xtregar — Fixed- and random-effects linear models with an AR(1) disturbance

Description

xtregar fits cross-sectional time-series regression models when the disturbance term is first-order autoregressive. xtregar offers a within estimator for fixed-effects models and a GLS estimator for random-effects models. xtregar can accommodate unbalanced panels whose observations are unequally spaced over time.

Quick start

Random-effects model of \( y \) on \( x_1 \) with an AR(1) disturbance using \texttt{xtset} data

\begin{verbatim}
xtregar y x1
\end{verbatim}

Add \( x_2 \) and \( x_3 \) as covariates and perform Baltagi–Wu LBI test

\begin{verbatim}
xtregar y x1 x2 x3, lbi
\end{verbatim}

Fixed-effects model using the within estimator and observations where \texttt{tvar} is greater than 2,000

\begin{verbatim}
xtregar y x1 x2 x3 if tvar > 2000, fe
\end{verbatim}

A panel variable and a time variable must be specified; use xtset; see [XT] xtset. 

*indepvars* may contain factor variables; see [U] 11.4.3 Factor variables. 

*depvar* and *indepvars* may contain time-series operators; see [U] 11.4.4 Time-series varlists. 

by and stataby are allowed; see [U] 11.1.10 Prefix commands. 

fweights and aweights are allowed for the fixed-effects model with rhotype(regress) or rhotype(freg), or with a fixed rho; see [U] 11.1.6 weight. Weights must be constant within panel. 

coefflegend does not appear in the dialog box. 

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**

**Model**

*re* requests the GLS estimator of the random-effects model, which is the default. 

*fe* requests the within estimator of the fixed-effects model.
rhotype(rhmethod) allows the user to specify any of the following estimators of $\rho$:

\[
\begin{align*}
\text{dw} & \quad \rho_{\text{dw}} = 1 - d/2, \text{ where } d \text{ is the Durbin–Watson } d \text{ statistic} \\
\text{regress} & \quad \rho_{\text{reg}} = \beta \text{ from the residual regression } \epsilon_t = \beta \epsilon_{t-1} \\
\text{freg} & \quad \rho_{\text{freg}} = \beta \text{ from the residual regression } \epsilon_t = \beta \epsilon_{t+1} \\
\text{tscorr} & \quad \rho_{\text{tscorr}} = \epsilon' \epsilon_{t-1} / \epsilon' \epsilon, \text{ where } \epsilon \text{ is the vector of residuals and } \epsilon_{t-1} \text{ is the vector of lagged residuals} \\
\text{theil} & \quad \rho_{\text{theil}} = \rho_{\text{tscorr}} (N - k)/N \\
\text{nagar} & \quad \rho_{\text{nagar}} = (\rho_{\text{dw}} N^2 + k^2) / (N^2 - k^2) \\
\text{onestep} & \quad \rho_{\text{onestep}} = (n/m_c) (\epsilon' \epsilon_{t-1} / \epsilon' \epsilon), \text{ where } \epsilon \text{ is the vector of residuals, } n \text{ is the number of observations, and } m_c \text{ is the number of consecutive pairs of residuals}
\end{align*}
\]

$\text{dw}$ is the default method. Except for $\text{onestep}$, the details of these methods are given in [TS] prais. prais handles unequally spaced data. $\text{onestep}$ is the one-step method proposed by Baltagi and Wu (1999). More details on this method are available below in Methods and formulas.

rhof(#) specifies that the given number be used for $\rho$ and that $\rho$ not be estimated.

twostep requests that a two-step implementation of the $\text{rhmethod}$ estimator of $\rho$ be used. Unless a fixed value of $\rho$ is specified (with the rhof() option), $\rho$ is estimated by running prais on the de-meaned data. When twostep is specified, prais will stop on the first iteration after the equation is transformed by $\rho$—the two-step efficient estimator. Although it is customary to iterate these estimators to convergence, they are efficient at each step. When twostep is not specified, the FGLS process iterates to convergence as described in the Methods and formulas of [TS] prais.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fwwrap(#), fwwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

The following option is available with xtregar but is not shown in the dialog box:

coeflegend; see [R] Estimation options.
Remarks and examples

Remarks are presented under the following headings:

Introduction

The fixed-effects model

The random-effects model

Introduction

If you have not read [XT] xt, please do so.

xtregar fits cross-sectional time-series regression models when the disturbance term is first-order autoregressive. The models of interest are described by

\[ y_{it} = \alpha + x_{it} \beta + \nu_i + \epsilon_{it} \quad i = 1, \ldots, N; \quad t = 1, \ldots, T_i \]  

(1)

where

\[ \epsilon_{it} = \rho \epsilon_{i,t-1} + \eta_{it} \]  

(2)

and where \(|\rho| < 1\) and \(\eta_{it}\) is independent and identically distributed (i.i.d.) with mean 0 and variance \(\sigma_{\eta}^2\).

In the fixed-effects model, the \(\nu_i\) are assumed to be correlated with the covariates \(x_{it}\), whereas in the random-effects model they are assumed to follow an i.i.d. process with mean 0 and variance \(\sigma_{\eta}^2\) and to be uncorrelated with the \(x_{it}\).

Similar to other linear panel-data models, any \(x_{it}\) that do not vary over \(t\) are collinear with the \(\nu_i\) and will be dropped from the fixed-effects model. In contrast, the random-effects model can accommodate covariates that are constant over time.

xtregar offers a within estimator for the fixed-effect model and the Baltagi–Wu (1999) GLS estimator of the random-effects model. Both of these estimators offer several estimators of \(\rho\).

The Baltagi–Wu (1999) GLS estimator extends the balanced panel estimator in Baltagi and Li (1991) to a case of exogenously unbalanced panels with unequally spaced observations. Specifically, the dataset contains observations on individual \(i\) at times \(t_{ij}\) for \(j = 1, \ldots, n_i\). The difference \(t_{ij} - t_{i,j-1}\) plays an integral role in the estimation techniques used by xtregar.

For this reason, you must specify the delta() option when you xtset panelvar timevar if, for example, you have quarterly data with a monthly timevar recorded every three months instead of a quarterly timevar; see [XT] xtset.

The fixed-effects model

Let’s examine the fixed-effect model first. The basic approach is common to all fixed-effects models. The \(\nu_i\) are treated as nuisance parameters. We use a transformation of the model that removes the nuisance parameters and leaves behind the parameters of interest in an estimable form. Subtracting the group means from (1) removes the \(\nu_i\) from the model

\[ y_{it_{ij}} - \bar{y}_i = (\bar{x}_{it_{ij}} - \bar{x}_i) \beta + \epsilon_{it_{ij}} - \bar{\epsilon}_i \]  

(3)

where

\[ \bar{y}_i = \frac{1}{n_i} \sum_{j=1}^{n_i} y_{it_{ij}} \quad \bar{x}_i = \frac{1}{n_i} \sum_{j=1}^{n_i} x_{it_{ij}} \quad \bar{\epsilon}_i = \frac{1}{n_i} \sum_{j=1}^{n_i} \epsilon_{it_{ij}} \]
After the transformation, (3) is a linear AR(1) model, potentially with unequally spaced observations. (3) can be used to estimate \( \rho \). Given an estimate of \( \rho \), we must do a Cochrane–Orcutt transformation on each panel and then remove the within-panel means and add back the overall mean for each variable. OLS on the transformed data will produce the within estimates of \( \alpha \) and \( \beta \).

Example 1: Fixed-effects model

Let’s use the Grunfeld investment dataset to illustrate how \texttt{xtregar} can be used to fit the fixed-effects model. This dataset contains information on 10 firms’ investment, market value, and the value of their capital stocks. The data were collected annually between 1935 and 1954. The following output shows that we have \texttt{xtset} our data and gives the results of running a fixed-effects model with investment as a function of market value and the capital stock.

```
. use https://www.stata-press.com/data/r16/grunfeld
. xtset panel variable: company (strongly balanced)
   time variable: year, 1935 to 1954
   delta: 1 year
. xtregar invest mvalue kstock, fe
```

```
FE (within) regression with AR(1) disturbances
Number of obs = 190
Group variable: company
Number of groups = 10
R-sq: Obs per group:
   within = 0.5927 min = 19
   between = 0.7989 avg = 19.0
   overall = 0.7904 max = 19
F(2,178) = 129.49
corr(u_i, Xb) = -0.0454
```

```
Coef. Std. Err. t P>|t|  [95% Conf. Interval]
```

| invest        | Coef.   | Std. Err. | t      | P>|t| | [95% Conf. Interval] |
|---------------|---------|-----------|--------|------|----------------------|
| mvalue        | .09499999 | .0091377  | 10.40  | 0.000 | .0769677 .113032    |
| kstock        | .350161  | .0293747  | 11.92  | 0.000 | .2921935 .4081286   |
| _cons         | -63.22022 | 5.648271 | -11.19 | 0.000 | -74.36641 -52.07402 |
| rho_ar        | .67210608 |           |        |      |                      |
| sigma_u       | 91.507609 |           |        |      |                      |
| sigma_e       | 40.992469 |           |        |      |                      |
| rho_fov       | .8328647  |           |        |      | (fraction of variance because of u_i) |

```
F test that all u_i=0: F(9,178) = 11.53
Prob > F = 0.0000

Because there are 10 groups, the panel-by-panel Cochrane–Orcutt method decreases the number of available observations from 200 to 190. The above example used the default \texttt{dw} estimator of \( \rho \). Using the \texttt{tscorr} estimator of \( \rho \) yields
. xtregar invest mvalue kstock, fe rhotype(tscorr)

| sigma_u| 90.893572  |          |       |     |                     |
| sigma_e| 41.592151  |          |       |     |                     |
| rho_fov | 0.82686297 |          |       |     |                     |

F test that all u_i=0: F(9,178) = 19.73  Prob > F  =  0.0000

Technical note

The tscorr estimator of $\rho$ is bounded in $[-1, 1]$. The other estimators of $\rho$ are not. In samples with short panels, the estimates of $\rho$ produced by the other estimators of $\rho$ may be outside $[-1, 1]$. If this happens, use the tscorr estimator. However, simulations have shown that the tscorr estimator is biased toward zero. dw is the default because it performs well in Monte Carlo simulations. In the example above, the estimate of $\rho$ produced by tscorr is much smaller than the one produced by dw.

Example 2: Using xtset

xtregar will complain if you try to run xtregar on a dataset that has not been xtset:

. xtset, clear

. xtregar invest mvalue kstock, fe

must specify panelvar and timevar; use xtset
r(459);

You must xtset your data to ensure that xtregar understands the nature of your time variable. Suppose that our observations were taken quarterly instead of annually. We will get the same results with the quarterly variable t2 that we did with the annual variable year.
In all the examples thus far, we have assumed that $\epsilon_{it}$ is first-order autoregressive. Testing the hypothesis of $\rho = 0$ in a first-order autoregressive process produces test statistics with extremely complicated distributions. Bhargava, Franzini, and Narendranathan (1982) extended the Durbin–Watson statistic to the case of balanced, equally spaced panel datasets. Baltagi and Wu (1999) modify their statistic to account for unbalanced panels with unequally spaced data. In the same article, Baltagi and Wu (1999) derive the locally best invariant test statistic of $\rho = 0$. Both these test statistics have extremely complicated distributions, although Bhargava, Franzini, and Narendranathan (1982) did publish some critical values in their article. Specifying the lbi option to xtregar causes Stata to calculate and report the modified Bhargava et al. Durbin–Watson and the Baltagi–Wu LBI.

Example 3: Testing for autocorrelation

In this example, we calculate the modified Bhargava et al. Durbin–Watson statistic and the Baltagi–Wu LBI. We exclude periods 9 and 10 from the sample, thereby reproducing the results of Baltagi
and Wu (1999, 822). \( p \)-values are not reported for either statistic. Although Bhargava, Franzini, and Narendranathan (1982) published critical values for their statistic, no tables are currently available for the Baltagi–Wu (LBI). Baltagi and Wu (1999) did derive a normalized version of their statistic, but this statistic cannot be computed for datasets of moderate size.

```
.xtregar invest mvalue kstock if year !=1934 & year !=1944, fe lbi
```

Baltagi-Wu LBI = 1.0134522

---

**The random-effects model**

In the random-effects model, the \( \nu_i \) are assumed to be realizations of an i.i.d. process with mean 0 and variance \( \sigma^2_\nu \). Furthermore, the \( \nu_i \) are assumed to be independent of both the \( \epsilon_{it} \) and the covariates \( x_{it} \). The latter of these assumptions can be strong, but inference is not conditional on the particular realizations of the \( \nu_i \) in the sample. See Mundlak (1978) for a discussion of this point.

**Example 4: Random-effects model**

By specifying the `re` option, we obtain the Baltagi–Wu GLS estimator of the random-effects model. This estimator can accommodate unbalanced panels and unequally spaced data. We run this model on the Grunfeld dataset:
```
xtregar invest mvalue kstock if year !=1934 & year !=1944, re lbi

RE GLS regression with AR(1) disturbances
Number of obs = 190  
Number of groups = 10

R-sq:  
within = 0.7707  min = 19
between = 0.8039  avg = 19.0
overall = 0.7958  max = 19

Wald chi2(3) = 351.37
Prob > chi2 = 0.0000

|     | Coef.  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|-----|--------|-----------|-------|-----|---------------------|
| invest |       |           |       |     |                     |
| mvalue | .0947714 | .0083691 | 11.32 | 0.000 | .0783683 - .1111746 |
| kstock | .3223932 | .0263226 | 12.25 | 0.000 | .2708019 - .3739845 |

Methods and formulas

Consider a linear panel-data model described by (1) and (2). The data can be unbalanced and unequally spaced. Specifically, the dataset contains observations on individual \( i \) at times \( t_{ij} \) for \( j = 1, \ldots, n_i \).

Methods and formulas are presented under the following headings:

- Estimating \( \rho \)
- Transforming the data to remove the AR(1) component
- The within estimator of the fixed-effects model
- The Baltagi–Wu GLS estimator
- The test statistics

Estimating \( \rho \)

The estimate of \( \rho \) is always obtained after removing the group means. Let \( \tilde{y}_{it} = y_{it} - \bar{y}_i \), let \( \tilde{x}_{it} = x_{it} - \bar{x}_i \), and let \( \tilde{\epsilon}_{it} = \epsilon_{it} - \bar{\epsilon}_i \).

Then, except for the one-step method, all the estimates of \( \rho \) are obtained by running Stata’s prais on

\[
\tilde{y}_{it} = \tilde{x}_{it} \beta + \tilde{\epsilon}_{it}
\]

See [TS] prais for the formulas for each of the methods.

When one-step is specified, a regression is run on the above equation, and the residuals are obtained. Let \( e_{it_{ij}} \) be the residual used to estimate the error \( \tilde{\epsilon}_{it_{ij}} \). If \( t_{ij} - t_{i, j-1} > 1 \), \( e_{it_{ij}} \) is set to zero. Given this series of residuals

\[
\hat{\rho}_{\text{onestep}} = \frac{n}{m_c} \frac{\sum_{i=1}^{N} \sum_{t=2}^{T} e_{it} e_{i,t-1}}{\sum_{i=1}^{N} \sum_{t=1}^{T} e_{it}^2}
\]

where \( n \) is the number of nonzero elements in \( e \) and \( m_c \) is the number of consecutive pairs of nonzero \( e_{it} \)s.

Transforming the data to remove the AR(1) component

After estimating \( \rho \), Baltagi and Wu (1999) derive a transformation of the data that removes the AR(1) component. Their \( C_i(\rho) \) can be written as

\[
y_{it_{ij}}^* = \begin{cases} 
(1 - \rho^2)^{1/2} y_{it_{ij}} & \text{if } t_{ij} = 1 \\
(1 - \rho^2)^{1/2} \left\{ y_{i,t_{ij}} \left( \frac{1}{1 - \rho^2 (t_{ij} - t_{i,j-1})} \right)^{1/2} - y_{i,t_{i,j-1}} \left( \frac{\rho (t_{ij} - t_{i,j-1})}{1 - \rho^2 (t_{ij} - t_{i,j-1})} \right)^{1/2} \right\} & \text{if } t_{ij} > 1
\end{cases}
\]

Using the analogous transform on the independent variables generates transformed data without the AR(1) component. Performing simple OLS on the transformed data leaves behind the residuals \( \mu^* \).
The within estimator of the fixed-effects model

To obtain the within estimator, we must transform the data that come from the AR(1) transform. For the within transform to remove the fixed effects, the first observation of each panel must be dropped. Specifically, let

$$
\tilde{y}_{itij} = y_{itij}^* - \bar{y}_i + \bar{y}^* \quad \forall j > 1
$$

$$
\tilde{x}_{itij} = x_{itij}^* - \bar{x}_i + \bar{x}^* \quad \forall j > 1
$$

$$
\tilde{\epsilon}_{itij} = \epsilon_{itij}^* - \bar{\epsilon}_i + \bar{\epsilon}^* \quad \forall j > 1
$$

where

$$
\bar{y}_i = \frac{\sum_{j=2}^{n_i-1} y_{itij}^*}{n_i - 1}
$$

$$
\bar{y}^* = \frac{\sum_{i=1}^{N} \sum_{j=2}^{n_i-1} y_{itij}^*}{\sum_{i=1}^{N} n_i - 1}
$$

$$
\bar{x}_i = \frac{\sum_{j=2}^{n_i-1} x_{itij}^*}{n_i - 1}
$$

$$
\bar{x}^* = \frac{\sum_{i=1}^{N} \sum_{j=2}^{n_i-1} x_{itij}^*}{\sum_{i=1}^{N} n_i - 1}
$$

$$
\bar{\epsilon}_i = \frac{\sum_{j=2}^{n_i-1} \epsilon_{itij}^*}{n_i - 1}
$$

$$
\bar{\epsilon}^* = \frac{\sum_{i=1}^{N} \sum_{j=2}^{n_i-1} \epsilon_{itij}^*}{\sum_{i=1}^{N} n_i - 1}
$$

The within estimator of the fixed-effects model is then obtained by running OLS on

$$
\tilde{y}_{itij} = \alpha + \tilde{x}_{itij} \beta + \tilde{\epsilon}_{itij}
$$

Reported as $R^2$ within is the $R^2$ from the above regression.

Reported as $R^2$ between is $\left\{ \text{corr}(\bar{x}_i \hat{\beta}, \bar{y}_i) \right\}^2$.

Reported as $R^2$ overall is $\left\{ \text{corr}(x_{it} \hat{\beta}, y_{it}) \right\}^2$. 
The Baltagi–Wu GLS estimator

The residuals $\mu^*$ can be used to estimate the variance components. Translating the matrix formulas given in Baltagi and Wu (1999) into summations yields the following variance-components estimators:

$$
\hat{\sigma}^2_\omega = \sum_{i=1}^{N} \frac{(\mu^*_i' g_i)^2}{(g'_i g_i)}
$$

$$
\hat{\sigma}^2_\mu = \frac{\sum_{i=1}^{N} (\mu_i' g_i)^2}{\sum_{i=1}^{N} (g'_i g_i)} - \hat{\sigma}^2_\omega
$$

$$
\hat{\sigma}^2_\epsilon = \frac{\sum_{i=1}^{N} \left\{ (\mu_i' g_i)^2 / (g'_i g_i) \right\}}{\sum_{i=1}^{N} (g'_i g_i)}
$$

where

$$
g_i = \begin{bmatrix}
1, & \{1 - \rho^{(t_i,2-t_i,1)}\}, & \{1 - \rho^{(t_i,n_i-t_i,n_i-1)}\} \\
\left\{1 - \rho^{2(t_i,2-t_i,1)}\right\}^{\frac{1}{2}}, & \ldots, & \left\{1 - \rho^{2(t_i,n_i-t_i,n_i-1)}\right\}^{\frac{1}{2}}
\end{bmatrix}'
$$

and $\mu_i^*$ is the $n_i \times 1$ vector of residuals from $\mu^*$ that correspond to person $i$.

Then

$$
\hat{\theta}_i = 1 - \left( \frac{\hat{\sigma}_\mu}{\hat{\omega}_i} \right)
$$

where

$$
\hat{\omega}_i^2 = g_i g_i \hat{\sigma}_\mu^2 + \hat{\sigma}_\epsilon^2
$$

With these estimates in hand, we can transform the data via

$$
z_{itij}^{**} = z_{itij}^* - \hat{\theta}_i g_{ij} \frac{\sum_{s=1}^{n_i} g_{is} z_{is}^*}{\sum_{s=1}^{n_i} g_{is}^2}
$$

for $z \in \{y, x\}$.

Running OLS on the transformed data $y^{**}, x^{**}$ yields the feasible GLS estimator of $\alpha$ and $\beta$.

Reported as $R^2$ between is $\left\{ \text{corr}(\overline{x_i} \hat{\beta}, \overline{y}_i) \right\}^2$.

Reported as $R^2$ within is $\left\{ \text{corr}\{ (x_{it} - \overline{x_i}) \hat{\beta}, y_{it} - \overline{y}_i \} \right\}^2$.

Reported as $R^2$ overall is $\left\{ \text{corr}(x_{it} \hat{\beta}, y_{it}) \right\}^2$. 
The test statistics

The Baltagi–Wu LBI is the sum of terms

\[ d_* = d_1 + d_2 + d_3 + d_4 \]

where

\[ d_1 = \frac{\sum_{i=1}^{N} \sum_{j=1}^{n_i} (\tilde{z}_{it_{ij}} - \tilde{z}_{it_{i,j-1}} I(t_{ij} - t_{i,j-1} = 1))^2}{\sum_{i=1}^{N} \sum_{j=1}^{n_i} \tilde{z}_{it_{ij}}^2} \]

\[ d_2 = \frac{\sum_{i=1}^{N} \sum_{j=1}^{n_i-1} \tilde{z}_{it_{ij}}^2 \{1 - I(t_{i,j+1} - t_{ij} = 1)\}}{\sum_{i=1}^{N} \sum_{j=1}^{n_i} \tilde{z}_{it_{ij}}^2} \]

\[ d_3 = \frac{\sum_{i=1}^{N} \tilde{z}_{it_{i1}}^2}{\sum_{i=1}^{N} \sum_{j=1}^{n_i} \tilde{z}_{it_{ij}}^2} \]

\[ d_4 = \frac{\sum_{i=1}^{N} \tilde{z}_{itti_{ini}}^2}{\sum_{i=1}^{N} \sum_{j=1}^{n_i} \tilde{z}_{it_{ij}}^2} \]

\( I() \) is the indicator function that takes the value of 1 if the condition is true and 0 otherwise. The \( \tilde{z}_{it_{i,j-1}} \) are residuals from the within estimator.

Baltagi and Wu (1999) also show that \( d_1 \) is the Bhargava et al. Durbin–Watson statistic modified to handle cases of unbalanced panels and unequally spaced data.

Acknowledgment

We thank Badi Baltagi of the Department of Economics at Syracuse University for his helpful comments.
