / \sigma_{*} \right)}{1 - \Phi \left( -\mu_{*i} / \sigma_{*} \right)} \right\} \exp \left( -s\mu_{*i} + \frac{1}{2} \sigma_{*}^2 \right)
\]
where \( \mu_i^* \) and \( \sigma_* \) are defined for the normal/half-normal model as

\[
\mu_i^* = -s \epsilon_i \sigma_u^2 / \sigma_S^2 \\
\sigma_* = \sigma_u \sigma_v / \sigma_S
\]

for the normal/exponential model as

\[
\mu_i^* = -s \epsilon_i - \sigma_v^2 / \sigma_u \\
\sigma_* = \sigma_v
\]

and for the normal/truncated-normal model as

\[
\mu_i^* = -s \epsilon_i \sigma_u^2 + \mu \sigma_v^2 / \sigma_S^2 \\
\sigma_* = \sigma_u \sigma_v / \sigma_S
\]

In the half-normal and exponential models, when heteroskedasticity is assumed, the standard deviations, \( \sigma_u \) or \( \sigma_v \), will be replaced in the above equations by

\[
\sigma_i^2 = \exp(w_i \delta)
\]

where \( w \) is the vector of explanatory variables in the variance function.

In the conditional mean model, the mean parameter of the truncated normal distribution, \( \mu \), is modeled as a linear combination of the set of covariates, \( w \).

\[
\mu = w_i \delta
\]

Therefore, the log-likelihood function can be rewritten as

\[
\ln L = \sum_{i=1}^{N} \left[ -\frac{1}{2} \ln (2\pi) - \ln \sigma_S - \ln \Phi \left( \frac{w_i \delta}{\sigma_S} \right) + \ln \Phi \left\{ \frac{(1-\gamma) w_i \delta - s \gamma \epsilon_i}{\sigma_S \gamma (1-\gamma)} \right\} - \frac{1}{2} \left( \frac{\epsilon_i + s w_i \delta}{\sigma_S} \right)^2 \right]
\]

The \( z \) test reported in the output of the truncated-normal model is a third-moment test developed by Coelli (1995) as an extension of a test previously developed by Pagan and Hall (1983). Coelli shows that under the null of normally distributed errors, the statistic

\[
z = \frac{m_3}{\left( \frac{6m_2^3}{N} \right)^{1/2}}
\]

has a standard normal distribution, where \( m_3 \) is the third moment from the OLS regression. Because the residuals are either negatively skewed (production function) or positively skewed (cost function), a one-sided \( p \)-value is used.
