Syntax

String variable to numeric variable

```
\underline{en}code varname [if] [in], \underline{g}enerate(newvar) [\underline{l}abel(name) \underline{noe}xtend]
```

Numeric variable to string variable

```
\underline{\text{dec}}ode varname \ [if] \ [in], \underline{\text{generate}}(newvar) \ [\underline{\text{maxlength}}(\#)]
```

Menu

encode

Data > Create or change data > Other variable-transformation commands > Encode value labels from string variable

decode

Data > Create or change data > Other variable-transformation commands > Decode strings from labeled numeric variable

Description

encode creates a new variable named *newvar* based on the string variable *varname*, creating, adding to, or just using (as necessary) the value label *newvar* or, if specified, *name*. Do not use encode if *varname* contains numbers that merely happen to be stored as strings; instead, use generate *newvar* = real(*varname*) or destring; see [U] 23.2 Categorical string variables, *String functions* in [D] functions, and [D] destring.

decode creates a new string variable named *newvar* based on the "encoded" numeric variable *varname* and its value label.

Options for encode

generate(newvar) is required and specifies the name of the variable to be created.

label(name) specifies the name of the value label to be created or used and added to if the named
value label already exists. If label() is not specified, encode uses the same name for the label
as it does for the new variable.

noextend specifies that *varname* not be encoded if there are values contained in *varname* that are not present in label(*name*). By default, any values not present in label(*name*) will be added to that label.

Options for decode

generate(newvar) is required and specifies the name of the variable to be created.

maxlength(#) specifies how many characters of the value label to retain; # must be between 1 and 2045. The default is maxlength(2045).

Remarks and examples

stata.com

Remarks are presented under the following headings:

encode decode

encode

encode is most useful in making string variables accessible to Stata's statistical routines, most of which can work only with numeric variables. encode is also useful in reducing the size of a dataset. If you are not familiar with value labels, read [U] 12.6.3 Value labels.

The maximum number of associations within each value label is 65,536 (1,000 for Small Stata). Each association in a value label maps a string of up to 2045 characters to a number. If your string has entries longer than that, only the first 2045 characters are retained and are significant.

Example 1

We have a dataset on high blood pressure, and among the variables is sex, a string variable containing either "male" or "female". We wish to run a regression of high blood pressure on race, sex, and age group. We type regress hbp race sex age_grp and get the message "no observations".

- . use http://www.stata-press.com/data/r13/hbp2
- . regress hbp sex race age_grp no observations r(2000);

Stata's statistical procedures cannot directly deal with string variables; as far as they are concerned, all observations on sex are missing. encode provides the solution:

- . encode sex, gen(gender)
- . regress hbp gender race age_grp

Source	SS	df		MS		Number of obs = F(3, 1117) =	1121 15.15
Model Residual	2.01013476 49.3886164	3 1117		004492 215413		Prob > F = 0 R-squared = 0	0.0000 0.0391 0.0365
Total	51.3987511	1120	.045	891742			.21027
hbp	Coef.	Std.	Err.	t	P> t	[95% Conf. Int	erval]
gender	.0394747	.0130	022	3.04	0.002	.0139633 .0	649861
race	0409453	.0113	721	-3.60	0.000	06325840	186322
age_grp	.0241484	.00	624	3.87	0.000	.0119049 .03	363919
_cons	016815	.0389	167	-0.43	0.666	093173 .	059543

encode looks at a string variable and makes an internal table of all the values it takes on, here "male" and "female". It then alphabetizes that list and assigns numeric codes to each entry. Thus 1 becomes "female" and 2 becomes "male". It creates a new int variable (gender) and substitutes a 1 where sex is "female", a 2 where sex is "male", and a missing (.) where sex is null (""). It creates a value label (also named gender) that records the mapping $1 \leftrightarrow \text{female}$ and $2 \leftrightarrow \text{male}$. Finally, encode labels the values of the new variable with the value label.

Example 2

It is difficult to distinguish the result of encode from the original string variable. For instance, in our last two examples, we typed encode sex, gen(gender). Let's compare the two variables:

. list sex gender in 1/4

	sex	gender
1.	female	female
2. 3.	male	male
4.	male	male

They look almost identical, although you should notice the missing value for gender in the second observation.

The difference does show, however, if we tell list to ignore the value labels and show how the data really appear:

. list sex gender in 1/4, nolabel

	sex	gender
1. 2.	female	1
3.	male	2
4.	male	2

We could also ask to see the underlying value label:

. label list gender gender:

1 female 2 male

gender really is a numeric variable, but because all Stata commands understand value labels, the variable displays as "male" and "female", just as the underlying string variable sex would.

Example 3

We can drastically reduce the size of our dataset by encoding strings and then discarding the underlying string variable. We have a string variable, sex, that records each person's sex as "male" and "female". Because female has six characters, the variable is stored as a str6.

We can encode the sex variable and use compress to store the variable as a byte, which takes only 1 byte. Because our dataset contains 1,130 people, the string variable takes 6,780 bytes, but the encoded variable will take only 1,130 bytes.

1

- . use http://www.stata-press.com/data/r13/hbp2, clear
- . describe

Contains data from http://www.stata-press.com/data/r13/hbp2.dta

obs: 1,130 vars: 7 size: 24,860

3 Mar 2013 06:47

variable name	storage type	display format	value label	variable label
id city year	str10 byte int	%10s %8.0g %8.0g		Record identification number
age_grp race	byte byte	%8.0g %8.0g	${\tt agefmt} \\ {\tt racefmt}$	
hbp sex	byte str6	%8.0g %9s	yn	high blood pressure

Sorted by:

- . encode sex, generate(gender)
- . list sex gender in 1/5

	sex	gender
1.	female	female
2. 3.	male	$_{ t male}$
4.	male	male
5.	female	female

- . drop sex
- . rename gender sex
- . compress
 sex was long now byte
 (3,390 bytes saved)
- . describe

Contains data from http://www.stata-press.com/data/r13/hbp2.dta

obs: 1,130 vars: 7 size: 19,210

3 Mar 2013 06:47

variable name	storage type	display format	value label	variable label
id city year age_grp race	str10 byte int byte byte	%10s %8.0g %8.0g %8.0g %8.0g	agefmt racefmt	Record identification number
hbp sex	byte byte	%8.0g %8.0g	yn gender	high blood pressure

Sorted by:

Note: dataset has changed since last saved

The size of our dataset has fallen from 24,860 bytes to 19,210 bytes.

□ Technical note

In the examples above, the value label did not exist before encode created it, because that is not required. If the value label does exist, encode uses your encoding as far as it can and adds new mappings for anything not found in your value label. For instance, if you wanted "female" to be encoded as 0 rather than 1 (possibly for use in linear regression), you could type

- . label define gender 0 "female"
- . encode sex, gen(gender)

You can also specify the name of the value label. If you do not, the value label is assumed to have the same name as the newly created variable. For instance,

- . label define sex1bl 0 "female"
- . encode sex, gen(gender) label(sexlbl)

decode

decode is used to convert numeric variables with associated value labels into true string variables.

Example 4

We have a numeric variable named female that records the values 0 and 1. female is associated with a value label named sexlbl that says that 0 means male and 1 means female:

- . use http://www.stata-press.com/data/r13/hbp3, clear
- . describe female

variable name	storage type	display format	value label	variable label	
female	byte	%8.0g	sexlbl		
. label list sexlbl:	sexlbl				
0 :	male				
1	female				

We see that female is stored as a byte. It is a numeric variable. Nevertheless, it has an associated value label describing what the numeric codes mean, so if we tabulate the variable, for instance, it appears to contain the strings "male" and "female":

. tabulate female

Cum.	Percent	Freq.	female
61.61 100.00	61.61 38.39	695 433	male female
	100.00	1,128	Total

We can create a real string variable from this numerically encoded variable by using decode:

- . decode female, gen(sex)
- . describe sex

variable name	0	display format	variable label	
sex	str6	%9s		

We have a new variable called sex. It is a string, and Stata automatically created the shortest possible string. The word "female" has six characters, so our new variable is a str6. female and sex appear indistinguishable:

. list female sex in 1/4

female	sex
female	female
male male	male male
	female . male

But when we add nolabel, the difference is apparent:

. list female sex in 1/4, nolabel

	female	sex
1. 2.	1	female
3.	. 0	male
4.	0	male
	i	

Example 5

decode is most useful in instances when we wish to match-merge two datasets on a variable that has been encoded inconsistently.

For instance, we have two datasets on individual states in which one of the variables (state) takes on values such as "CA" and "NY". The state variable was originally a string, but along the way the variable was encoded into an integer with a corresponding value label in one or both datasets.

We wish to merge these two datasets, but either 1) one of the datasets has a string variable for state and the other an encoded variable or 2) although both are numeric, we are not certain that the codings are consistent. Perhaps "CA" has been coded 5 in one dataset and 6 in another.

Because decode will take an encoded variable and turn it back into a string, decode provides the solution:

```
(load the first dataset)
use first
decode state, gen(st)
                                 (make a string state variable)
                                 (discard the encoded variable)
drop state
                                 (sort on string)
sort st
save first, replace
                                 (save the dataset)
use second
                                 (load the second dataset)
                                 (make a string variable)
decode state, gen(st)
                                (discard the encoded variable)
drop state
sort st
                                 (sort on string)
merge 1:1 st using first
                                (merge the data)
```
