egen — Extensions to generate

Syntax

egen [type] newvar = fcn(arguments) [if] [in] [ , options ]

by is allowed with some of the egen functions, as noted below.

where depending on the fcn, arguments refers to an expression, varlist, or numlist, and the options are also fcn dependent, and where fcn is

anycount(varlist), values(integer numlist)

may not be combined with by. It returns the number of variables in varlist for which values are equal to any integer value in a supplied numlist. Values for any observations excluded by either if or in are set to 0 (not missing). Also see anyvalue(varname) and anymatch(varlist).

anymatch(varlist), values(integer numlist)

may not be combined with by. It is 1 if any variable in varlist is equal to any integer value in a supplied numlist and 0 otherwise. Values for any observations excluded by either if or in are set to 0 (not missing). Also see anyvalue(varname) and anycount(varlist).

anyvalue(varname), values(integer numlist)

may not be combined with by. It takes the value of varname if varname is equal to any integer value in a supplied numlist and is missing otherwise. Also see anymatch(varlist) and anycount(varlist).

concat(varlist) [ , format(%fmt) decode maxlength(#) punct(pchars) ]

may not be combined with by. It concatenates varlist to produce a string variable. Values of string variables are unchanged. Values of numeric variables are converted to string, as is, or are converted using a numeric format under the format(%fmt) option or decoded under the decode option, in which case maxlength() may also be used to control the maximum label length used. By default, variables are added end to end: punct(pchars) may be used to specify punctuation, such as a space, punct(" "), or a comma, punct(,).

count(exp) (allows by varlist:)

creates a constant (within varlist) containing the number of nonmissing observations of exp. Also see rrownonmiss() and rowmiss().

cut(varname), { at(#,#,...,#) | group(#) } [ icodes label]

may not be combined with by. It creates a new categorical variable coded with the left-hand ends of the grouping intervals specified in the at() option, which expects an ascending numlist.

at(#,#,...,#) supplies the breaks for the groups, in ascending order. The list of breakpoints may be simply a list of numbers separated by commas but can also include the syntax a(b)c, meaning from a to c in steps of size b. If no breaks are specified, the command expects the group() option.

group(#) specifies the number of equal frequency grouping intervals to be used in the absence of breaks. Specifying this option automatically invokes icodes.
icodes requests that the codes 0, 1, 2, etc., be used in place of the left-hand ends of the intervals.

label requests that the integer-coded values of the grouped variable be labeled with the left-hand ends of the grouping intervals. Specifying this option automatically invokes icodes.

diff(varlist)
may not be combined with by. It creates an indicator variable equal to 1 if the variables in varlist are not equal and 0 otherwise.

ends(strvar) [, punct(pchars) trim [head | last | tail]]
may not be combined with by. It gives the first “word” or head (with the head option), the last “word” (with the last option), or the remainder or tail (with the tail option) from string strvar.

head, last, and tail are determined by the occurrence of pchars, which is by default one space (“ ”).

The head is whatever precedes the first occurrence of pchars, or the whole of the string if it does not occur. For example, the head of “frog toad” is “frog” and that of “frog” is “frog”. With punct(,), the head of “frog,toad” is “frog”.

The last word is whatever follows the last occurrence of pchars or is the whole of the string if a space does not occur. The last word of “frog toad newt” is “newt” and that of “frog” is “frog”. With punct(,), the last word of “frog,toad” is “toad”.

The remainder or tail is whatever follows the first occurrence of pchars, which will be the empty string "" if pchars does not occur. The tail of “frog toad newt” is “toad newt” and that of “frog” is "". With punct(,), the tail of “frog,toad” is “toad”.

The trim option trims any leading or trailing spaces.

fill(numlist)
may not be combined with by. It creates a variable of ascending or descending numbers or complex repeating patterns. numlist must contain at least two numbers and may be specified using standard numlist notation; see [U] 11.1.8 numlist. if and in are not allowed with fill().

group(varlist) [, missing label lname(name) truncate(num)]
may not be combined with by. It creates one variable taking on values 1, 2, ... for the groups formed by varlist. varlist may contain numeric variables, string variables, or a combination of the two. The order of the groups is that of the sort order of varlist. missing indicates that missing values in varlist (either . or "") are to be treated like any other value when assigning groups, instead of as missing values being assigned to the group missing. The label option returns integers from 1 up according to the distinct groups of varlist in sorted order. The integers are labeled with the values of varlist or the value labels, if they exist. lname() specifies the name to be given to the value label created to hold the labels; lname() implies label. The truncate() option truncates the values contributed to the label from each variable in varlist to the length specified by the integer argument num. The truncate option cannot be used without specifying the label option. The truncate option does not change the groups that are formed; it changes only their labels.

iqr(exp) (allows by varlist:)
creates a constant (within varlist) containing the interquartile range of exp. Also see ptile().

kurt(varname) (allows by varlist:)
returns the kurtosis (within varlist) of varname.

mad(exp) (allows by varlist:)
returns the median absolute deviation from the median (within varlist) of exp.
\texttt{egen} — Extensions to generate

\texttt{max(exp)} (allows by \texttt{varlist:})

creates a constant (within \texttt{varlist}) containing the maximum value of \texttt{exp}.

\texttt{mdev(exp)} (allows by \texttt{varlist:})

returns the mean absolute deviation from the mean (within \texttt{varlist}) of \texttt{exp}.

\texttt{mean(exp)} (allows by \texttt{varlist:})

creates a constant (within \texttt{varlist}) containing the mean of \texttt{exp}.

\texttt{median(exp)} (allows by \texttt{varlist:})

creates a constant (within \texttt{varlist}) containing the median of \texttt{exp}. Also see \texttt{pctile()}.

\texttt{min(exp)} (allows by \texttt{varlist:})

creates a constant (within \texttt{varlist}) containing the minimum value of \texttt{exp}.

\texttt{mode(varname) [ , minmode maxmode nummode(integer) missing]} (allows by \texttt{varlist:})

produces the mode (within \texttt{varlist}) for \texttt{varname}, which may be numeric or string. The mode is the value occurring most frequently. If two or more modes exist or if \texttt{varname} contains all missing values, the mode produced will be a missing value. To avoid this, the \texttt{minmode}, \texttt{maxmode}, or \texttt{nummode()} option may be used to specify choices for selecting among the multiple modes, and the \texttt{missing} option will treat missing values as categories. \texttt{minmode} returns the lowest value, and \texttt{maxmode} returns the highest value. \texttt{nummode(#)} will return the \texttt{#}th mode, counting from the lowest up. Missing values are excluded from determination of the mode unless \texttt{missing} is specified. Even so, the value of the mode is recorded for observations for which the values of \texttt{varname} are missing unless they are explicitly excluded, that is, by if \texttt{varname < .} or if \texttt{varname !=""}.

\texttt{mtr(year income)}

may not be combined with \texttt{by}. It returns the U.S. marginal income tax rate for a married couple with taxable income \texttt{income} in year \texttt{year}, where \(1930 \leq \texttt{year} \leq 2013\). \texttt{year} and \texttt{income} may be specified as variable names or constants; for example, \texttt{mtr(1993 faminc)}, \texttt{mtr(surveyyr 28000)}, or \texttt{mtr(surveyyr faminc)}. A blank or comma may be used to separate \texttt{income} from \texttt{year}.

\texttt{pc(exp) [ , prop]} (allows by \texttt{varlist:})

returns \texttt{exp} (within \texttt{varlist}) scaled to be a percentage of the total, between 0 and 100. The \texttt{prop} option returns \texttt{exp} scaled to be a proportion of the total, between 0 and 1.

\texttt{pctile(exp) [ , p(#)]} (allows by \texttt{varlist:})

creates a constant (within \texttt{varlist}) containing the \texttt{#}th percentile of \texttt{exp}. If \texttt{p(#)} is not specified, 50 is assumed, meaning medians. Also see \texttt{median()}.

\texttt{rank(exp) [ , field|track|unique]} (allows by \texttt{varlist:})

creates ranks (within \texttt{varlist}) of \texttt{exp}; by default, equal observations are assigned the average rank. The \texttt{field} option calculates the field rank of \texttt{exp}: the highest value is ranked 1, and there is no correction for ties. That is, the field rank is \(1 + \text{the number of values that are higher} \). The \texttt{track} option calculates the track rank of \texttt{exp}: the lowest value is ranked 1, and there is no correction for ties. That is, the track rank is \(1 + \text{the number of values that are lower} \). The \texttt{unique} option calculates the unique rank of \texttt{exp}: values are ranked 1, \ldots, \#, and values and ties are broken arbitrarily. Two values that are tied for second are ranked 2 and 3.

\texttt{rowfirst(varlist)}

may not be combined with \texttt{by}. It gives the first nonmissing value in \texttt{varlist} for each observation (row). If all values in \texttt{varlist} are missing for an observation, \texttt{newvar} is set to missing.

\texttt{rowlast(varlist)}

may not be combined with \texttt{by}. It gives the last nonmissing value in \texttt{varlist} for each observation (row). If all values in \texttt{varlist} are missing for an observation, \texttt{newvar} is set to missing.

\textbf{rowmax(\textit{varlist})}

may not be combined with \textit{by}. It gives the maximum value (ignoring missing values) in \textit{varlist} for each observation (row). If all values in \textit{varlist} are missing for an observation, \textit{newvar} is set to missing.

\textbf{rowmean(\textit{varlist})}

may not be combined with \textit{by}. It creates the (row) means of the variables in \textit{varlist}, ignoring missing values; for example, if three variables are specified and, in some observations, one of the variables is missing, in those observations \textit{newvar} will contain the mean of the two variables that do exist. Other observations will contain the mean of all three variables. Where none of the variables exist, \textit{newvar} is set to missing.

\textbf{rowmedian(\textit{varlist})}

may not be combined with \textit{by}. It gives the (row) median of the variables in \textit{varlist}, ignoring missing values. If all variables in \textit{varlist} are missing for an observation, \textit{newvar} is set to missing in that observation. Also see \texttt{rowpctile()}.

\textbf{rowmin(\textit{varlist})}

may not be combined with \textit{by}. It gives the minimum value in \textit{varlist} for each observation (row). If all values in \textit{varlist} are missing for an observation, \textit{newvar} is set to missing.

\textbf{rowmiss(\textit{varlist})}

may not be combined with \textit{by}. It gives the number of missing values in \textit{varlist} for each observation (row).

\textbf{rownonmiss(\textit{varlist})[, \textit{strok}]} \\

may not be combined with \textit{by}. It gives the number of nonmissing values in \textit{varlist} for each observation (row)—this is the value used by \texttt{rowmean()} for the denominator in the mean calculation.

String variables may not be specified unless the \textit{strok} option is also specified. If \textit{strok} is specified, string variables will be counted as containing missing values when they contain ".". Numeric variables will be counted as containing missing when their value is ">= .".

\textbf{rowpctile(\textit{varlist})[, \textit{p(#)}]} \\

may not be combined with \textit{by}. It gives the \textit{#}th percentile of the variables in \textit{varlist}, ignoring missing values. If all variables in \textit{varlist} are missing for an observation, \textit{newvar} is set to missing in that observation. If \textit{p()} is not specified, \textit{p(50)} is assumed, meaning medians. Also see \texttt{rowmedian()}.

\textbf{rowsd(\textit{varlist})} \\

may not be combined with \textit{by}. It creates the (row) standard deviations of the variables in \textit{varlist}, ignoring missing values.

\textbf{rowtotal(\textit{varlist})[, \textit{missing}]} \\

may not be combined with \textit{by}. It creates the (row) sum of the variables in \textit{varlist}, treating missing values as 0. If \textit{missing} is specified and all values in \textit{varlist} are missing for an observation, \textit{newvar} is set to missing.

\textbf{sd(\textit{exp})} \hspace{1cm} \text{(allows by \textit{varlist}:)}

creates a constant (within \textit{varlist}) containing the standard deviation of \textit{exp}. Also see \texttt{mean()}.

\textbf{seq(\textit{[, from(#) to(#) block(#)]})} \hspace{1cm} \text{(allows by \textit{varlist}:)}

returns integer sequences. Values start from \texttt{from} (default 1) and increase to \texttt{to} (the default is the maximum number of values) in blocks (default size 1). If \texttt{to} is less than the maximum number, sequences restart at \texttt{from}. Numbering may also be separate within groups defined by \textit{varlist} or decreasing if \texttt{to} is less than \texttt{from}. Sequences depend on the sort order of observations, following three rules: 1) observations excluded by \texttt{if} or \texttt{in} are not
counted; 2) observations are sorted by varlist, if specified; and 3) otherwise, the order is that when called. No arguments are specified.

**skew(varname)**

returns the skewness (within varlist) of varname.

**std(exp) [ , mean(#) std(#)]**

may not be combined with by. It creates the standardized values of exp. The options specify the desired mean and standard deviation. The default is mean(0) and std(1), producing a variable with mean 0 and standard deviation 1.

**tag(varlist) [ , missing]**

may not be combined with by. It tags just 1 observation in each distinct group defined by varlist. When all observations in a group have the same value for a summary variable calculated for the group, it will be sufficient to use just one value for many purposes. The result will be 1 if the observation is tagged and never missing, and 0 otherwise. Values for any observations excluded by either if or in are set to 0 (not missing). Hence, if tag is the variable produced by egen tag = tag(varlist), the idiom if tag is always safe. missing specifies that missing values of varlist may be included.

**total(exp) [ , missing]** (allows by varlist:)

creates a constant (within varlist) containing the sum of exp treating missing as 0. If missing is specified and all values in exp are missing, newvar is set to missing. Also see mean().

**Menu**

Data > Create or change data > Create new variable (extended)

**Description**

**egen** creates newvar of the optionally specified storage type equal to fcn(arguments). Here fcn() is a function specifically written for egen, as documented below or as written by users. Only egen functions may be used with egen, and conversely, only egen may be used to run egen functions.

Depending on fcn(), arguments, if present, refers to an expression, varlist, or a numlist, and the options are similarly fcn dependent. Explicit subscripting (using _N and _n), which is commonly used with generate, should not be used with egen; see [U] 13.7 Explicit subscripting.

**Remarks and examples**

stata.com

Remarks are presented under the following headings:

- Summary statistics
- Generating patterns
- Marking differences among variables
- Ranks
- Standardized variables
- Row functions
- Categorical and integer variables
- String variables
- U.S. marginal income tax rate

See Mitchell (2010) for numerous examples using egen.
Summary statistics

The functions `count()`, `iqr()`, `kurt()`, `max()`, `mdev()`, `mean()`, `median()`, `min()`, `mode()`, `pc()`, `pctile()`, `sd()`, `skew()`, and `total()` create variables containing summary statistics. These functions take a by ... prefix and, if specified, calculate the summary statistics within each by-group.

Example 1: Without the by prefix

Without the by prefix, the result produced by these functions is a constant for every observation in the data. For instance, we have data on cholesterol levels (chol) and wish to have a variable that, for each patient, records the deviation from the average across all patients:

```
. use http://www.stata-press.com/data/r13/egenxmpl
. egen avg = mean(chol)
. generate deviation = chol - avg
```

Example 2: With the by prefix

These functions are most useful when the by prefix is specified. For instance, assume that our dataset includes `dcode`, a hospital–patient diagnostic code, and `los`, the number of days that the patient remained in the hospital. We wish to obtain the deviation in length of stay from the median for all patients having the same diagnostic code:

```
. use http://www.stata-press.com/data/r13/egenxmpl2, clear
. by dcode, sort: egen medstay = median(los)
. generate deltalos = los - medstay
```

Technical note

Distinguish carefully between Stata’s `sum()` function and `egen`’s `total()` function. Stata’s `sum()` function creates the running sum, whereas `egen`’s `total()` function creates a constant equal to the overall sum; for example,

```
. clear
. set obs 5
  obs was 0, now 5
. generate a = _n
. generate sum1=sum(a)
. egen sum2=total(a)
. list
     +------------------+
<table>
<thead>
<tr>
<th>a</th>
<th>sum1</th>
<th>sum2</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>1</td>
<td>15</td>
</tr>
<tr>
<td>2.</td>
<td>2</td>
<td>15</td>
</tr>
<tr>
<td>3.</td>
<td>3</td>
<td>15</td>
</tr>
<tr>
<td>4.</td>
<td>4</td>
<td>15</td>
</tr>
<tr>
<td>5.</td>
<td>5</td>
<td>15</td>
</tr>
</tbody>
</table>
   +------------------+
```
Technical note

The definitions and formulas used by these functions are the same as those used by `summarize`; see [R] `summarize`. For comparison with `summarize`, `mean()` and `sd()` correspond to the mean and standard deviation. `total()` is the numerator of the mean, and `count()` is its denominator. `min()` and `max()` correspond to the minimum and maximum. `median()`—or, equally well, `pctile()` with `p(50)`—is the median. `pctile()` with `p(5)` refers to the fifth percentile, and so on. `iqr()` is the difference between the 75th and 25th percentiles.

The mode is the most common value of a dataset, whether it contains numeric or string variables. It is perhaps most useful for categorical variables (whether defined by integers or strings) or for other integer-valued values, but `mode()` can be applied to variables of any type. Nevertheless, the modes of continuous (or nearly continuous) variables are perhaps better estimated either from inspection of a graph of a frequency distribution or from the results of some density estimation (see [R] `kdensity`).

Missing values need special attention. It is possible that missing is the most common value in a variable (whether missing is defined by the period `[.]` or extended missing values `[.a, .b, ..., .z]` for numeric variables or the empty string `""` for string variables). However, missing values are by default excluded from determination of modes. If you wish to include them, use the `missing` option.

In contrast, `egen mode = mode(varname)` allows the generation of nonmissing modes for observations for which `varname` is missing. This allows use of the mode as one simple means of imputing categorical variables. If you want the mode to be missing whenever `varname` is missing, you can specify `if varname < .` or `if varname != ""` or, most generally, `if !missing(varname)`.

`mad()` and `mdev()` produce alternative measures of spread. The median absolute deviation from the median and even the mean deviation will both be more resistant than the standard deviation to heavy tails or outliers, in particular from distributions with heavier tails than the normal or Gaussian. The first measure was named the MAD by Andrews et al. (1972) but was already known to K. F. Gauss in 1816, according to Hampel et al. (1986). For more historical and statistical details, see David (1998) and Wilcox (2003, 72–73).

Generating patterns

To create a sequence of numbers, simply “show” the `fill()` function how the sequence should look. It must be a linear progression to produce the expected results. Stata does not understand geometric progressions. To produce repeating patterns, you present `fill()` with the pattern twice in the `numlist`.

Example 3: Sequences produced by `fill()`

Here are some examples of ascending and descending sequences produced by `fill()`:

```
. clear
. set obs 12
    obs was 0, now 12
. egen i=fill(1 2)
. egen w=fill(100 99)
. egen x=fill(22 17)
. egen y=fill(1 1 2 2)
. egen z=fill(8 8 8 7 7)
```
Example 4: Patterns produced by `fill()`

Here are examples of patterns produced by `fill()`:

```
. clear
. set obs 12
obs was 0, now 12
. egen a=fill(0 0 1 0 0 1)
. egen b=fill(1 3 8 1 3 8)
. egen c=fill(-3(3)6 -3(3)6)
. egen d=fill(10 20 to 50 10 20 to 50)
. list, sep(4)
```

```
a  b  c  d
1. 0 1 -3 10
2. 0 3  0 20
3. 1 8  3 30
4. 0 1  6 40
5. 0 3 -3 50
6. 1 8  0 10
7. 0 1  3 20
8. 0 3  6 30
9. 1 8 -3 40
10. 0 1  0 50
11. 0 3  3 10
12. 1 8  6 20
```
Example 5: seq()

seq() creates a new variable containing one or more sequences of integers. It is useful mainly for quickly creating observation identifiers or automatically numbering levels of factors or categorical variables.

. clear
. set obs 12

In the simplest case,

. egen a = seq()

is just equivalent to the common idiom

. generate a = _n

a may also be obtained from

. range a 1 _N

(the actual value of _N may also be used).

In more complicated cases, seq() with option calls is equivalent to calls to the versatile functions int and mod.

. egen b = seq(), b(2)

produces integers in blocks of 2, whereas

. egen c = seq(), t(6)

restarts the sequence after 6 is reached.

. egen d = seq(), f(10) t(12)

shows that sequences may start with integers other than 1, and

. egen e = seq(), f(3) t(1)

shows that they may decrease.

The results of these commands are shown by

. list, sep(4)

<table>
<thead>
<tr>
<th></th>
<th>a</th>

</tr>
<tr>
<td>12.</td>
<td>12</td>
<td>6</td>
<td>6</td>
<td>12</td>
<td>1</td>
</tr>
</tbody>
</table>
All of these sequences could have been generated in one line with `generate` and with the use of the `int` and `mod` functions. The variables b through e are obtained with

```stata
. gen b = 1 + int(_n - 1)/2
. gen c = 1 + mod(_n - 1, 6)
. gen d = 10 + mod(_n - 1, 3)
. gen e = 3 - mod(_n - 1, 3)
```

Nevertheless, `seq()` may save users from puzzling out such solutions or from typing in the needed values.

In general, the sequences produced depend on the sort order of observations, following three rules:
1. observations excluded by `if` or `in` are not counted;
2. observations are sorted by `varlist`, if specified; and
3. otherwise, the order is that specified when `seq()` is called.

The `fill()` and `seq()` functions are alternatives. In essence, `fill()` requires a minimal example that indicates the kind of sequence required, whereas `seq()` requires that the rule be specified through options. There are sequences that `fill()` can produce that `seq()` cannot, and vice versa. `fill()` cannot be combined with `if` or `in`, in contrast to `seq()`, which can.

### Marking differences among variables

#### Example 6: `diff()`

We have three measures of respondents’ income obtained from different sources. We wish to create the variable `differ` equal to 1 for disagreements:

```stata
. use http://www.stata-press.com/data/r13/egenxmpl3, clear
. egen byte differ = diff(inc*)
. list if differ==1
```

<table>
<thead>
<tr>
<th></th>
<th>inc1</th>
<th>inc2</th>
<th>inc3</th>
<th>id</th>
<th>differ</th>
</tr>
</thead>
<tbody>
<tr>
<td>10.</td>
<td>42,491</td>
<td>41,491</td>
<td>41,491</td>
<td>110</td>
<td>1</td>
</tr>
<tr>
<td>11.</td>
<td>26,075</td>
<td>25,075</td>
<td>25,075</td>
<td>111</td>
<td>1</td>
</tr>
<tr>
<td>12.</td>
<td>26,283</td>
<td>25,283</td>
<td>25,283</td>
<td>112</td>
<td>1</td>
</tr>
<tr>
<td>78.</td>
<td>41,780</td>
<td>41,780</td>
<td>41,880</td>
<td>178</td>
<td>1</td>
</tr>
<tr>
<td>100.</td>
<td>25,687</td>
<td>26,687</td>
<td>25,687</td>
<td>200</td>
<td>1</td>
</tr>
<tr>
<td>101.</td>
<td>25,359</td>
<td>26,359</td>
<td>25,359</td>
<td>201</td>
<td>1</td>
</tr>
<tr>
<td>102.</td>
<td>25,969</td>
<td>26,969</td>
<td>25,969</td>
<td>202</td>
<td>1</td>
</tr>
<tr>
<td>103.</td>
<td>25,339</td>
<td>26,339</td>
<td>25,339</td>
<td>203</td>
<td>1</td>
</tr>
<tr>
<td>104.</td>
<td>25,296</td>
<td>26,296</td>
<td>25,296</td>
<td>204</td>
<td>1</td>
</tr>
<tr>
<td>105.</td>
<td>41,800</td>
<td>41,000</td>
<td>41,000</td>
<td>205</td>
<td>1</td>
</tr>
<tr>
<td>134.</td>
<td>26,233</td>
<td>26,233</td>
<td>26,133</td>
<td>234</td>
<td>1</td>
</tr>
</tbody>
</table>

Rather than typing `diff(inc*)`, we could have typed `diff(inc1 inc2 inc3)`.
Ranks

➢ Example 7: rank()

Most applications of rank() will be to one variable, but the argument exp can be more general, namely, an expression. In particular, rank(-varname) reverses ranks from those obtained by rank(varname).

The default ranking and those obtained by using one of the track, field, and unique options differ principally in their treatment of ties. The default is to assign the same rank to tied values such that the sum of the ranks is preserved. The track option assigns the same rank but resembles the convention in track events; thus, if one person had the lowest time and three persons tied for second-lowest time, their ranks would be 1, 2, 2, and 2, and the next person(s) would have rank 5. The field option acts similarly except that the highest is assigned rank 1, as in field events in which the greatest distance or height wins. The unique option breaks ties arbitrarily: its most obvious use is assigning ranks for a graph of ordered values. See also group() for another kind of “ranking”.

. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. keep in 1/10
(64 observations deleted)
. egen rank = rank(mpg)
. egen rank_r = rank(-mpg)
. egen rank_f = rank(mpg), field
. egen rank_t = rank(mpg), track
. egen rank_u = rank(mpg), unique
. egen rank_ur = rank(-mpg), unique
. sort rank_u
. list mpg rank*

<table>
<thead>

</tr>
</tbody>
</table>

Standardized variables

➢ Example 8: std()

We have a variable called age recording the median age in the 50 states. We wish to create the standardized value of age and verify the calculation:
# egen — Extensions to generate

```
. use http://www.stata-press.com/data/r13/states1, clear
  (State data)
. egen stdage = std(age)
. summarize age stdage

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>age</td>
<td>50</td>
<td>29.54</td>
<td>1.693445</td>
<td>24.2</td>
<td>34.7</td>
</tr>
<tr>
<td>stdage</td>
<td>50</td>
<td>6.41e-09</td>
<td>1 -3.153336</td>
<td>3.047044</td>
<td></td>
</tr>
</tbody>
</table>
```

```
. correlate age stdage
  (obs=50)

<table>
<thead>
<tr>
<th></th>
<th>age</th>
<th>stdage</th>
</tr>
</thead>
<tbody>
<tr>
<td>age</td>
<td>1.0000</td>
<td>1.0000</td>
</tr>
<tr>
<td>stdage</td>
<td>1.0000</td>
<td>1.0000</td>
</tr>
</tbody>
</table>
```

`summarize` shows that the new variable has a mean of approximately zero; $10^{-9}$ is the precision of a float and is close enough to zero for all practical purposes. If we wanted, we could have typed `egen double stdage = std(age)`, making `stdage` a double-precision variable, and the mean would have been $10^{-16}$. In any case, `summarize` also shows that the standard deviation is 1. `correlate` shows that the new variable and the original variable are perfectly correlated.

We may optionally specify the mean and standard deviation for the new variable. For instance,

```
. egen newage1 = std(age), std(2)
. egen newage2 = std(age), mean(2) std(4)
. egen newage3 = std(age), mean(2)
. summarize age newage1-newage3
```

```
<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>age</td>
<td>50</td>
<td>29.54</td>
<td>1.693445</td>
<td>24.2</td>
<td>34.7</td>
</tr>
<tr>
<td>newage1</td>
<td>50</td>
<td>1.28e-08</td>
<td>2 -6.306671</td>

<td></td>
</tr>
<tr>
<td>newage2</td>
<td>50</td>
<td>2</td>
<td>4 -10.61334</td>
<td>14.18818</td>
<td></td>
</tr>
<tr>
<td>newage3</td>
<td>50</td>
<td>2</td>
<td>1 -1.153336</td>
<td>5.047044</td>
<td></td>
</tr>
</tbody>
</table>
```

```
. correlate age newage1-newage3
  (obs=50)

<table>
<thead>
<tr>
<th></th>
<th>age</th>
<th>newage1</th>
<th>newage2</th>
<th>newage3</th>
</tr>
</thead>
<tbody>
<tr>
<td>age</td>
<td>1.0000</td>
<td>1.0000</td>
<td>1.0000</td>
<td>1.0000</td>
</tr>
<tr>
<td>newage1</td>

## Row functions

> **Example 9: rowtotal( )**

`generate`’s `sum()` function creates the vertical, running sum of its argument, whereas `egen`’s `total()` function creates a constant equal to the overall sum. `egen`’s `rowtotal()` function, however, creates the horizontal sum of its arguments. They all treat missing as zero. However, if the `missing` option is specified with `total()` or `rowtotal()`, then `newvar` will contain missing values if all values of `exp` or `varlist` are missing.
. use http://www.stata-press.com/data/r13/egenxmpl4, clear
. egen hsum = rowtotal(a b c)
. generate vsum = sum(hsum)
. egen sum = total(hsum)
. list

<table>
<thead>
<tr>
<th>a</th>
<th>b</th>
<th>c</th>
<th>hsum</th>
<th>vsum</th>
<th>sum</th>
</tr>
</thead>
<tbody>

</tr>
<tr>
<td>4.</td>
<td>10</td>
<td>11</td>
<td>12</td>
<td>33</td>
<td>63</td>
</tr>
</tbody>
</table>

Example 10: rowmean(), rowmedian(), rowpctile(), rowsd(), and rownonmiss()

summarize displays the mean and standard deviation of a variable across observations; program writers can access the mean in r(mean) and the standard deviation in r(sd) (see [R] summarize). egen’s rowmean() function creates the means of observations across variables. rowmedian() creates the medians of observations across variables. rowpctile() returns the #th percentile of the variables specified in varlist. rowsd() creates the standard deviations of observations across variables. rownonmiss() creates a count of the number of nonmissing observations, the denominator of the rowmean() calculation:

. use http://www.stata-press.com/data/r13/egenxmpl4, clear
. egen avg = rowmean(a b c)
. egen median = rowmedian(a b c)
. egen pct25 = rowpctile(a b c), p(25)
. egen std = rowsd(a b c)
. egen n = rownonmiss(a b c)
. list

<table>
<thead>
<tr>
<th>a</th>
<th>b</th>
<th>c</th>
<th>avg</th>
<th>median</th>
<th>pct25</th>
<th>std</th>
<th>n</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>.</td>
<td>2</td>
<td>3</td>
<td>2.5</td>
<td>2.5</td>
<td>.7071068</td>
<td>2</td>
</tr>
<tr>
<td>2.</td>
<td>4</td>
<td>.</td>
<td>6</td>
<td>5</td>
<td>5</td>
<td>1.414214</td>
<td>2</td>
</tr>
<tr>
<td>3.</td>
<td>7</td>
<td>8</td>
<td>.</td>
<td>7.5</td>
<td>7.5</td>
<td>.7071068</td>
<td>2</td>
</tr>
<tr>
<td>4.</td>
<td>10</td>
<td>11</td>
<td>12</td>
<td>11</td>
<td>11</td>
<td>10</td>
<td>1</td>
</tr>
</tbody>
</table>
Example 11: rowmiss()

`rowmiss()` returns \( k - \text{rownonmiss}() \), where \( k \) is the number of variables specified. `rowmiss()` can be especially useful for finding casewise-deleted observations caused by missing values.

```
use http://www.stata-press.com/data/r13/auto3, clear
(1978 Automobile Data)
correlate price weight mpg
(obs=70)

<table>
<thead>
<tr>
<th></th>
<th>price</th>

</tbody>
</table>
Categorical and integer variables

Example 13: anyvalue(), anymatch(), and anycount()

anyvalue(), anymatch(), and anycount() are for categorical or other variables taking integer values. If we define a subset of values specified by an integer numlist (see [U] 11.1.8 numlist), anyvalue() extracts the subset, leaving every other value missing; anymatch() defines an indicator variable (1 if in subset, 0 otherwise); and anycount() counts occurrences of the subset across a set of variables. Therefore, with just one variable, anymatch(varname) and anycount(varname) are equivalent.

With the auto dataset, we can generate a variable containing the high values of rep78 and a variable indicating whether rep78 has a high value:

```
. use http://www.stata-press.com/data/r13/auto, clear
  (1978 Automobile Data)
. egen hirep = anyvalue(rep78), v(3/5)
  (15 missing values generated)
. egen ishirep = anymatch(rep78), v(3/5)
```

Here it is easy to produce the same results with official Stata commands:

```
. generate hirep = rep78 if inlist(rep78,3,4,5)
. generate byte ishirep = inlist(rep78,3,4,5)
```

However, as the specification becomes more complicated or involves several variables, the egen functions may be more convenient.

Example 14: group()

group() maps the distinct groups of a varlist to a categorical variable that takes on integer values from 1 to the total number of groups. order of the groups is that of the sort order of varlist. The varlist may be of numeric variables, string variables, or a mixture of the two. The resulting variable can be useful for many purposes, including stepping through the distinct groups easily and systematically and cleaning up an untidy ordering. Suppose that the actual (and arbitrary) codes present in the data are 1, 2, 4, and 7, but we desire equally spaced numbers, as when the codes will be values on one axis of a graph. group() maps these to 1, 2, 3, and 4.

We have a variable agegrp that takes on the values 24, 40, 50, and 65, corresponding to age groups 18–24, 25–40, 41–50, and 51 and above. Perhaps we created this coding using the recode() function (see [U] 13.3 Functions and [U] 25 Working with categorical data and factor variables) from another age-in-years variable:

```
. generate agegrp=recode(age,24,40,50,65)
```

We now want to change the codes to 1, 2, 3, and 4:

```
. egen agegrp2 = group(agegrp)
```
Example 15: `group()` with missing values

We have two categorical variables, `race` and `sex`, which may be string or numeric. We want to use `ir` (see [ST] `epitab`) to create a Mantel–Haenszel weighted estimate of the incidence rate. `ir`, however, allows only one variable to be specified in its `by()` option. We type

```
. use http://www.stata-press.com/data/r13/egenxmpl6, clear
. egen racesex = group(race sex)
   (2 missing values generated)
. ir deaths smokes pyears, by(racesex)
   (output omitted)
```

The new numeric variable, `racesex`, will be missing wherever `race` or `sex` is missing (meaning `.` for numeric variables and `""` for string variables), so missing values will be handled correctly. When we list some of the data, we see

```
. list race sex racesex in 1/7, sep(0)
race   sex   racesex
1. White   Female   1
2. White      Male   2
3. Black   Female   3
4. Black       Male   4
5. Black      Male   4
6.      .  Female  .
7.  Black      .     5
```

`group()` began by putting the data in the order of the grouping variables and then assigned the numeric codes. Observations 6 and 7 were assigned to `racesex==.` because, in one case, `race` was not known, and in the other, `sex` was not known. (These observations were not used by `ir`.)

If we wanted the unknown groups to be treated just as any other category, we could have typed

```
. egen rs2=group(race sex), missing
. list race sex rs2 in 1/7, sep(0)
race   sex   rs2
1. White   Female   1
2. White      Male   2
3. Black   Female   3
4. Black       Male   4
5. Black      Male   4
6.      .  Female  6
7.  Black      .     5
```

The resulting variable from `group()` does not have value labels. Therefore, the values carry no indication of meaning. Interpretation requires comparison with the original `varlist`.

The `label` option produces a categorical variable with value labels. These value labels are either the actual values of `varname` or any value labels of `varname`, if they exist. The values of `varname` could be as long as those of one `str2045` variable, but value labels may be no longer than 80 characters.
String variables

Concatenation of string variables is provided in Stata. In context, Stata understands the addition symbol `+` as specifying concatenation or adding strings end to end. "soft" + "ware" produces "software", and given string variables `s1` and `s2`, `s1 + s2` indicates their concatenation.

The complications that may arise in practice include wanting 1) to concatenate the string versions of numeric variables and 2) to concatenate variables, together with some separator such as a space or a comma. Given numeric variables `n1` and `n2`,

```
. generate newstr = s1 + string(n1) + string(n2) + s2
```

shows how numeric values may be converted to their string equivalents before concatenation, and

```
. generate newstr = s1 + " " + s2 + " " + s3
```

shows how spaces may be added between variables. Stata will automatically assign the most appropriate data type for the new string variables.

Example 16: `concat()`

`concat()` allows us to do everything in one line concisely.

```
. egen newstr = concat(s1 n1 n2 s2)
```

carries with it an implicit instruction to convert numeric values to their string equivalents, and the appropriate string data type is worked out within `concat()` by Stata’s automatic promotion. Moreover,

```
. egen newstr = concat(s1 s2 s3), p(" ")
```

specifies that spaces be used as separators. (The default is to have no separation of concatenated strings.)

As an example of punctuation other than a space, consider

```
. egen fullname = concat(surname forename), p("", ")
```

Noninteger numerical values can cause difficulties, but

```
. egen newstr = concat(n1 n2), format(%9.3f) p(" ")
```

specifies the use of format `%9.3f`. This is equivalent to

```
. generate str1 newstr = ""
. replace newstr = string(n1,"%9.3f") + " " + string(n2,"%9.3f")
```

See [D] functions for more about `string()`.

As a final flourish, the `decode` option instructs `concat()` to use value labels. With that option, the `maxlength()` option may also be used. For more details about `decode`, see [D] `encode`. Unlike the `decode` command, however, `concat()` uses `string(varname)`, not " ", whenever values of `varname` are not associated with value labels, and the `format()` option, whenever specified, applies to this use of `string()`.

Example 17: `ends()`

The `ends(strvar)` function is used for subdividing strings. The approach is to find specified separators by using the `strpos()` string function and then to extract what is desired, which either precedes or follows the separators, using the `substr()` string function.
By default, substrings are considered to be separated by individual spaces, so we will give definitions in those terms and then generalize.

The head of the string is whatever precedes the first space or is the whole of the string if no space occurs. This could also be called the first “word”. The tail of the string is whatever follows the first space. This could be nothing or one or more words. The last word in the string is whatever follows the last space or is the whole of the string if no space occurs.

To clarify, let’s look at some examples. The quotation marks here just mark the limits of each string and are not part of the strings.

<table>
<thead>
<tr>
<th></th>
<th>head</th>
<th>tail</th>
<th>last</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;frog&quot;</td>
<td>&quot;frog&quot;</td>
<td>&quot;&quot;</td>
<td>&quot;frog&quot;</td>
</tr>
<tr>
<td>&quot;frog toad&quot;</td>
<td>&quot;frog&quot;</td>
<td>&quot;toad&quot;</td>
<td>&quot;toad&quot;</td>
</tr>
<tr>
<td>&quot;frog toad newt&quot;</td>
<td>&quot;frog&quot;</td>
<td>&quot;toad newt&quot;</td>
<td>&quot;newt&quot;</td>
</tr>
<tr>
<td>&quot;frog toad newt&quot;</td>
<td>&quot;frog&quot;</td>
<td>&quot;toad newt&quot;</td>
<td>&quot;newt&quot;</td>
</tr>
<tr>
<td>&quot;frog toad newt&quot;</td>
<td>&quot;frog&quot;</td>
<td>&quot;toad newt&quot;</td>
<td>&quot;newt&quot;</td>
</tr>
</tbody>
</table>

The main subtlety is that these functions are literal, so the tail of "frog toad newt", in which two spaces follow "frog", includes the second of those spaces, and is thus " toad newt". Therefore, you may prefer to use the trim option to trim the result of any leading or trailing spaces, producing "toad newt" in this instance.

The punct(pchars) option may be used to specify separators other than spaces. The general definitions of the head, tail, and last options are therefore interpreted in terms of whatever separator has been specified; that is, they are relative to the first or last occurrence of the separator in the string value. Thus, with punct(.) and the string "Darwin, Charles Robert", the head is "Darwin", and the tail and the last are both " Charles Robert". Note again the leading space in this example, which may be trimmed with trim. The punctuation (here the comma, ",") is discarded, just as it is with one space.

pchars, the argument of punct(), will usually, but not always, be one character. If two or more characters are specified, these must occur together; for example, punct(:;) would mean that words are separated by a colon followed by a semicolon (that is, ;:). It is not implied, in particular, that the colon and semicolon are alternatives. To do that, you would have to modify the programs presented here or resort to first principles by using split; see [D] split.

With personal names, the head or last option might be applied to extract surnames if strings were similar to "Darwin, Charles Robert" or "Charles Robert Darwin", with the surname coming first or last. What then happens with surnames like "von Neumann" or "de la Mare"? "von Neumann, John" is no problem, if the comma is specified as a separator, but the last option is not intelligent enough to handle "Walter de la Mare" properly. For that, the best advice is to use programs specially written for person-name extraction, such as extrname (Gould 1993).

U.S. marginal income tax rate

mtr(year income) (Schmidt 1993, 1994) returns the U.S. marginal income tax rate for a married couple with taxable income income in year year, where 1930 ≤ year ≤ 2013.
Schmidt (1993) examines the change in the progressivity of the U.S. tax schedule over the period from 1930 to 1990. As a measure of progressivity, he calculates the difference in the marginal tax rates at the 75th and 25th percentiles of income, using a dataset of percentiles of taxable income developed by Hakkio, Rush, and Schmidt (1996). (Certain aspects of the income distribution are imputed in these data.) A subset of the data contains the following:

```
. describe
Contains data from income1.dta
obs: 61                              12 Feb 2013 03:33
vars: 4
size: 1,020

storage  display value
variable name type format label variable label

  year    float  %9.0g  Year
  inc25   float  %9.0g  25th percentile
  inc50   float  %9.0g  50th percentile
  inc75   float  %9.0g  75th percentile

Sorted by:
```

```
. summarize
Variable       Obs   Mean    Std. Dev.   Min    Max
  year          61   1960   17.75293    1930   1990
  inc25         61  6948.272  6891.921    819.4  27227.35
  inc50         61 11645.15  11550.71   1373.29  45632.43
  inc75         61 18166.43  18019.1   2142.33  71186.58
```

Given the series for income and the four-digit year, we can generate the marginal tax rates corresponding to the 25th and 75th percentiles of income:

```
. egen mtr25 = mtr(year inc25)
. egen mtr75 = mtr(year inc75)
. summarize mtr25 mtr75
```

Methods and formulas

Stata users have written many extra functions for `egen`. Type `net search egen` to locate Internet sources of programs.

Acknowledgments

The `mtr()` function of `egen` was written by Timothy J. Schmidt of the Federal Reserve Bank of Kansas City.
The `cut()` function was written by David Clayton of the Cambridge Institute for Medical Research and Michael Hills (retired) of the London School of Hygiene and Tropical Medicine (1999a, 1999b, 1999c).

Many of the other `egen` functions were written by Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal*.
