A well-known result is that if we define the matrix \(S_0\) to be the covariance of \(z_iu_i\) and set \(W = S_0^{-1}\), then we obtain the optimal two-step GMM estimator, where by optimal estimator we mean the one that results in the smallest variance given the moment conditions defined in (3).

Suppose that the errors \(u_i\) are heteroskedastic but independent among observations. Then

\[
S_0 = E(z_iu_iu_i^\prime) = E(u_i^2z_i^2) \tag{6}
\]

and the sample analogue is

\[
\hat{S} = \frac{1}{N} \sum \hat{u}_i^2z_i^2 \tag{6}
\]

To implement this estimator, we need estimates of the sample residuals \(\hat{u}_i\). \text{ivregress gmm} obtains the residuals by estimating \(\beta_1\) and \(\beta_2\) by 2SLS and then evaluates (6) and sets \(W = \hat{S}^{-1}\). Equation (6) is the same as the center term of the “sandwich” robust covariance matrix available from most Stata estimation commands through the \(\text{vce(robust)}\) option.

### Example 3: GMM estimator

Here we refit our model of rents by using the GMM estimator, allowing for heteroskedasticity in \(u_i\):

```
. ivregress gmm rent pcturban (hsngval = faminc i.region), wmatrix(robust)
```

```
Instrumental variables (GMM) regression
Number of obs = 50
Wald chi2(2) = 112.09
Prob > chi2 = 0.0000
R-squared = 0.6616
GMM weight matrix: Robust
Root MSE = 20.358

</tbody>
</table>

Instrumented: hsngval
Instruments: pcturban faminc 2.region 3.region 4.region
```

Because we requested that a heteroskedasticity-consistent weighting matrix be used during estimation but did not specify the \(\text{vce()}\) option, \text{ivregress} reported standard errors that are robust to heteroskedasticity. Had we specified \(\text{vce(unadjusted)}\), we would have obtained standard errors that would be correct only if the weighting matrix \(W\) does in fact converge to \(S_0^{-1}\).
Technical note

Many software packages that implement GMM estimation use the same heteroskedasticity-consistent weighting matrix we used in the previous example to obtain the optimal two-step estimates but do not use a heteroskedasticity-consistent VCE, even though they may label the standard errors as being “robust”. To replicate results obtained from other packages, you may have to use the vce(unadjusted) option. See Methods and formulas below for a discussion of robust covariance matrix estimation in the GMM framework.

By changing our definition of $S_0$, we can obtain GMM estimators suitable for use with other types of data that violate the assumption that the errors are independent and identically distributed. For example, you may have a dataset that consists of multiple observations for each person in a sample. The observations that correspond to the same person are likely to be correlated, and the estimation technique should account for that lack of independence. Say that in your dataset, people are identified by the variable personid and you type

```
.ivregress gmm ..., wmatrix(cluster personid)
```

Here `ivregress` estimates $S_0$ as

$$
\hat{S} = \frac{1}{N} \sum_{c \in C} q_c q_c' 
$$

where $C$ denotes the set of clusters and

$$
q_c = \sum_{i \in c_j} \hat{u}_i z_i 
$$

where $c_j$ denotes the $j$th cluster. This weighting matrix accounts for the within-person correlation among observations, so the GMM estimator that uses this version of $S_0$ will be more efficient than the estimator that ignores this correlation.

Example 4: GMM estimator with clustering

We have data from the National Longitudinal Survey on young women’s wages as reported in a series of interviews from 1968 through 1988, and we want to fit a model of wages as a function of each woman’s age and age squared, job tenure, birth year, and level of education. We believe that random shocks that affect a woman’s wage also affect her job tenure, so we treat tenure as endogenous. As additional instruments, we use her union status, number of weeks worked in the past year, and a dummy indicating whether she lives in a metropolitan area. Because we have several observations for each woman (corresponding to interviews done over several years), we want to control for clustering on each person.
. use http://www.stata-press.com/data/r13/nlswork
(National Longitudinal Survey. Young Women 14–26 years of age in 1968)
. ivregress gmm ln_wage age c.age#c.age birth_yr grade > (tenure = union wks_work msp), wmatrix(cluster idcode)

Instrumental variables (GMM) regression

| Variable  | Coef.  | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|-----------|--------|-----------|-------|------|----------------------|
| ln_wage   | .099221| .003776   | 26.27 | 0.000| .0918194 – .1066227 |
| tenure    | .017115| .006689   | 2.56  | 0.011| .0040034 – .0302259 |
| age       | -.000519| .000111| -4.68 | 0.000| -.0007366 – -.0003016|
| c.age#c.age| -.008599| .002193 | -3.92 | 0.000| -.012898 – -.0043008 |
| birth_yr  | .071574 | .002994  | 23.91 | 0.000| .0657062 – .0774417 |
| grade     | .857507 | .161627  | 5.31  | 0.000| .5407231 – 1.174291 |

Instrumented: tenure
Instruments: age c.age#c.age birth_yr grade union wks_work msp

Both job tenure and years of schooling have significant positive effects on wages.

Time-series data are often plagued by serial correlation. In these cases, we can construct a weighting matrix to account for the fact that the error in period $t$ is probably correlated with the errors in periods $t-1$, $t-2$, etc. An HAC weighting matrix can be used to account for both serial correlation and potential heteroskedasticity.

To request an HAC weighting matrix, you specify the `wmatrix(hac kernel [ # | opt ])` option. `kernel` specifies which of three kernels to use: `bartlett`, `parzen`, or `quadraticspectral`. `kernel` determines the amount of weight given to lagged values when computing the HAC matrix, and `#` denotes the maximum number of lags to use. Many texts refer to the bandwidth of the kernel instead of the number of lags; the bandwidth is equal to the number of lags plus one. If neither `opt` nor `#` is specified, then $N-2$ lags are used, where $N$ is the sample size.

If you specify `wmatrix(hac kernel opt)`, then `ivregress` uses Newey and West’s (1994) algorithm for automatically selecting the number of lags to use. Although the authors’ Monte Carlo simulations do show that the procedure may result in size distortions of hypothesis tests, the procedure is still useful when little other information is available to help choose the number of lags.

For more on GMM estimation, see Baum (2006); Baum, Schaffer, and Stillman (2003, 2007); Cameron and Trivedi (2005); Davidson and MacKinnon (1993, 2004); Hayashi (2000); or Wooldridge (2010). See Newey and West (1987) and Wang and Wu (2012) for an introduction to HAC covariance matrix estimation.
ivregress — Single-equation instrumental-variables regression

ivregress stores the following in e():

Scalars
- e(N) number of observations
- e(mss) model sum of squares
- e(df_m) model degrees of freedom
- e(rss) residual sum of squares
- e(df_r) residual degrees of freedom
- e(r2) \( R^2 \)
- e(r2_a) adjusted \( R^2 \)
- e(F) F statistic
- e(rmse) root mean squared error
- e(N_clust) number of clusters
- e(chi2) \( \chi^2 \)
- e(kappa) \( \kappa \) used in LIML estimator
- e(J) value of GMM objective function
- e(vclustvar) name of HAC cluster variable
- e(wtype) weight type
- e(wexp) weight expression

- e(V) variance–covariance matrix of the estimators
- e(V_modelbased) model-based variance

Functions
- e(sample) marks estimation sample
Methods and formulas

Methods and formulas are presented under the following headings:

- Notation
- 2SLS and LIML estimators
- GMM estimator

Notation

Items printed in lowercase and italicized (for example, $x$) are scalars. Items printed in lowercase and boldfaced (for example, $\mathbf{x}$) are vectors. Items printed in uppercase and boldfaced (for example, $\mathbf{X}$) are matrices.

The model is

$$\mathbf{y} = \mathbf{Y}\beta_1 + \mathbf{X}_1\beta_2 + \mathbf{u} = \mathbf{X}\beta + \mathbf{u}$$

$$\mathbf{Y} = \mathbf{X}_1\mathbf{I}_1 + \mathbf{X}_2\mathbf{I}_2 + \mathbf{v} = \mathbf{Z}\mathbf{I}_2 + \mathbf{V}$$

where $\mathbf{y}$ is an $N \times 1$ vector of the left-hand-side variable; $N$ is the sample size; $\mathbf{Y}$ is an $N \times p$ matrix of $p$ endogenous regressors; $\mathbf{X}_1$ is an $N \times k_1$ matrix of $k_1$ included exogenous regressors; $\mathbf{X}_2$ is an $N \times k_2$ matrix of $k_2$ excluded exogenous variables; $\mathbf{X} = [\mathbf{Y} \; \mathbf{X}_1]$, $\mathbf{Z} = [\mathbf{X}_1 \; \mathbf{X}_2]$; $\mathbf{u}$ is an $N \times 1$ vector of errors; $\mathbf{V}$ is an $N \times p$ matrix of errors; $\beta = [\beta_1 \; \beta_2]$ is a $k = (p + k_1) \times 1$ vector of parameters; and $\mathbf{I}_2$ is a $(k_1 + k_2) \times p$ vector of parameters. If a constant term is included in the model, then one column of $\mathbf{X}_1$ contains all ones.

Let $\mathbf{v}$ be a column vector of weights specified by the user. If no weights are specified, $\mathbf{v} = 1$. Let $\mathbf{w}$ be a column vector of normalized weights. If no weights are specified or if the user specified fweights or iweights, $\mathbf{w} = \mathbf{v}$; otherwise, $\mathbf{w} = \{\mathbf{v}/(1'\mathbf{v})\}(1'1)$. Let $\mathbf{D}$ denote the $N \times N$ matrix with $\mathbf{w}$ on the main diagonal and zeros elsewhere. If no weights are specified, $\mathbf{D}$ is the identity matrix.

The weighted number of observations $n$ is defined as $1'\mathbf{w}$. For iweights, this is truncated to an integer. The sum of the weights is $1'\mathbf{v}$. Define $c = 1$ if there is a constant in the regression and zero otherwise.

The order condition for identification requires that $k_2 \geq p$: the number of excluded exogenous variables must be at least as great as the number of endogenous regressors.

In the following formulas, if weights are specified, $\mathbf{X}_i'\mathbf{X}_i$, $\mathbf{X}'\mathbf{X}$, $\mathbf{X}'\mathbf{y}$, $\mathbf{y}'\mathbf{y}$, $\mathbf{Z}'\mathbf{Z}$, $\mathbf{Z}'\mathbf{X}$, and $\mathbf{Z}'\mathbf{y}$ are replaced with $\mathbf{X}_i'\mathbf{D}\mathbf{X}_i$, $\mathbf{X}'\mathbf{D}\mathbf{X}$, $\mathbf{X}'\mathbf{Dy}$, $\mathbf{y}'\mathbf{Dy}$, $\mathbf{Z}'\mathbf{DZ}$, $\mathbf{Z}'\mathbf{DX}$, and $\mathbf{Z}'\mathbf{Dy}$, respectively. We suppress the $\mathbf{D}$ below to simplify the notation.

2SLS and LIML estimators

Define the $\kappa$-class estimator of $\beta$ as

$$\mathbf{b} = \{\mathbf{X}'(\mathbf{I} - \kappa\mathbf{M}_Z)\mathbf{X}\}^{-1}\mathbf{X}'(\mathbf{I} - \kappa\mathbf{M}_Z)\mathbf{y}$$

where $\mathbf{M}_Z = \mathbf{I} - \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$. The 2SLS estimator results from setting $\kappa = 1$. The LIML estimator results from selecting $\kappa$ to be the minimum eigenvalue of $(\mathbf{Y}'\mathbf{M}_Z\mathbf{Y})^{-1/2}\mathbf{Y}'\mathbf{M}_{X_1}\mathbf{Y}(\mathbf{Y}'\mathbf{M}_Z\mathbf{Y})^{-1/2}$, where $\mathbf{M}_{X_1} = \mathbf{I} - \mathbf{X}_1(\mathbf{X}_1'\mathbf{X}_1)^{-1}\mathbf{X}_1'$.

The total sum of squares (TSS) equals $\mathbf{y}'\mathbf{y}$ if there is no intercept and $\mathbf{y}'\mathbf{y} - \{(1'\mathbf{y})^2/n\}$ otherwise. The degrees of freedom is $n - c$. The error sum of squares (ESS) is defined as $\mathbf{y}'\mathbf{y} - 2\mathbf{b}'\mathbf{X}'\mathbf{y} + \mathbf{b}'\mathbf{X}'\mathbf{X}\mathbf{b}$. The model sum of squares (MSS) equals TSS - ESS. The degrees of freedom is $k - c$. 

The mean squared error, $s^2$, is defined as $\frac{\text{ESS}}{n-k}$ if `small` is specified and $\frac{\text{ESS}}{n}$ otherwise. The root mean squared error is $s$, its square root.

If $c=1$ and `small` is not specified, a Wald statistic, $W$, of the joint significance of the $k-1$ parameters of $\beta$ except the constant term is calculated: $W \sim \chi^2(k-1)$. If $c=1$ and `small` is specified, then an $F$ statistic is calculated as $F = W/(k-1)$; $F \sim F(k-1, n-k)$.

The $R$-squared is defined as $R^2 = 1 - \frac{\text{ESS}}{\text{TSS}}$.

The adjusted $R$-squared is $R^2_a = 1 - \frac{(1 - R^2)(n - c)}{(n - k)}$.

If `robust` is not specified, then $\text{Var}(b) = s^2 \{X'(I - \kappa M_Z)X\}^{-1}$. For a discussion of robust variance estimates in regression and regression with instrumental variables, see `Methods and formulas` in [R] `regress`. If `small` is not specified, then $k = 0$ in the formulas given there.

This command also supports estimation with survey data. For details on VCEs with survey data, see [SVY] `variance estimation`.

**GMM estimator**

We obtain an initial consistent estimate of $\beta$ by using the 2SLS estimator; see above. Using this estimate of $\beta$, we compute the weighting matrix $W$ and calculate the GMM estimator

$$b_{\text{GMM}} = \{X'ZWZ'X\}^{-1}X'ZWZ'y$$

The variance of $b_{\text{GMM}}$ is

$$\text{Var}(b_{\text{GMM}}) = n\{X'ZWZ'X\}^{-1}X'Z\hat{S}WZ'X\{X'ZWZ'X\}^{-1}$$

$\text{Var}(b_{\text{GMM}})$ is of the sandwich form $DMD$; see [P] `robnst`. If the user specifies the `small` option, `ivregress` implements a small-sample adjustment by multiplying the VCE by $N/(N-k)$.

If `vce(unadjusted)` is specified, then we set $\hat{S} = W^{-1}$ and the VCE reduces to the “optimal” GMM variance estimator

$$\text{Var}(\beta_{\text{GMM}}) = n\{X'ZWZ'X\}^{-1}$$

However, if $W^{-1}$ is not a good estimator of $E(z_iu_iu_i'z_i')$, then the optimal GMM estimator is inefficient, and inference based on the optimal variance estimator could be misleading.

$W$ is calculated using the residuals from the initial 2SLS estimates, whereas $S$ is estimated using the residuals based on $b_{\text{GMM}}$. The `wmatrix()` option affects the form of $W$, whereas the `vce()` option affects the form of $S$. Except for different residuals being used, the formulas for $W^{-1}$ and $S$ are identical, so we focus on estimating $W^{-1}$.

If `wmatrix(unadjusted)` is specified, then

$$W^{-1} = \frac{s^2}{n} \sum_i z_i z_i'$$

where $s^2 = \sum_i u_i^2/n$. This weight matrix is appropriate if the errors are homoskedastic.

If `wmatrix(robust)` is specified, then

$$W^{-1} = \frac{1}{n} \sum_i u_i^2 z_i z_i'$$

which is appropriate if the errors are heteroskedastic.
If `wmatrix(cluster clustvar)` is specified, then

$$W^{-1} = \frac{1}{n} \sum_{c} q_c q'_c$$

where $c$ indexes clusters,

$$q_c = \sum_{i \in c_j} u_i z_i$$

and $c_j$ denotes the $j$th cluster.

If `wmatrix(hac kernel [#])` is specified, then

$$W^{-1} = \frac{1}{n} \sum_{i} u_i^2 z_i z'_i + \frac{1}{n} \sum_{l=1}^{l=n-1} \sum_{i=l+1}^{l=n} K(l, m) u_i u_{i-l} (z_i z'_{i-l} + z_{i-l} z'_{i})$$

where $m = #$ if # is specified and $m = n - 2$ otherwise. Define $z = l/(m + 1)$. If `kernel` is `nw`, then

$$K(l, m) = \begin{cases} 1 - z & 0 \leq z \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

If `kernel` is `gallant`, then

$$K(l, m) = \begin{cases} 1 - 6z^2 + 6z^3 & 0 \leq z \leq 0.5 \\ 2(1-z)^3 & 0.5 < z \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

If `kernel` is `quadraticspectral`, then

$$K(l, m) = \begin{cases} 1 & z = 0 \\ 3 \{\sin(\theta)/\theta - \cos(\theta)\} / \theta^2 & \text{otherwise} \end{cases}$$

where $\theta = 6\pi z/5$.

If `wmatrix(hac kernel opt)` is specified, then `ivregress` uses Newey and West’s (1994) automatic lag-selection algorithm, which proceeds as follows. Define $h$ to be a $(k_1 + k_2) \times 1$ vector containing ones in all rows except for the row corresponding to the constant term (if present); that row contains a zero. Define

$$f_i = (u_i z_i) h$$

$$\hat{\sigma}_j = \frac{1}{n} \sum_{i=j+1}^{n} f_i f_{i-j} \quad j = 0, \ldots, m^*$$

$$\hat{s}^{(q)} = 2 \sum_{j=1}^{m^*} \hat{\sigma}_j j^q$$

$$\hat{s}^{(0)} = \hat{\sigma}_0 + 2 \sum_{j=1}^{m^*} \hat{\sigma}_j$$

$$\hat{\gamma} = c_\gamma \left\{ \left( \frac{\hat{s}^{(q)}}{\hat{s}^{(0)}} \right)^2 \right\}^{1/2q+1}$$

$$m = \hat{\gamma} n^1/(2q+1)$$
where $q$, $m^*$, and $c_\gamma$ depend on the kernel specified:

<table>
<thead>
<tr>
<th>Kernel</th>
<th>$q$</th>
<th>$m^*$</th>
<th>$c_\gamma$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bartlett</td>
<td>1</td>
<td>$\text{int} \left{ 20(T/100)^{2/9} \right}$</td>
<td>1.1447</td>
</tr>
<tr>
<td>Parzen</td>
<td>2</td>
<td>$\text{int} \left{ 20(T/100)^{4/25} \right}$</td>
<td>2.6614</td>
</tr>
<tr>
<td>Quadratic spectral</td>
<td>2</td>
<td>$\text{int} \left{ 20(T/100)^{2/25} \right}$</td>
<td>1.3221</td>
</tr>
</tbody>
</table>

where $\text{int}(x)$ denotes the integer obtained by truncating $x$ toward zero. For the Bartlett and Parzen kernels, the optimal lag is $\min\{\text{int}(m), m^*\}$. For the quadratic spectral, the optimal lag is $\min\{m, m^*\}$.

If `center` is specified, when computing weighting matrices `ivregress` replaces the term $u_i z_i$ in the formulas above with $u_i z_i - \overline{u z}$, where $\overline{u z} = \sum_i u_i z_i / N$.

¹ forecast is not appropriate with svy estimation results.
Special-interest postestimation commands

`estat endogenous` performs tests to determine whether endogenous regressors in the model are in fact exogenous. After GMM estimation, the $C$ (difference-in-Sargan) statistic is reported. After 2SLS estimation with an unadjusted VCE, the Durbin (1954) and Wu–Hausman (Wu 1974; Hausman 1978) statistics are reported. After 2SLS estimation with a robust VCE, Wooldridge’s (1995) robust score test and a robust regression-based test are reported. In all cases, if the test statistic is significant, then the variables being tested must be treated as endogenous. `estat endogenous` is not available after LIML estimation.

`estat firststage` reports various statistics that measure the relevance of the excluded exogenous variables. By default, whether the equation has one or more than one endogenous regressor determines what statistics are reported.

`estat overid` performs tests of overidentifying restrictions. If the 2SLS estimator was used, Sargan’s (1958) and Basman’s (1960) $\chi^2$ tests are reported, as is Wooldridge’s (1995) robust score test; if the LIML estimator was used, Anderson and Rubin’s (1950) $\chi^2$ test and Basman’s $F$ test are reported; and if the GMM estimator was used, Hansen’s (1982) $J$ statistic $\chi^2$ test is reported. A statistically significant test statistic always indicates that the instruments may not be valid.

Syntax for `predict`

```
predict [type] newvar [if] [in] [ , statistic ]
predict [type] { stub*| newvarlist } [if] [in], scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td>residuals</td>
<td>residuals</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the prediction</td>
</tr>
<tr>
<td>stdf</td>
<td>standard error of the forecast</td>
</tr>
<tr>
<td>pr(a,b)</td>
<td>$\Pr(a &lt; y_j &lt; b)$</td>
</tr>
<tr>
<td>e(a,b)</td>
<td>$E(y_j</td>
</tr>
<tr>
<td>ystar(a,b)</td>
<td>$E(y_j^<em>), y_j^</em> = \max{a, \min(y_j, b)}$</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if `e(sample)` ... if wanted only for the estimation sample.

`stdf` is not allowed with `svy` estimation results.

where $a$ and $b$ may be numbers or variables; $a$ missing ($a \geq -$) means $-\infty$, and $b$ missing ($b \geq -$) means $+\infty$; see [U] 12.2.1 Missing values.

Menu for `predict`

Statistics > Postestimation > Predictions, residuals, etc.
Options for predict

xb, the default, calculates the linear prediction.

residuals calculates the residuals, that is, $y_j - x_j \beta$. These are based on the estimated equation when the observed values of the endogenous variables are used—not the projections of the instruments onto the endogenous variables.

stdp calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. This is also referred to as the standard error of the fitted value.

stdf calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by stdf are always larger than those produced by stdp; see Methods and formulas in [R] regress postestimation.

pr(a, b) calculates $P(a < x_j \beta + u_j < b)$, the probability that $y_j | x_j$ would be observed in the interval $(a, b)$.

$ a $ and $ b $ may be specified as numbers or variable names; $ lb $ and $ ub $ are variable names;

pr(20, 30) calculates $P(20 < x_j \beta + u_j < 30)$;

pr(lb, ub) calculates $P(lb < x_j \beta + u_j < ub)$; and

pr(20, ub) calculates $P(20 < x_j \beta + u_j < ub)$.

$ a $ missing (a ≥ .) means $-\infty$; pr(., 30) calculates $P(-\infty < x_j \beta + u_j < 30)$; and calculates $P(lb < x_j \beta + u_j < 30)$ elsewhere.

$ b $ missing (b ≥ .) means $+\infty$; pr(20, .) calculates $P(+\infty > x_j \beta + u_j > 20)$; and calculates $P(20 < x_j \beta + u_j < ub)$ elsewhere.

e(a, b) calculates $E(x_j \beta + u_j | a < x_j \beta + u_j < b)$, the expected value of $y_j | x_j$ conditional on $y_j | x_j$ being in the interval $(a, b)$, meaning that $y_j | x_j$ is truncated.

$ a $ and $ b $ are specified as they are for pr().

ystar(a, b) calculates $E(y_j^*), \text{ where } y_j^* = a \text{ if } x_j \beta + u_j \leq a, y_j^* = b \text{ if } x_j \beta + u_j \geq b, \text{ and } y_j^* = x_j \beta + u_j \text{ otherwise, meaning that } y_j^* \text{ is censored. } a \text{ and } b \text{ are specified as they are for pr().}$

scores calculates the scores for the model. A new score variable is created for each endogenous regressor, as well as an equation-level score that applies to all exogenous variables and constant term (if present).

Syntax for estat

Perform tests of endogeneity

```
estat endogenous [varlist] [ , lags(#) forweights forcenonrobust]
```

Report “first-stage” regression statistics

```
estat firststage [ , all forcenonrobust]
```
Perform tests of overidentifying restrictions

`estat overid [, lags(#) forceweights forcenonrobust]`

**Menu for estat**

Statistics > Postestimation > Reports and statistics

**Options for estat**

Options for `estat` are presented under the following headings:

*Options for estat endogenous*
*Options for estat firststage*
*Options for estat overid*

**Options for estat endogenous**

`lags(#)` specifies the number of lags to use for prewhitening when computing the heteroskedasticity- and autocorrelation-consistent (HAC) version of the score test of endogeneity. Specifying `lags(0)` requests no prewhitening. This option is valid only when the model was fit via 2SLS and an HAC covariance matrix was requested when the model was fit. The default is `lags(1)`.

`forceweights` requests that the tests of endogeneity be computed even though `aweight`, `pweight`, or `iweight` were used in the previous estimation. By default, these tests are conducted only after unweighted or frequency-weighted estimation. The reported critical values may be inappropriate for weighted data, so the user must determine whether the critical values are appropriate for a given application.

`forcenonrobust` requests that the Durbin and Wu–Hausman tests be performed after 2SLS estimation even though a robust VCE was used at estimation time. This option is available only if the model was fit by 2SLS.

**Options for estat firststage**

`all` requests that all first-stage goodness-of-fit statistics be reported regardless of whether the model contains one or more endogenous regressors. By default, if the model contains one endogenous regressor, then the first-stage $R^2$, adjusted $R^2$, partial $R^2$, and $F$ statistics are reported, whereas if the model contains multiple endogenous regressors, then Shea’s partial $R^2$ and adjusted partial $R^2$ are reported instead.

`forcenonrobust` requests that the minimum eigenvalue statistic and its critical values be reported even though a robust VCE was used at estimation time. The reported critical values assume that the errors are independent and identically distributed (i.i.d.) normal, so the user must determine whether the critical values are appropriate for a given application.
Options for estat overid

`lags(#)` specifies the number of lags to use for prewhitening when computing the heteroskedasticity-and autocorrelation-consistent (HAC) version of the score test of overidentifying restrictions. Specifying `lags(0)` requests no prewhitening. This option is valid only when the model was fit via 2SLS and an HAC covariance matrix was requested when the model was fit. The default is `lags(1)`. 

`forceweights` requests that the tests of overidentifying restrictions be computed even though `aweight`s, `pweight`s, or `iweight`s were used in the previous estimation. By default, these tests are conducted only after unweighted or frequency-weighted estimation. The reported critical values may be inappropriate for weighted data, so the user must determine whether the critical values are appropriate for a given application. 

`forcenonrobust` requests that the Sargan and Basmann tests of overidentifying restrictions be performed after 2SLS or LIML estimation even though a robust VCE was used at estimation time. These tests assume that the errors are i.i.d. normal, so the user must determine whether the critical values are appropriate for a given application. 

Remarks and examples

Remarks are presented under the following headings:

- `estat endogenous`
- `estat firststage`
- `estat overid`

`estat endogenous`

A natural question to ask is whether a variable presumed to be endogenous in the previously fit model could instead be treated as exogenous. If the endogenous regressors are in fact exogenous, then the OLS estimator is more efficient; and depending on the strength of the instruments and other factors, the sacrifice in efficiency by using an instrumental-variables estimator can be significant. Thus, unless an instrumental-variables estimator is really needed, OLS should be used instead. `estat endogenous` provides several tests of endogeneity after 2SLS and GMM estimation. 

Example 1

In example 1 of [R] `ivregress`, we fit a model of the average rental rate for housing in a state as a function of the percentage of the population living in urban areas and the average value of houses. We treated `hsngval` as endogenous because unanticipated shocks that affect rental rates probably affect house prices as well. We used family income and region dummies as additional instruments for `hsngval`. Here we test whether we could treat `hsngval` as exogenous.

```
  . use http://www.stata-press.com/data/r13/hsng
(1980 Census housing data)
  . ivregress 2sls rent pcturban (hsngval = faminc i.region)
(output omitted)
  . estat endogenous

Tests of endogeneity
Ho: variables are exogenous
  Durbin (score) chi2(1) =  12.8473  (p = 0.0003)
  Wu-Hausman F(1,46) =  15.9067  (p = 0.0002)
```
Because we did not specify any variable names after the `estat endogenous` command, Stata by default tested all the endogenous regressors (namely, `hsngval`) in our model. The null hypothesis of the Durbin and Wu–Hausman tests is that the variable under consideration can be treated as exogenous. Here both test statistics are highly significant, so we reject the null of exogeneity; we must continue to treat `hsngval` as endogenous.

The difference between the Durbin and Wu–Hausman tests of endogeneity is that the former uses an estimate of the error term’s variance based on the model assuming the variables being tested are exogenous, while the latter uses an estimate of the error variance based on the model assuming the variables being tested are endogenous. Under the null hypothesis that the variables being tested are exogenous, both estimates of the error variance are consistent. What we label the Wu–Hausman statistic is Wu’s (1974) “$T_2$” statistic, which Hausman (1978) showed can be calculated very easily via linear regression. Baum, Schaffer, and Stillman (2003, 2007) provide a lucid discussion of these tests.

When you fit a model with multiple endogenous regressors, you can test the exogeneity of a subset of the regressors while continuing to treat the others as endogenous. For example, say you have three endogenous regressors, $y_1$, $y_2$, and $y_3$, and you fit your model by typing

```
. ivregress depvar ... (y1 y2 y3 = ...)
```

Suppose you are confident that $y_1$ must be treated as endogenous, but you are undecided about $y_2$ and $y_3$. To test whether $y_2$ and $y_3$ can be treated as exogenous, you would type

```
. estat endogenous y2 y3
```

The Durbin and Wu–Hausman tests assume that the error term is i.i.d. Therefore, if you requested a robust VCE at estimation time, `estat endogenous` will instead report Wooldridge’s (1995) score test and a regression-based test of exogeneity. Both these tests can tolerate heteroskedastic and autocorrelated errors, while only the regression-based test is amenable to clustering.

#### Example 2

We refit our housing model, requesting robust standard errors, and then test the exogeneity of `hsngval`:

```
. use http://www.stata-press.com/data/r13/hsng
   (1980 Census housing data)
. ivregress 2sls rent pcturban (hsngval = faminc i.region), vce(robust)
   (output omitted)
. estat overid
   Tests of endogeneity
   Ho: variables are exogenous
   Robust score chi2(1) = 2.10428 (p = 0.1469)
   Robust regression F(1,46) = 4.31101 (p = 0.0435)
```

Wooldridge’s score test does not reject the null hypothesis that `hsngval` is exogenous at conventional significance levels ($p = 0.1469$). However, the regression-based test does reject the null hypothesis at the 5% significance level ($p = 0.0435$). Typically, these two tests yield the same conclusion; the fact that our dataset has only 50 observations could be contributing to the discrepancy. Here we would be inclined to continue to treat `hsngval` as endogenous. Even if `hsngval` is exogenous, the 2SLS estimates are still consistent. On the other hand, if `hsngval` is in fact endogenous, the OLS estimates would not be consistent. Moreover, as we will see in our discussion of the `estat overid` command, our additional instruments may be invalid. To test whether an endogenous variable can be treated as exogenous, we must have a valid set of instruments to use to fit the model in the first place!
Unlike the Durbin and Wu–Hausman tests, Wooldridge’s score and the regression-based tests do not allow you to test a subset of the endogenous regressors in the model; you can test only whether all the endogenous regressors are in fact exogenous.

After GMM estimation, `estat endogenous` calculates what Hayashi (2000, 220) calls the $C$ statistic, also known as the difference-in-Sargan statistic. The $C$ statistic can be made robust to heteroskedasticity, autocorrelation, and clustering; and the version reported by `estat endogenous` is determined by the weight matrix requested via the `wmatrix()` option used when fitting the model with `ivregress`. Additionally, the test can be used to determine the exogeneity of a subset of the endogenous regressors, regardless of the type of weight matrix used.

If you fit your model using the LIML estimator, you can use the `hausman` command to carry out a traditional Hausman (1978) test between the OLS and LIML estimates.

### `estat firststage`

For an excluded exogenous variable to be a valid instrument, it must be sufficiently correlated with the included endogenous regressors but uncorrelated with the error term. In recent decades, researchers have paid considerable attention to the issue of instruments that are only weakly correlated with the endogenous regressors. In such cases, the usual 2SLS, GMM, and LIML estimators are biased toward the OLS estimator, and inference based on the standard errors reported by, for example, `ivregress` can be severely misleading. For more information on the theory behind instrumental-variables estimation with weak instruments, see Nelson and Startz (1990); Staiger and Stock (1997); Hahn and Hausman (2003); the survey article by Stock, Wright, and Yogo (2002); and Angrist and Pischke (2009, chap. 4).

When the instruments are only weakly correlated with the endogenous regressors, some Monte Carlo evidence suggests that the LIML estimator performs better than the 2SLS and GMM estimators; see, for example, Poi (2006) and Stock, Wright, and Yogo (2002) (and the papers cited therein). On the other hand, the LIML estimator often results in confidence intervals that are somewhat larger than those from the 2SLS estimator.

Moreover, using more instruments is not a solution, because the biases of instrumental-variables estimators increase with the number of instruments. See Hahn and Hausman (2003).

`estat firststage` produces several statistics for judging the explanatory power of the instruments and is most easily explained with examples.

### Example 3

Again building on the model fit in example 1 of [R] `ivregress`, we now explore the degree of correlation between the additional instruments `faminc`, `2.region`, `3.region`, and `4.region` and the endogenous regressor `hsngval`:

```stata
. use http://www.stata-press.com/data/r13/hsng
   (1980 Census housing data)
. ivregress 2sls rent pcturban (hsngval = faminc i.region)
   (output omitted)
. estat firststage
```

To understand these results, recall that the first-stage regression is

\[ \text{hsngval}_i = \pi_0 + \pi_1 \text{pcturban}_i + \pi_2 \text{faminc} + \pi_3 \text{2.region} + \pi_4 \text{3.region} + \pi_5 \text{4.region} + \nu_i \]

where \( \nu_i \) is an error term. The column marked “R-sq.” is the simple \( R^2 \) from fitting the first-stage regression by OLS, and the column marked “Adjusted R-sq.” is the adjusted \( R^2 \) from that regression. Higher values purportedly indicate stronger instruments, and instrumental-variables estimators exhibit less bias when the instruments are strongly correlated with the endogenous variable.

Looking at just the \( R^2 \) and adjusted \( R^2 \) can be misleading, however. If \( \text{hsngval} \) were strongly correlated with the included exogenous variable \( \text{pcturban} \) but only weakly correlated with the additional instruments, then these statistics could be large even though a weak-instrument problem is present.

The partial \( R^2 \) statistic measures the correlation between \( \text{hsngval} \) and the additional instruments after partialling out the effect of \( \text{pcturban} \). Unlike the \( R^2 \) and adjusted \( R^2 \) statistics, the partial \( R^2 \) statistic will not be inflated because of strong correlation between \( \text{hsngval} \) and \( \text{pcturban} \). Bound, Jaeger, and Baker (1995) and others have promoted using this statistic.

The column marked “F(4, 44)” is an \( F \) statistic for the joint significance of \( \pi_2, \pi_3, \pi_4, \) and \( \pi_5 \), the coefficients on the additional instruments. Its \( p \)-value is listed in the column marked “Prob > F”. If the \( F \) statistic is not significant, then the additional instruments have no significant explanatory power for \( \text{hsngval} \) after controlling for the effect of \( \text{pcturban} \). However, Hall, Rudebusch, and Wilcox (1996) used Monte Carlo simulation to show that simply having an \( F \) statistic that is significant at the typical 5% or 10% level is not sufficient. Stock, Wright, and Yogo (2002) suggest that the \( F \) statistic should exceed 10 for inference based on the 2SLS estimator to be reliable when there is one endogenous regressor.

`estat firststage` also presents the Cragg and Donald (1993) minimum eigenvalue statistic as a further test of weak instruments. Stock and Yogo (2005) discuss two characterizations of weak instruments: first, weak instruments cause instrumental-variables estimators to be biased; second, hypothesis tests of parameters estimated by instrumental-variables estimators may suffer from severe size distortions. The test statistic in our example is 13.30, which is identical to the \( F \) statistic just discussed because our model contains one endogenous regressor.

The null hypothesis of each of Stock and Yogo’s tests is that the set of instruments is weak. To perform these tests, we must first choose either the largest relative bias of the 2SLS estimator we are willing to tolerate or the largest rejection rate of a nominal 5% Wald test we are willing to tolerate. If the test statistic exceeds the critical value, we can conclude that our instruments are not weak.

The row marked “2SLS relative bias” contains critical values for the test that the instruments are weak based on the bias of the 2SLS estimator relative to the bias of the OLS estimator. For example, from past experience we might know that the OLS estimate of a parameter \( \beta \) may be 50% too high. Saying that we are willing to tolerate a 10% relative bias means that we are willing to tolerate a bias of the 2SLS estimator no greater than 5% (that is, 10% of 50%). In our rental rate model, if we
are willing to tolerate a 10% relative bias, then we can conclude that our instruments are not weak because the test statistic of 13.30 exceeds the critical value of 10.22. However, if we were willing to tolerate only a relative bias of 5%, we would conclude that our instruments are weak because 13.30 < 16.85.

The rows marked “2SLS Size of nominal 5% Wald test” and “LIML Size of nominal 5% Wald test” contain critical values pertaining to Stock and Yogo’s (2005) second characterization of weak instruments. This characterization defines a set of instruments to be weak if a Wald test at the 5% level can have an actual rejection rate of no more than 10%, 15%, 20%, or 25%. Using the current example, suppose that we are willing to accept a rejection rate of at most 10%. Because 13.30 < 24.58, we cannot reject the null hypothesis of weak instruments. On the other hand, if we use the LIML estimator instead, then we can reject the null hypothesis because 13.30 > 5.44.

Technical note

Stock and Yogo (2005) tabulated critical values for 2SLS relative biases of 5%, 10%, 20%, and 30% for models with 1, 2, or 3 endogenous regressors and between 3 and 30 excluded exogenous variables (instruments). They also provide critical values for worst-case rejection rates of 5%, 10%, 20%, and 25% for nominal 5% Wald tests of the endogenous regressors with 1 or 2 endogenous regressors and between 1 and 30 instruments. If the model previously fit by ivregress has more instruments or endogenous regressors than these limits, the critical values are not shown. Stock and Yogo did not consider GMM estimators.

When the model being fit contains more than one endogenous regressor, the $R^2$ and $F$ statistics described above can overstate the relevance of the excluded instruments. Suppose that there are two endogenous regressors, $Y_1$ and $Y_2$, and that there are two additional instruments, $z_1$ and $z_2$. Say that $z_1$ is highly correlated with both $Y_1$ and $Y_2$ but $z_2$ is not correlated with either $Y_1$ or $Y_2$. Then the first-stage regression of $Y_1$ on $z_1$ and $z_2$ (along with the included exogenous variables) will produce large $R^2$ and $F$ statistics, as will the regression of $Y_2$ on $z_1$, $z_2$, and the included exogenous variables. Nevertheless, the lack of correlation between $z_2$ and $Y_1$ and $Y_2$ is problematic. Here, although the order condition indicates that the model is just identified (the number of excluded instruments equals the number of endogenous regressors), the irrelevance of $z_2$ implies that the model is in fact not identified. Even if the model is overidentified, including irrelevant instruments can adversely affect the properties of instrumental-variables estimators, because their biases increase as the number of instruments increases.

Example 4

`estat firststage` presents different statistics when the model contains multiple endogenous regressors. For illustration, we refit our model of rental rates, assuming that both `hsngval` and `faminc` are endogenously determined. We use `i.region` along with `popden`, a measure of population density, as additional instruments.
Consider the endogenous regressor \textit{hsngval}. Part of its variation is attributable to its correlation with the other regressors \textit{pcturb}an and \textit{faminc}. The other component of \textit{hsngval}'s variation is peculiar to it and orthogonal to the variation in the other regressors. Similarly, we can think of the instruments as predicting the variation in \textit{hsngval} in two ways, one stemming from the fact that the predicted values of \textit{hsngval} are correlated with the predicted values of the other regressors and one from the variation in the predicted values of \textit{hsngval} that is orthogonal to the variation in the predicted values of the other regressors.

What really matters for instrumental-variables estimation is whether the component of \textit{hsngval} that is orthogonal to the other regressors can be explained by the component of the predicted value of \textit{hsngval} that is orthogonal to the predicted values of the other regressors in the model. Shea's (1997) partial $R^2$ statistic measures this correlation. Because the bias of instrumental-variables estimators increases as more instruments are used, Shea's adjusted partial $R^2$ statistic is often used instead, as it makes a degrees-of-freedom adjustment for the number of instruments, analogous to the adjusted $R^2$ measure used in OLS regression. Although what constitutes a "low" value for Shea's partial $R^2$ depends on the specifics of the model being fit and the data used, these results, taken in isolation, do not strike us as being a particular cause for concern.

However, with this specification the minimum eigenvalue statistic is low. We cannot reject the null hypothesis of weak instruments for either of the characterizations we have discussed.

By default, \texttt{estat firststage} determines which statistics to present based on the number of endogenous regressors in the model previously fit. However, you can specify the \texttt{all} option to obtain all the statistics.

\begin{footnotesize}
\begin{tabular}{l|c|c|c|c}
\hline
Variable & Shea's Partial R-sq. & Shea's Adj. Partial R-sq. \\
\hline
hsngval & 0.3477 & 0.2735 \\
faminc & 0.1893 & 0.0972 \\
\hline
\end{tabular}
\end{footnotesize}

\begin{footnotesize}
Minimum eigenvalue statistic = 2.51666

Critical Values & # of endogenous regressors: 2 & # of excluded instruments: 4 \\
\hline
2SLS relative bias & 5\% & 10\% & 20\% & 30\% \\
& 11.04 & 7.56 & 5.57 & 4.73 \\
2SLS Size of nominal 5\% Wald test & 10\% & 15\% & 20\% & 25\% \\
& 16.87 & 9.93 & 7.54 & 6.28 \\
LIML Size of nominal 5\% Wald test & 4.72 & 3.39 & 2.99 & 2.79 \\
\hline
\end{footnotesize}

\textbf{Technical note}

If the previous estimation was conducted using \texttt{aweights}, \texttt{pweights}, or \texttt{iweights}, then the first-stage regression summary statistics are computed using those weights. However, in these cases the minimum eigenvalue statistic and its critical values are not available.
If the previous estimation included a robust VCE, then the first-stage $F$ statistic is based on a robust VCE as well; for example, if you fit your model with an HAC VCE using the Bartlett kernel and four lags, then the $F$ statistic reported is based on regression results using an HAC VCE using the Bartlett kernel and four lags. By default, the minimum eigenvalue statistic and its critical values are not displayed. You can use the `forcenonrobust` option to obtain them in these cases; the minimum eigenvalue statistic is computed using the weights, though the critical values reported may not be appropriate.

### estat overid

In addition to the requirement that instrumental variables be correlated with the endogenous regressors, the instruments must also be uncorrelated with the structural error term. If the model is overidentified, meaning that the number of additional instruments exceeds the number of endogenous regressors, then we can test whether the instruments are uncorrelated with the error term. If the model is just identified, then we cannot perform a test of overidentifying restrictions.

The estimator you used to fit the model determines which tests of overidentifying restrictions `estat overid` reports. If you used the 2SLS estimator without a robust VCE, `estat overid` reports Sargan’s (1958) and Basmann’s (1960) $\chi^2$ tests. If you used the 2SLS estimator and requested a robust VCE, Wooldridge’s robust score test of overidentifying restrictions is performed instead; without a robust VCE, Wooldridge’s test statistic is identical to Sargan’s test statistic. If you used the LIML estimator, `estat overid` reports the Anderson–Rubin (1950) likelihood-ratio test and Basmann’s (1960) $F$ test. `estat overid` reports Hansen’s (1982) $J$ statistic if you used the GMM estimator. Davidson and MacKinnon (1993, 235–236) give a particularly clear explanation of the intuition behind tests of overidentifying restrictions. Also see Judge et al. (1985, 614–616) for a summary of tests of overidentifying restrictions for the 2SLS and LIML estimators.

Tests of overidentifying restrictions actually test two different things simultaneously. One, as we have discussed, is whether the instruments are uncorrelated with the error term. The other is that the equation is misspecified and that one or more of the excluded exogenous variables should in fact be included in the structural equation. Thus a significant test statistic could represent either an invalid instrument or an incorrectly specified structural equation.

#### Example 5

Here we refit the model that treated just `hsngval` as endogenous using 2SLS, and then we perform tests of overidentifying restrictions:

```bash
. ivregress 2sls rent pcturban (hsngval = faminc i.region)
(output omitted)
. estat overid
Tests of overidentifying restrictions:
  Sargan (score) chi2(3) = 11.2877  (p = 0.0103)
  Basmann chi2(3) = 12.8294  (p = 0.0050)
```

Both test statistics are significant at the 5% test level, which means that either one or more of our instruments are invalid or that our structural model is specified incorrectly.

One possibility is that the error term in our structural model is heteroskedastic. Both Sargan’s and Basmann’s tests assume that the errors are i.i.d.: if the errors are not i.i.d., then these tests are not valid. Here we refit the model by requesting heteroskedasticity-robust standard errors, and then we use `estat overid` to obtain Wooldridge’s score test of overidentifying restrictions, which is robust to heteroskedasticity.
Here we no longer reject the null hypothesis that our instruments are valid at the 5% significance level, though we do reject the null at the 10% level. You can verify that the robust standard error on the coefficient for $\text{hsngval}$ is more than twice as large as its nonrobust counterpart and that the robust standard error for $\text{pcturban}$ is nearly 50% larger.

### Technical note

The test statistic for the test of overidentifying restrictions performed after GMM estimation is simply the sample size times the value of the objective function $Q(\beta_1, \beta_2)$ defined in (5) of [R] ivregress, evaluated at the GMM parameter estimates. If the weighting matrix $W$ is optimal, meaning that $W = \text{Var}(z_iu_i)$, then $Q(\beta_1, \beta_2) \overset{A}{\sim} \chi^2(q)$, where $q$ is the number of overidentifying restrictions. However, if the estimated $W$ is not optimal, then the test statistic will not have an asymptotic $\chi^2$ distribution.

Like the Sargan and Basmann tests of overidentifying restrictions for the 2SLS estimator, the Anderson–Rubin and Basmann tests after LIML estimation are predicated on the errors’ being i.i.d. If the previous LIML results were reported with robust standard errors, then estat overid by default issues an error message and refuses to report the Anderson–Rubin and Basmann test statistics. You can use the forcenonrobust option to override this behavior. You can also use forcenonrobust to obtain the Sargan and Basmann test statistics after 2SLS estimation with robust standard errors.

By default, estat overid issues an error message if the previous estimation was conducted using aweights, pweights, or iweights. You can use the forceweights option to override this behavior, though the test statistics may no longer have the expected $\chi^2$ distributions.

### Stored results

After 2SLS estimation, estat endogenous stores the following in $r()$:

Scalars
- $r(\text{durbin})$: Durbin $\chi^2$ statistic
- $r(\text{p_durbin})$: $p$-value for Durbin $\chi^2$ statistic
- $r(\text{wu})$: Wu–Hausman $F$ statistic
- $r(\text{p_wu})$: $p$-value for Wu–Hausman $F$ statistic
- $r(\text{df})$: degrees of freedom
- $r(\text{wudf_r})$: denominator degrees of freedom for Wu–Hausman $F$

After GMM estimation, `estat endogenous` stores the following in `r()`:

Scalars
- \( r(C) \): \( C \chi^2 \) statistic
- \( r(p_C) \): \( p \)-value for \( C \chi^2 \) statistic
- \( r(df) \): degrees of freedom

`estat firststage` stores the following in `r()`:

Scalars
- \( r(\text{mineig}) \): minimum eigenvalue statistic

Matrices
- \( r(\text{mineigcv}) \): critical values for minimum eigenvalue statistic
- \( r(\text{multiresults}) \): Shea’s partial \( R^2 \) statistics
- \( r(\text{singleresults}) \): first-stage \( R^2 \) and \( F \) statistics

After 2SLS estimation, `estat overid` stores the following in `r()`:

Scalars
- \( r(\text{lags}) \): lags used in prewhitening
- \( r(df) \): \( \chi^2 \) degrees of freedom
- \( r(score) \): score \( \chi^2 \) statistic
- \( r(p_score) \): \( p \)-value for score \( \chi^2 \) statistic
- \( r(basmann) \): Basmann \( \chi^2 \) statistic
- \( r(p_basmann) \): \( p \)-value for Basmann \( \chi^2 \) statistic
- \( r(sargan) \): Sargan \( \chi^2 \) statistic
- \( r(p_sargan) \): \( p \)-value for Sargan \( \chi^2 \) statistic

After LIML estimation, `estat overid` stores the following in `r()`:

Scalars
- \( r(ar) \): Anderson–Rubin \( \chi^2 \) statistic
- \( r(p_ar) \): \( p \)-value for Anderson–Rubin \( \chi^2 \) statistic
- \( r(ar_df) \): \( \chi^2 \) degrees of freedom
- \( r(basmann) \): Basmann \( F \) statistic
- \( r(p_basmann) \): \( p \)-value for Basmann \( F \) statistic
- \( r(basmann_df_n) \): \( F \) numerator degrees of freedom
- \( r(basmann_df_d) \): \( F \) denominator degrees of freedom

After GMM estimation, `estat overid` stores the following in `r()`:

Scalars
- \( r(HansenJ) \): Hansen’s \( J \chi^2 \) statistic
- \( r(p_HansenJ) \): \( p \)-value for Hansen’s \( J \chi^2 \) statistic
- \( r(J_df) \): \( \chi^2 \) degrees of freedom

Methods and formulas

Methods and formulas are presented under the following headings:

- **Notation**
- `estat endogenous`
- `estat firststage`
- `estat overid`
Recall from [R] ivregress that the model is

\[ y = Y\beta_1 + X_1\beta_2 + u = X\beta + u \]

\[ Y = X_1\Pi_1 + X_2\Pi_2 + V = Z\Pi + V \]

where \( y \) is an \( N \times 1 \) vector of the left-hand-side variable, \( N \) is the sample size, \( Y \) is an \( N \times p \) matrix of \( p \) endogenous regressors, \( X_1 \) is an \( N \times k_1 \) matrix of \( k_1 \) included exogenous regressors, \( X_2 \) is an \( N \times k_2 \) matrix of \( k_2 \) excluded exogenous variables, \( X = [Y X_1] \), \( Z = [X_1 X_2] \), \( u \) is an \( N \times 1 \) vector of errors, \( V \) is an \( N \times p \) matrix of errors, \( \beta = [\beta_1 \beta_2] \) is a \( k = (p + k_1) \times 1 \) vector of parameters, and \( \Pi \) is a \((k_1 + k_2) \times p \) vector of parameters. If a constant term is included in the model, then one column of \( X_1 \) contains all ones.

estat endogenous

Partition \( Y \) as \( Y = [Y_1 Y_2] \), where \( Y_1 \) represents the \( p_1 \) endogenous regressors whose endogeneity is being tested and \( Y_2 \) represents the \( p_2 \) endogenous regressors whose endogeneity is not being tested. If the endogeneity of all endogenous regressors is being tested, \( Y = Y_1 \) and \( p_2 = 0 \). After GMM estimation, estat endogenous refits the model treating \( Y_1 \) as exogenous using the same type of weight matrix as requested at estimation time with the \( \text{wmatrix()} \) option; denote the Sargan statistic from this model by \( J_e \) and the estimated weight matrix by \( W_e \). Let \( S_e = W_e^{-1} \). estat endogenous removes from \( S_e \) the rows and columns corresponding to the variables represented by \( Y_1 \); denote the inverse of the resulting matrix by \( W_e' \). Next estat endogenous fits the model treating both \( Y_1 \) and \( Y_2 \) as endogenous, using the weight matrix \( W_e' \), denote the Sargan statistic from this model by \( J_e \). Then \( C = (J_e - J_c) \sim \chi^2(p_1) \). If one simply used the \( J \) statistic from the original model fit by ivregress in place of \( J_e \), then in finite samples \( J_e - J \) might be negative. The procedure used by estat endogenous is guaranteed to yield \( C \geq 0 \); see Hayashi (2000, 220).

Let \( \tilde{u}_e \) denote the residuals from the model treating both \( Y_1 \) and \( Y_2 \) as endogenous, and let \( \hat{u}_e \) denote the residuals from the model treating only \( Y_2 \) as endogenous. Then Durbin’s (1954) statistic is

\[ D = \frac{\tilde{u}_e' P_{ZY_1} \tilde{u}_e - \hat{u}_e' P_{ZY} \hat{u}_e}{\hat{u}_e' \hat{u}_e / N} \]

where \( P_Z = Z(Z'Z)^{-1}Z' \) and \( P_{ZY_1} = [Z Y_1][(Z Y_1)'[Z Y_1]]^{-1}[Z Y_1]' \) \( D \sim \chi^2(p_1) \). The Wu–Hausman (Wu 1974; Hausman 1978) statistic is

\[ WH = \frac{(\tilde{u}_e' P_{ZY_1} \tilde{u}_e - \hat{u}_e' P_{ZY} \hat{u}_e) / p_1}{\{\tilde{u}_e' \tilde{u}_e - (\tilde{u}_e' P_{ZY_1} \tilde{u}_e - \hat{u}_e' P_{ZY} \hat{u}_e)\} / (N - k_1 - p - p_1) / (N - k_1 - p - p_1)} \]

\[ WH \sim F(p_1, N - k_1 - p - p_1) \]. Baum, Schaffer, and Stillman (2003, 2007) discuss these tests in more detail.

Next we describe Wooldridge’s (1995) score test. The nonrobust version of Wooldridge’s test is identical to Durbin’s test. Suppose a robust covariance matrix was used at estimation time. Let \( \tilde{e} \) denote the sample residuals obtained by fitting the model via OLS, treating \( Y \) as exogenous. We then regress each variable represented in \( Y \) on \( Z \); call the residuals for the \( j \)th regression \( \tilde{r}_j \), \( j = 1, \ldots, p \). Define \( \hat{k}_{ij} = \tilde{e}_i \tilde{r}_{ij} \), \( i = 1, \ldots, N \). We then run the regression

\[ 1 = \theta_1 \hat{k}_1 + \cdots + \theta_p \hat{k}_p + \epsilon \]
where $\mathbf{1}$ is an $N \times 1$ vector of ones and $\epsilon$ is a regression error term. $N - \text{RSS} \sim \chi^2(p)$, where RSS is the residual sum of squares from the regression just described. If instead an HAC VCE was used at estimation time, then before running the final regression we prewhiten the $\hat{\kappa}_j$ series by using a VAR($q$) model, where $q$ is the number of lags specified with the `lags()` option.

The regression-based test proceeds as follows. Following Hausman (1978, 1259), we regress $\mathbf{Y}$ on $\mathbf{Z}$ and obtain the residuals $\hat{\mathbf{V}}$. Next we fit the augmented regression
\[
\mathbf{y} = \mathbf{Y} \beta_1 + \mathbf{X}_1 \beta_2 + \hat{\mathbf{V}} \gamma + \epsilon
\]
by OLS regression, where $\epsilon$ is a regression error term. A test of the exogeneity of $\mathbf{Y}$ is equivalent to a test of $\gamma = 0$. As Cameron and Trivedi (2005, 276) suggest, this test can be made robust to heteroskedasticity, autocorrelation, or clustering by using the appropriate robust VCE when testing $\gamma = 0$. When a nonrobust VCE is used, this test is equivalent to the Wu–Hausman test described earlier. One cannot simply fit this augmented regression via 2SLS and obtain the residuals $\hat{\mathbf{V}}$. To calculate Shea’s partial $R^2$, let $\mathbf{y}_1$ denote the endogenous regressor whose statistic is being calculated and $\mathbf{Y}_0$ denote the other endogenous regressors. Define $\bar{\mathbf{y}}_1$ as the residuals obtained from regressing $\mathbf{y}_1$ on $\mathbf{Y}_0$ and $\mathbf{X}_1$. Let $\hat{\mathbf{y}}_1$ denote the fitted values obtained from regressing $\mathbf{y}_1$ on $\mathbf{X}_1$ and $\mathbf{X}_2$; that is, $\hat{\mathbf{y}}_1$ are the fitted values from the first-stage regression for $\mathbf{y}_1$, and define the columns of $\hat{\mathbf{Y}}_0$ analogously. Finally, let $\tilde{\mathbf{y}}_1$ denote the residuals from regressing $\hat{\mathbf{y}}_1$ on $\hat{\mathbf{Y}}_0$ and $\mathbf{X}_1$. Shea’s partial $R^2$ is the simple $R^2$ from the regression of $\bar{\mathbf{y}}_1$ on $\tilde{\mathbf{y}}_1$; denote this as $R^2_S$. Shea’s adjusted partial $R^2$ is equal to $1 - (1 - R^2_S)(N - 1)/(N - k_Z + 1)$ if a constant term is included and $1 - (1 - R^2_S)(N - 1)/(N - k_Z)$ if there is no constant term included in the model, where $k_Z = k_1 + k_2$. For one endogenous regressor, one instrument, no exogenous regressors, and a constant term, $R^2_S$ equals the adjusted $R^2$. The Stock and Yogo minimum eigenvalue statistic, first proposed by Cragg and Donald (1993) as a test for underidentification, is the minimum eigenvalue of the matrix
\[
\mathbf{G} = \frac{1}{k_Z} \Sigma_{VV}^{-1/2} \mathbf{Y}'\mathbf{M}_{X_1} \mathbf{X}_2(\mathbf{X}_2'\mathbf{M}_{X_1} \mathbf{X}_2)^{-1}\mathbf{X}_2'\mathbf{M}_{X_1} \mathbf{Y} \Sigma_{VV}^{-1/2}
\]
\[
\hat{\Sigma}_{VV} = \frac{1}{N - k_Z} Y' M_Z Y
\]

\[M_Z = I - Z (Z' Z)^{-1} Z', \text{ and } Z = [X_1 \ X_2].\]

Critical values are obtained from the tables in Stock and Yogo (2005).

**estat overid**

The Sargan (1958) and Basmann (1960) \( \chi^2 \) statistics are calculated by running the auxiliary regression

\[
\hat{u} = Z \delta + e
\]

where \( \hat{u} \) are the sample residuals from the model and \( e \) is an error term. Then Sargan’s statistic is

\[
S = N \left( 1 - \frac{\hat{e}' \hat{e}}{\hat{u}' \hat{u}} \right)
\]

where \( \hat{e} \) are the residuals from that auxiliary regression. Basmann’s statistic is calculated as

\[
B = S \frac{N - k_Z}{N - S}
\]

Both \( S \) and \( B \) are distributed \( \chi^2(m) \), where \( m \), the number of overidentifying restrictions, is equal to \( k_Z - k \), where \( k \) is the number of endogenous regressors.

Wooldridge’s (1995) score test of overidentifying restrictions is identical to Sargan’s (1958) statistic under the assumption of i.i.d. and therefore is not recomputed unless a robust VCE was used at estimation time. If a heteroskedasticity-robust VCE was used, Wooldridge’s test proceeds as follows. Let \( \hat{Y} \) denote the \( N \times k \) matrix of fitted values obtained by regressing the endogenous regressors on \( X_1 \) and \( X_2 \). Let \( Q \) denote an \( N \times m \) matrix of excluded exogenous variables; the test statistic to be calculated is invariant to whichever \( m \) of the \( k_2 \) excluded exogenous variables is chosen. Define the \( i \)th element of \( \hat{k}_j \), \( i = 1, \ldots, N \), \( j = 1, \ldots, m \), as

\[
k_{ij} = \hat{q}_{ij} u_i
\]

where \( \hat{q}_{ij} \) is the \( i \)th element of \( \hat{q}_j \), the fitted values from regressing the \( j \)th column of \( Q \) on \( \hat{Y} \) and \( X_1 \). Finally, fit the regression

\[
1 = \theta_1 \hat{k}_1 + \cdots + \theta_m \hat{k}_m + \epsilon
\]

where \( 1 \) is an \( N \times 1 \) vector of ones and \( \epsilon \) is a regression error term, and calculate the residual sum of squares, RSS. Then the test statistic is \( W = N - \text{RSS} \). \( W \sim \chi^2(m) \). If an HAC VCE was used at estimation, then the \( \hat{k}_j \) are prewhitened using a VAR\((p)\) model, where \( p \) is specified using the `lags()` option.

The Anderson–Rubin (1950), AR, test of overidentifying restrictions for use after the LIML estimator is calculated as \( \text{AR} = N (\kappa - 1) \), where \( \kappa \) is the minimal eigenvalue of a certain matrix defined in Methods and formulas of [R] ivregress. \( \text{AR} \sim \chi^2(m) \). (Some texts define this statistic as \( N \ln(\kappa) \) because \( \ln(x) \approx (x - 1) \) for \( x \) near one.) Basmann’s \( F \) statistic for use after the LIML estimator is calculated as \( B_F = (\kappa - 1) (N - k_Z) / m \). \( B_F \sim F(m, N - k_Z) \).

Hansen’s \( J \) statistic is simply the sample size times the value of the GMM objective function defined in (5) of [R] ivregress, evaluated at the estimated parameter values. Under the null hypothesis that the overidentifying restrictions are valid, \( J \sim \chi^2(m) \).

*You must specify at least one of \texttt{ll[#]} and \texttt{ul[#]}.
ivtobit fits tobit models where one or more of the regressors is endogenously determined. By default, ivtobit uses maximum likelihood estimation. Alternatively, Newey’s (1987) minimum chi-squared estimator can be invoked with the twostep option. Both estimators assume that the endogenous regressors are continuous and so are not appropriate for use with discrete endogenous regressors. See [R] ivprobit for probit estimation with endogenous regressors and [R] tobit for tobit estimation when the model contains no endogenous regressors.
Options for ML estimator

11(#) and ul(#) indicate the lower and upper limits for censoring, respectively. You may specify one or both. Observations with depvar ≤ 11() are left-censored; observations with depvar ≥ ul() are right-censored; and remaining observations are not censored. You do not have to specify the censoring values at all. It is enough to type 11, ul, or both. When you do not specify a censoring value, ivtobit assumes that the lower limit is the minimum observed in the data (if 11 is specified) and that the upper limit is the maximum (if ul is specified).

mle requests that the conditional maximum-likelihood estimator be used. This is the default.

constraints(constraints); see [R] estimation options.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#); see [R] estimation options.

first requests that the parameters for the reduced-form equations showing the relationships between the endogenous variables and instruments be displayed. For the two-step estimator, first shows the first-stage regressions. For the maximum likelihood estimator, these parameters are estimated jointly with the parameters of the tobit equation. The default is not to show these parameter estimates.

nocnsreport; see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] estimation options.

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. This model’s likelihood function can be difficult to maximize, especially with multiple endogenous variables. The difficult and technique(bfgs) options may be helpful in achieving convergence.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following option is available with ivtobit but is not shown in the dialog box:

coefflegend; see [R] estimation options.

Options for two-step estimator

twostep is required and requests that Newey’s (1987) efficient two-step estimator be used to obtain the coefficient estimates.
$ll(#)$ and $ul(#)$ indicate the lower and upper limits for censoring, respectively. You may specify one or both. Observations with $depvar ≤ ll()$ are left-censored; observations with $depvar ≥ ul()$ are right-censored; and remaining observations are not censored. You do not have to specify the censoring values at all. It is enough to type $ll$, $ul$, or both. When you do not specify a censoring value, `ivtobit` assumes that the lower limit is the minimum observed in the data (if $ll$ is specified) and that the upper limit is the maximum (if $ul$ is specified).

The following option is available with `ivtobit` but is not shown in the dialog box: `coeflegend`; see [R] estimation options.

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`twostep`) and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] vce option.

`level(#)`; see [R] estimation options.

`first` requests that the parameters for the reduced-form equations showing the relationships between the endogenous variables and instruments be displayed. For the two-step estimator, `first` shows the first-stage regressions. For the maximum likelihood estimator, these parameters are estimated jointly with the parameters of the tobit equation. The default is not to show these parameter estimates.

`display_options`: `noomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch`; see [R] estimation options.

The following option is available with `ivtobit` but is not shown in the dialog box: `coeflegend`; see [R] estimation options.

### Remarks and examples

`ivtobit` fits models with censored dependent variables and endogenous regressors. You can use it to fit a tobit model when you suspect that one or more of the regressors is correlated with the error term. `ivtobit` is to tobit what `ivregress` is to linear regression analysis; see [R] ivregress for more information.

Formally, the model is

$$\begin{align*}
y_i^* &= y_{2i} \beta + x_{1i} \gamma + u_i \\
y_{2i} &= x_{1i} \Pi_1 + x_{2i} \Pi_2 + v_i
\end{align*}$$

where $i = 1, \ldots, N$; $y_{2i}$ is a $1 \times p$ vector of endogenous variables; $x_{1i}$ is a $1 \times k_1$ vector of exogenous variables; $x_{2i}$ is a $1 \times k_2$ vector of additional instruments; and the equation for $y_{2i}$ is written in reduced form. By assumption $(u_i, v_i) \sim N(0)$. $\beta$ and $\gamma$ are vectors of structural parameters, and $\Pi_1$ and $\Pi_2$ are matrices of reduced-form parameters. We do not observe $y_{1i}^*$; instead, we observe

$$y_{1i} = \begin{cases} 
a & y_{1i}^* < a \\
y_{1i}^* & a \leq y_{1i}^* \leq b \\
b & y_{1i}^* > b \end{cases}$$

The order condition for identification of the structural parameters is that $k_2 ≥ p$. Presumably, $\Sigma$ is not block diagonal between $u_i$ and $v_i$; otherwise, $y_{2i}$ would not be endogenous.
This model is derived under the assumption that \((u_i, v_i)\) is independent and identically distributed multivariate normal for all \(i\). The \texttt{vce(cluster clustvar)} option can be used to control for a lack of independence. As with the standard tobit model without endogeneity, if \(u_i\) is heteroskedastic, point estimates will be inconsistent.

Example 1

Using the same dataset as in \texttt{[R] ivprobit}, we now want to estimate women’s incomes. In our hypothetical world, all women who choose not to work receive $10,000 in welfare and child-support payments. Therefore, we never observe incomes under $10,000: a woman offered a job with an annual wage less than that would not accept and instead would collect the welfare payment. We model income as a function of the number of years of schooling completed, the number of children at home, and other household income. We again believe that other\_inc is endogenous, so we use \texttt{male\_educ} as an instrument.

```

Because we did not specify \texttt{mle} or \texttt{twostep}, \texttt{ivtobit} used the maximum likelihood estimator by default. \texttt{ivtobit} fits a tobit model, ignoring endogeneity, to get starting values for the full model. The header of the output contains the maximized log likelihood, the number of observations, and a
Wald statistic and p-value for the test of the hypothesis that all the slope coefficients are jointly zero. At the end of the output, we see a count of the censored and uncensored observations.

Near the bottom of the output is a Wald test of the exogeneity of the instrumented variables. If the test statistic is not significant, there is not sufficient information in the sample to reject the null hypothesis of no endogeneity. Then the point estimates from ivtobit are consistent, although those from tobit are likely to have smaller standard errors.

Various two-step estimators have also been proposed for the endogenous tobit model, and Newey’s (1987) minimum chi-squared estimator is available with the twostep option.

Example 2

Refitting our labor-supply model with the two-step estimator yields

```
. ivtobit fem_inc fem_educ kids (other_inc = male_educ), ll twostep

All the coefficients have the same signs as their counterparts in the maximum likelihood model. The Wald test at the bottom of the output confirms our earlier finding of endogeneity.

Technical note

In the tobit model with endogenous regressors, we assume that \((u_i, v_i)\) is multivariate normal with covariance matrix

\[
\text{Var}(u_i, v_i) = \Sigma = \begin{bmatrix} \sigma_u^2 & \Sigma'_{21} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}
\]

Using the properties of the multivariate normal distribution, \(\text{Var}(u_i|v_i) = \sigma^2_{u|v} = \sigma_u^2 - \Sigma'_{21} \Sigma^{-1}_{22} \Sigma_{21}\). Calculating the marginal effects on the conditional expected values of the observed and latent dependent variables and on the probability of censoring requires an estimate of \(\sigma^2_{u|v}\). The two-step estimator identifies only \(\sigma^2_{u|v}\), not \(\sigma_u^2\), so only the linear prediction and its standard error are available after you have used the twostep option. However, unlike the two-step probit estimator described in \([R]\) ivprobit, the two-step tobit estimator does identify \(\beta\) and \(\gamma\). See Wooldridge (2010, 683–684) for more information.
Stored results

`ivtobit, mle` stores the following in `e()`:

Scalars
- `e(N)` number of observations
- `e(N_unc)` number of uncensored observations
- `e(N_lc)` number of left-censored observations
- `e(N_rc)` number of right-censored observations
- `e(llopt)` contents of `ll()`
- `e(ulopt)` contents of `ul()`
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_aux)` number of auxiliary parameters
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(ll)` log likelihood
- `e(N_clust)` number of clusters
- `e(endog_ct)` number of endogenous regressors
- `e(p)` model Wald $p$-value
- `e(p_exog)` exogeneity test Wald $p$-value
- `e(chi2)` model Wald $\chi^2$
- `e(chi2_exog)` Wald $\chi^2$ test of exogeneity

Functions

- `e(sample)`: marks estimation sample

**Methods and formulas**

The estimation procedure used by `ivtobit` is similar to that used by `ivprobit`. For compactness, we write the model as
\[ y_{1i}^* = z_i \delta + u_i \] (1a)

\[ y_{2i} = x_i \Pi + v_i \] (1b)

where \( z_i = (y_{2i}, x_{1i}) \), \( x_i = (x_{1i}, x_{2i}) \), \( \delta = (\beta', \gamma')' \), and \( \Pi = (\Pi_1', \Pi_2')' \). We do not observe \( y_{1i}^* \); instead, we observe

\[ y_{1i} = \begin{cases} 
\alpha & y_{1i}^* < a \\
\gamma & a \leq y_{1i}^* \leq b \\
\beta & y_{1i}^* > b 
\end{cases} \]

\((u_i, v_i)\) is distributed multivariate normal with mean zero and covariance matrix

\[ \Sigma = \begin{bmatrix} 
\sigma_u^2 & \Sigma'_{21} \\
\Sigma_{21} & \Sigma_{22}
\end{bmatrix} \]

Using the properties of the multivariate normal distribution, we can write \( u_i = v_i' \alpha + \epsilon_i \), where \( \alpha = \Sigma_{22}^{-1} \Sigma_{21} \); \( \epsilon_i \sim N(0; \sigma_{u|v}^2) \), where \( \sigma_{u|v}^2 = \sigma_u^2 - \Sigma_{21} \Sigma_{22}^{-1} \Sigma_{21} \); and \( \epsilon_i \) is independent of \( v_i, z_i, \) and \( x_i \).

The likelihood function is straightforward to derive because we can write the joint density \( f(y_{1i}, y_{2i}|x_i) \) as \( f(y_{1i}|y_{2i}, x_i) f(y_{2i}|x_i) \). With one endogenous regressor,

\[ \ln f(y_{2i}|x_i) = -\frac{1}{2} \left\{ \ln 2\pi + \ln \sigma_v^2 + \frac{(y_{2i} - x_i' \Pi)^2}{\sigma_v^2} \right\} \]

and

\[ \ln f(y_{1i}|y_{2i}, x_i) = \begin{cases} 
\ln \left\{ 1 - \Phi \left( \frac{m_i - a}{\sigma_{u|v}} \right) \right\} & y_{1i} = a \\
-\frac{1}{2} \left\{ \ln 2\pi + \ln \sigma_u^2 + \frac{(y_{1i} - m_i)^2}{\sigma_u^2} \right\} & a < y_{1i} < b \\
\ln \Phi \left( \frac{m_i - b}{\sigma_{u|v}} \right) & y_{1i} = b 
\end{cases} \]

where

\[ m_i = z_i \delta + \alpha (y_{2i} - x_i' \Pi) \]

and \( \Phi(\cdot) \) is the normal distribution function so that the log likelihood for observation \( i \) is

\[ \ln L_i = w_i \{ \ln f(y_{1i}|y_{2i}, x_i) + \ln f(y_{2i}|x_i) \} \]

where \( w_i \) is the weight for observation \( i \) or one if no weights were specified. Instead of estimating \( \sigma_{u|v} \) and \( \sigma_v \) directly, we estimate \( \ln \sigma_{u|v} \) and \( \ln \sigma_v \).

For multiple endogenous regressors, we have

\[ \ln f(y_{2i}|x_i) = -\frac{1}{2} \left( \ln 2\pi + \ln |\Sigma_{22}| + v_i' \Sigma_{22}^{-1} v_i \right) \]

and \( \ln f(y_{1i}|y_{2i}, x_i) \) is the same as before, except that now

\[ m_i = z_i \delta + (y_{2i} - x_i' \Pi) \Sigma_{22}^{-1} \Sigma_{21} \]

Instead of maximizing the log-likelihood function with respect to \( \Sigma \), we maximize with respect to the Cholesky decomposition \( S \) of \( \Sigma \); that is, there exists a lower triangular matrix \( S \) such that \( SS' = \Sigma \). This maximization ensures that \( \Sigma \) is positive definite, as a covariance matrix must be. Let
With maximum likelihood estimation, this command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] _robust, particularly *Maximum likelihood estimators* and *Methods and formulas*.

The maximum likelihood version of `ivtobit` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] variance estimation.

The two-step estimates are obtained using Newey’s (1987) minimum chi-squared estimator. The procedure is identical to the one described in [R] ivprobit, except that `tobit` is used instead of `probit`.

### Acknowledgments

The two-step estimator is based on the `tobitiv` command written by Jonah Gelbach of the Department of Economics at Yale University and the `ivtobit` command written by Joe Harkness of the Institute of Policy Studies at Johns Hopkins University.

<tr>
<td><em>ystar(a,b)</em></td>
<td>$E(y_j^*)$, $y_j = \max{a, \min(y_j, b)}$; not available with two-step estimator</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

`stdf` is not allowed with `svy` estimation results.

where *a* and *b* may be numbers or variables; *a* missing (`*a* ≥ .`) means $-\infty$, and *b* missing (`*b* ≥ .`) means $+\infty$; see [U] 12.2.1 Missing values.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

**Main**

- *xb*, the default, calculates the linear prediction.

- *stdp* calculates the standard error of the linear prediction. It can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

- *stdf* calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by *stdf* are always larger than those produced by *stdp*; see *Methods and formulas* in [R] regress postestimation. *stdf* is not available with the two-step estimator.

- *pr(a,b)* calculates $\Pr(a < x_jb + u_j < b)$, the probability that $y_j | x_j$ would be observed in the interval $(a, b)$.

  *a* and *b* may be specified as numbers or variable names; *lb* and *ub* are variable names; 
  - *pr(20,30)* calculates $\Pr(20 < x_jb + u_j < 30)$; 
  - *pr(lb,ub)* calculates $\Pr(lb < x_jb + u_j < ub)$; and 
  - *pr(20,ub)* calculates $\Pr(20 < x_jb + u_j < ub)$. 

Marginal effects

Example 1

We can obtain average marginal effects by using the \texttt{margins} command after \texttt{ivtobit}. For the labor-supply model of example 1 in [R] \texttt{ivtobit}, suppose that we wanted to know the average marginal effects on the woman’s expected income, conditional on her income being greater than $10,000.
. use http://www.stata-press.com/data/r13/laborsup
. ivtobit fem_inc fem_educ kids (other_inc = male_educ), ll
   (output omitted)
. margins, dydx(*) predict(e(10, .))

Average marginal effects Number of obs = 500
Model VCE : OIM
Expression : E(fem_inc|fem_inc>10), predict(e(10, .))
dy/dx w.r.t. : other_inc fem_educ kids male_educ

<table>

<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

In our sample, increasing the number of children in the family by one decreases the expected wage by $1,252 on average (wages in our dataset are measured in thousands of dollars). male_edu has no effect because it appears only as an instrument.

Obtaining predicted values

After fitting your model using ivtobit, you can obtain the linear prediction and its standard error for both the estimation sample and other samples using the predict command. If you used the maximum likelihood estimator, you can also obtain conditional expected values of the observed and latent dependent variables, the standard error of the forecast, and the probability of observing the dependent variable in a specified interval. See [U] 20 Estimation and postestimation commands and [R] predict.

Methods and formulas

The linear prediction is calculated as \( z_i \hat{\delta} \), where \( \hat{\delta} \) is the estimated value of \( \delta \), and \( z_i \) and \( \delta \) are defined in (1a) of [R] ivtobit. Expected values and probabilities are calculated using the same formulas as those used by the standard exogenous tobit model.

Syntax

description

Also see

Syntax

```
jackknife exp_list [ , options eform_option ] : command
```

**Options**

**Main**

- **eclass**
  - number of observations used is stored in `e(N)`

- **rclass**
  - number of observations used is stored in `r(N)`

- **n(exp)**
  - specify `exp` that evaluates to the number of observations used

**Options**

- **cluster(varlist)**
  - variables identifying sample clusters

- **idcluster(newvar)**
  - create new cluster ID variable

- **saving(filename, ...)**
  - save results to `filename`; save statistics in double precision;
    save results to `filename` every `#` replications

- **keep**
  - keep pseudovalues

- **mse**
  - use MSE formula for variance estimation

**Reporting**

- **level(#)**
  - set confidence level; default is `level(95)`

- **notable**
  - suppress table of results

- **noheader**
  - suppress table header

- **nolegend**
  - suppress table legend

- **verbose**
  - display the full table legend

- **nodots**
  - suppress replication dots

- **noisily**
  - display any output from `command`

- **trace**
  - trace `command`

- **title(text)**
  - use `text` as title for jackknife results

**display_options**

- **control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling**

**eform_option**

- **display coefficient table in exponentiated form**

**Advanced**

- **nodrop**
  - do not drop observations

- **reject(expr)**
  - identify invalid results

- **coeflegend**
  - display legend instead of statistics

svy is allowed; see [SVY] svy jackknife.
All weight types supported by `command` are allowed except `aweight`; see [U] 11.1.6 weight.
`coeflegend` does not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
exp_list contains (name: elist)
  elist
eexp

elist contains newvar = (exp)
  (exp)
eexp is specname
  [eqno]specname
specname is _b
  _b[]
  _se
  _se[]
eqno is ##
  name

exp is a standard Stata expression; see [U] 13 Functions and expressions.
Distinguish between [], which are to be typed, and [[]], which indicate optional arguments.

Menu
Statistics > Resampling > Jackknife estimation

Description
jackknife performs jackknife estimation. Typing

  . jackknife exp_list: command

executes command once for each observation in the dataset, leaving the associated observation out of the calculations that make up exp_list.

command defines the statistical command to be executed. Most Stata commands and user-written programs can be used with jackknife, as long as they follow standard Stata syntax and allow the if qualifier; see [U] 11 Language syntax. The by prefix may not be part of command.

exp_list specifies the statistics to be collected from the execution of command. If command changes the contents in e(b), exp_list is optional and defaults to _b.

Many estimation commands allow the vce(jackknife) option. For those commands, we recommend using vce(jackknife) over jackknife because the estimation command already handles clustering and other model-specific details for you. The jackknife prefix command is intended for use with nonestimation commands, such as summarize, user-written commands, or functions of coefficients.

jknife is a synonym for jackknife.

Options
[Main]
eclass, rclass, and n(exp) specify where command stores the number of observations on which it based the calculated results. We strongly advise you to specify one of these options.
Eclass specifies that command store the number of observations in e(N).

Rclass specifies that command store the number of observations in r(N).

n(exp) specifies an expression that evaluates to the number of observations used. Specifying n(r(N)) is equivalent to specifying the rclass option. Specifying n(e(N)) is equivalent to specifying the eclass option. If command stores the number of observations in r(N1), specify n(r(N1)).

If you specify no options, jackknife will assume eclass or rclass, depending on which of e(N) and r(N) is not missing (in that order). If both e(N) and r(N) are missing, jackknife assumes that all observations in the dataset contribute to the calculated result. If that assumption is incorrect, the reported standard errors will be incorrect. For instance, say that you specify

```
.jackknife coef=_b[x2]: myreg y x1 x2 x3
```

where myreg uses e(n) instead of e(N) to identify the number of observations used in calculations. Further assume that observation 42 in the dataset has x3 equal to missing. The 42nd observation plays no role in obtaining the estimates, but jackknife has no way of knowing that and will use the wrong N. If, on the other hand, you specify

```
.jackknife coef=_b[x2], n(e(n)): myreg y x1 x2 x3
```

jackknife will notice that observation 42 plays no role. The n(e(n)) option is specified because myreg is an estimation command but it stores the number of observations used in e(n) (instead of the standard e(N)). When jackknife runs the regression omitting the 42nd observation, jackknife will observe that e(n) has the same value as when jackknife previously ran the regression using all the observations. Thus jackknife will know that myreg did not use the observation.

Options

- `cluster(varlist)` specifies the variables identifying sample clusters. If cluster() is specified, one cluster is left out of each call to command, instead of 1 observation.
- `idcluster(newvar)` creates a new variable containing a unique integer identifier for each resampled cluster, starting at 1 and leading up to the number of clusters. This option may be specified only when the cluster() option is specified. idcluster() helps identify the cluster to which a pseudovalue belongs.
- `saving(filename[, suboptions])` creates a Stata data file (.dta file) consisting of (for each statistic in exp_list) a variable containing the replicates.
  - `double` specifies that the results for each replication be saved as doubles, meaning 8-byte reals. By default, they are saved as floats, meaning 4-byte reals. This option may be used without the `saving()` option to compute the variance estimates by using double precision.
  - `every(#)` specifies that results be written to disk every #th replication. every() should be specified only in conjunction with saving() when command takes a long time for each replication. This option will allow recovery of partial results should some other software crash your computer. See [P] postfile.
  - `replace` specifies that filename be overwritten if it exists. This option does not appear in the dialog box.
- `keep` specifies that new variables be added to the dataset containing the pseudovalue of the requested statistics. For instance, if you typed

```
.jackknife coef=_b[x2], eclass keep: regress y x1 x2 x3
```
new variable coef would be added to the dataset containing the pseudovalues for \_b[x2]. Let b be the value of \_b[x2] when all observations are used to fit the model, and let b(j) be the value when the jth observation is omitted. The pseudovalues are defined as

\[
\text{pseudovalue}_j = N \{b - b(j)\} + b(j)
\]

where N is the number of observations used to produce b.

When the cluster() option is specified, each cluster is given at most one nonmissing pseudovalue. The keep option implies the nodrop option.

mse specifies that jackknife compute the variance by using deviations of the replicates from the observed value of the statistics based on the entire dataset. By default, jackknife computes the variance by using deviations of the pseudovalues from their mean.

level(#)\}; see \[R\] estimation options.

notable suppresses the display of the table of results.

noheader suppresses the display of the table header. This option implies nolegend.

nolegend suppresses the display of the table legend. The table legend identifies the rows of the table with the expressions they represent.

verbose specifies that the full table legend be displayed. By default, coefficients and standard errors are not displayed.

nodots suppresses display of the replication dots. By default, one dot character is displayed for each successful replication. A red ‘x’ is displayed if command returns an error or if one of the values in exp_list is missing.

noisily specifies that any output from command be displayed. This option implies the nodots option.

trace causes a trace of the execution of command to be displayed. This option implies the noisily option.

title(text) specifies a title to be displayed above the table of jackknife results; the default title is Jackknife results or what is produced in e(title) by an estimation command.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see \[R\] estimation options.

eform_option causes the coefficient table to be displayed in exponentiated form; see \[R\] eform_option.

command determines which eform_option is allowed (eform(string) and eform are always allowed).
command determines which of the following are allowed (eform(string) and eform are always allowed):

<table>
<thead>
<tr>
<th>eform_option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>eform(string)</td>
<td>use string for the column title</td>
</tr>
<tr>
<td>eform</td>
<td>exponentiated coefficient, string is exp(b)</td>
</tr>
<tr>
<td>hr</td>
<td>hazard ratio, string is Haz. Ratio</td>
</tr>
<tr>
<td>shr</td>
<td>subhazard ratio, string is SHR</td>
</tr>
<tr>
<td>irr</td>
<td>incidence-rate ratio, string is IRR</td>
</tr>
<tr>
<td>or</td>
<td>odds ratio, string is Odds Ratio</td>
</tr>
<tr>
<td>rrr</td>
<td>relative-risk ratio, string is RRR</td>
</tr>
</tbody>
</table>

nодrop prevents observations outside e(sample) and the if and in qualifiers from being dropped before the data are resampled.

reject(exp) identifies an expression that indicates when results should be rejected. When exp is true, the resulting values are reset to missing values.

The following option is available with jackknife but is not shown in the dialog box: coeflegend; see [R] estimation options.

Remarks and examples

Remarks are presented under the following headings:

Introduction
Jackknifed standard deviation
Collecting multiple statistics
Collecting coefficients

Introduction

Although the jackknife—developed in the late 1940s and early 1950s—is of largely historical interest today, it is still useful in searching for overly influential observations. This feature is often forgotten. In any case, the jackknife is

- an alternative, first-order unbiased estimator for a statistic;
- a data-dependent way to calculate the standard error of the statistic and to obtain significance levels and confidence intervals; and
- a way of producing measures called pseudovalues for each observation, reflecting the observation’s influence on the overall statistic.

The idea behind the simplest form of the jackknife—the one implemented here—is to repeatedly calculate the statistic in question, each time omitting just one of the dataset’s observations. Assume that our statistic of interest is the sample mean. Let $y_j$ be the $j$th observation of our data on some measurement $y$, where $j = 1, \ldots, N$ and $N$ is the sample size. If $\bar{y}$ is the sample mean of $y$ using the entire dataset and $\bar{y}(j)$ is the mean when the $j$th observation is omitted, then

$$\bar{y} = \frac{(N - 1) \bar{y}(j) + y_j}{N}$$
Solving for $y_j$, we obtain

$$y_j = N \bar{y} - (N - 1) \bar{y}_{(j)}$$

These are the pseudovalues that jackknife calculates. To move this discussion beyond the sample mean, let $\hat{\theta}$ be the value of our statistic (not necessarily the sample mean) using the entire dataset, and let $\hat{\theta}_{(j)}$ be the computed value of our statistic with the $j$th observation omitted. The pseudovalue for the $j$th observation is

$$\hat{\theta}_j^* = N \hat{\theta} - (N - 1) \hat{\theta}_{(j)}$$

The mean of the pseudovalues is the alternative, first-order unbiased estimator mentioned above, and the standard error of the mean of the pseudovalues is an estimator for the standard error of $\hat{\theta}$ (Tukey 1958).

When the `cluster()` option is given, clusters are omitted instead of observations, and $N$ is the number of clusters instead of the sample size.

The jackknife estimate of variance has been largely replaced by the bootstrap estimate (see [R] bootstrap), which is widely viewed as more efficient and robust. The use of jackknife pseudovalues to detect outliers is too often forgotten and is something the bootstrap does not provide. See Mosteller and Tukey (1977, 133–163) and Mooney and Duval (1993, 22–27) for more information.

Example 1

As our first example, we will show that the jackknife standard error of the sample mean is equivalent to the standard error of the sample mean computed using the classical formula in the ci command. We use the `double` option to compute the standard errors with the same precision as the ci command.

```
use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
jackknife r(mean), double: summarize mpg
(running summarize on estimation sample)
Jackknife replications (74)
.............................................. 50
Jackknife results
command: summarize mpg

|                      | Coef. | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|----------------------|-------|-----------|-------|------|----------------------|
| _jk_1                | 21.2973 | .6725511 | 31.67 | 0.000 | 19.9569  22.63769    |

ci mpg

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6725511</td>
<td>19.9569  22.63769</td>
</tr>
</tbody>
</table>
```

Jackknife estimation

Example 2

Mosteller and Tukey (1977, 139–140) request a 95% confidence interval for the standard deviation of the 11 values:

0.1, 0.1, 0.1, 0.4, 0.5, 1.0, 1.1, 1.3, 1.9, 1.9, 4.7

Stata’s `summarize` command calculates the mean and standard deviation and stores them as `r(mean)` and `r(sd)`. To obtain the jackknifed standard deviation of the 11 values and save the pseudovalues as a new variable, `sd`, we would type

```
. clear
. input x
     x
  1. 0.1
  2. 0.1
  3. 0.1
  4. 0.4
  5. 0.5
  6. 1.0
  7. 1.1
  8. 1.3
  9. 1.9
 10. 1.9
 11. 4.7
 12. end
. jackknife sd=r(sd), rclass keep: summarize x
```

```
Jackknife replications (11)
       1          2          3          4          5
............
Jackknife results
     Number of obs    =     11
    Replications    =     11

    command:  summarize x
    sd:  r(sd)
    n():  r(N)

                     Jackknife                  
        Coef.     Std. Err.     t     P>|t|    [95% Conf. Interval]
----------------------- ------- ----------- ------ -------- ---------------------
    sd      1.343469    .624405    2.15    0.057    -.047792    2.734733
```

Interpreting the output, the standard deviation reported by `summarize mpg` is 1.34. The jackknife standard error is 0.62. The 95% confidence interval for the standard deviation is −0.048 to 2.73.
By specifying `keep`, `jackknife` creates in our dataset a new variable, `sd`, for the pseudovalues.

```
. list, sep(4)

<table>
<thead>
<tr>
<th></th>
<th>x</th>
<th>sd</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>.1</td>
<td>1.139977</td>
</tr>
<tr>
<td>2</td>
<td>.1</td>
<td>1.139977</td>
</tr>
<tr>
<td>3</td>
<td>.1</td>
<td>1.139977</td>
</tr>
<tr>
<td>4</td>
<td>.4</td>
<td>.8893147</td>
</tr>
<tr>
<td>5</td>
<td>.5</td>
<td>.824267</td>
</tr>
<tr>
<td>6</td>
<td>1</td>
<td>.632489</td>
</tr>
<tr>
<td>7</td>
<td>1.1</td>
<td>.6203189</td>
</tr>
<tr>
<td>8</td>
<td>1.3</td>
<td>.6218889</td>
</tr>
<tr>
<td>9</td>
<td>1.9</td>
<td>.835419</td>
</tr>
<tr>
<td>10</td>
<td>1.9</td>
<td>.835419</td>
</tr>
<tr>
<td>11</td>
<td>4.7</td>
<td>7.703949</td>
</tr>
</tbody>
</table>
```

The jackknife estimate is the average of the `sd` variable, so `sd` contains the individual values of our statistic. We can see that the last observation is substantially larger than the others. The last observation is certainly an outlier, but whether that reflects the considerable information it contains or indicates that it should be excluded from analysis depends on the context of the problem. Here Mosteller and Tukey created the dataset by sampling from an exponential distribution, so the observation is informative.

> Example 3

Let’s repeat the example above using the automobile dataset, obtaining the standard error of the standard deviation of `mpg`.

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. jackknife sd=r(sd), rclass keep: summarize mpg
                (running summarize on estimation sample)
Jackknife replications (74)
.................................................. 50
Jackknife results Number of obs = 74
                         Replications = 74
command:  summarize mpg
           sd:  r(sd)
           n():  r(N)

| Coef.  | Std. Err.  | t    | P>|t|  | [95% Conf. Interval] |
|--------|------------|------|------|---------------------|
| sd     | 5.785503   | .6072509 | 9.53 | 0.000              | 4.575254  6.995753 |
```
Let's look at sd more carefully:

```
.summarize sd, detail

pseudovalues: r(sd)
```

<table>
<thead>
<tr>
<th>Percentiles</th>
<th>Smallest</th>
</tr>
</thead>
<tbody>
<tr>
<td>1%</td>

</tbody>
</table>
```

Here the VW Diesel is the only diesel car in our dataset.

**Collecting multiple statistics**

▸ **Example 4**

`jackknife` is not limited to collecting just one statistic. For instance, we can use `summarize, detail` and then obtain the jackknife estimate of the standard deviation and skewness. `summarize, detail` stores the standard deviation in `r(sd)` and the skewness in `r(skewness)`, so we might type

```
.use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
.jackknife sd=r(sd) skew=r(skewness), rclass: summarize mpg, detail
(running summarize on estimation sample)
```

**Jackknife results**

<table>
<thead>
<tr>
<th>Number of obs</th>
<th>Replications</th>
</tr>
</thead>
<tbody>
<tr>
<td>74</td>
<td>74</td>
</tr>
</tbody>
</table>

```
command:  summarize mpg, detail
sd:    r(sd)
skew:  r(skewness)
n():  r(N)
```

<table>
<thead>
<tr>
<th></th>
<th>Jackknife</th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Coef.</td>
<td>Std. Err.</td>

<td>t</td>
</tr>
<tr>
<td>sd</td>
<td>5.785503</td>
<td>.6072509</td>
<td>9.53</td>
<td>0.000</td>
<td>4.575254</td>
</tr>
<tr>
<td>skew</td>
<td>.9487176</td>
<td>.3367242</td>
<td>2.82</td>
<td>0.006</td>
<td>.2776272</td>
</tr>
</tbody>
</table>
Collecting coefficients

Example 5

jackknife can also collect coefficients from estimation commands. For instance, using auto.dta, we might wish to obtain the jackknife standard errors of the coefficients from a regression in which we model the mileage of a car by its weight and trunk space. To do this, we could refer to the coefficients as _b[weight], _b[trunk], _se[weight], and _se[trunk] in the exp_list, or we could simply use the extended expressions _b. In fact, jackknife assumes _b by default when used with estimation commands.

. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. jackknife: regress mpg weight trunk
(running regress on estimation sample)
Jackknife replications (74)
.................................................. 50
........................
Linear regression

| Coef. | Std. Err. | t  | P>|t| | [95% Conf. Interval] |
|-------|-----------|----|------|----------------------|
| weight| -.0056527 | .0010216 | -5.53 | 0.000 | -.0076887 to -.0036167 |
| trunk | -.096229  | .1486236 | -0.65 | 0.519 | -.3924354 to .1999773 |
| _cons | 39.68913  | 1.873324  | 21.19 | 0.000 | 35.9556 to 43.42266 |

If you are going to use jackknife to estimate standard errors of model coefficients, we recommend using the vce(jackknife) option when it is allowed with the estimation command; see [R] vce_option.

. regress mpg weight trunk, vce(jackknife, nodots)
Linear regression

| Coef. | Std. Err. | t  | P>|t| | [95% Conf. Interval] |
|-------|-----------|----|------|----------------------|
| weight| -.0056527 | .0010216 | -5.53 | 0.000 | -.0076887 to -.0036167 |
| trunk | -.096229  | .1486236 | -0.65 | 0.519 | -.3924354 to .1999773 |
| _cons | 39.68913  | 1.873324  | 21.19 | 0.000 | 35.9556 to 43.42266 |
John Wilder Tukey (1915–2000) was born in Massachusetts. He studied chemistry at Brown and mathematics at Princeton and afterward worked at both Princeton and Bell Labs, as well as being involved in a great many government projects, consultancies, and committees. He made outstanding contributions to several areas of statistics, including time series, multiple comparisons, robust statistics, and exploratory data analysis. Tukey was extraordinarily energetic and inventive, not least in his use of terminology: he is credited with inventing the terms bit and software, in addition to ANOVA, boxplot, data analysis, hat matrix, jackknife, stem-and-leaf plot, trimming, and winsorizing, among many others. Tukey’s direct and indirect impacts mark him as one of the greatest statisticians of all time.

**Stored results**

`jackknife` stores the following in `e()`:

Scalars

- `e(N)` sample size
- `e(N_reps)` number of complete replications
- `e(N_misreps)` number of incomplete replications
- `e(N_clust)` number of clusters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_extra)` number of extra equations
- `e(k_exp)` number of expressions
- `e(k_eexp)` number of extended expressions (`.` or `_se`)
- `e(df_r)` degrees of freedom

Macros

- `e(cmdname)` command name from `command`
- `e(cmd)` same as `e(cmdname)` or `jackknife`
- `e(command)` command
- `e(cmdline)` command as typed
- `e(prefix)` `jackknife`
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(cluster)` cluster variables
- `e(pseudo)` new variables containing pseudovalues
- `e(nfunction)` `e(N)`, `r(N)`, `n()` option, or empty
- `e(exp#)` expression for the #th statistic
- `e(mse)` from `mse` option
- `e(vce)` `jackknife`
- `e(vcetype)` title used to label Std. Err.
- `e(properties)` `b V`

Matrices

- `e(b)` observed statistics
- `e(b_jk)` jackknife estimates
- `e(V)` jackknife variance–covariance matrix
- `e(V_modelbased)` model-based variance

When `exp_list` is `_b`, `jackknife` will also carry forward most of the results already in `e()` from `command`. 
Methods and formulas

Let $\hat{\theta}$ be the observed value of the statistic, that is, the value of the statistic calculated using the original dataset. Let $\hat{\theta}_{(j)}$ be the value of the statistic computed by leaving out the $j$th observation (or cluster); thus $j = 1, 2, \ldots, N$ identifies an individual observation (or cluster), and $N$ is the total number of observations (or clusters). The $j$th pseudovalue is given by

$$\hat{\theta}^*_j = \hat{\theta}_{(j)} + N\{\hat{\theta} - \hat{\theta}_{(j)}\}$$

When the `mse` option is specified, the standard error is estimated as

$$\hat{se} = \left\{ \frac{N - 1}{N} \sum_{j=1}^{N} (\hat{\theta}_{(j)} - \hat{\theta})^2 \right\}^{1/2}$$

and the jackknife estimate is

$$\bar{\theta}_{(.)} = \frac{1}{N} \sum_{j=1}^{N} \hat{\theta}_{(j)}$$

Otherwise, the standard error is estimated as

$$\hat{se} = \left\{ \frac{1}{N(N - 1)} \sum_{j=1}^{N} (\hat{\theta}^*_j - \bar{\theta}^*)^2 \right\}^{1/2}$$

$$\bar{\theta}^* = \frac{1}{N} \sum_{j=1}^{N} \hat{\theta}^*_j$$

where $\bar{\theta}^*$ is the jackknife estimate. The variance–covariance matrix is similarly computed.

### Menu

**kap: two unique raters**

Statistics > Epidemiology and related > Other > Interrater agreement, two unique raters

**kapwgt**

Statistics > Epidemiology and related > Other > Define weights for the above (kap)

**kap: nonunique raters**

Statistics > Epidemiology and related > Other > Interrater agreement, nonunique raters

**kappa**

Statistics > Epidemiology and related > Other > Interrater agreement, nonunique raters with frequencies
Description

_kap_ (first syntax) calculates the kappa-statistic measure of interrater agreement when there are two unique raters and two or more ratings.

_kapwgt_ defines weights for use by _kap_ in measuring the importance of disagreements.

_kap_ (second syntax) and _kappa_ calculate the kappa-statistic measure when there are two or more (nonunique) raters and two outcomes, more than two outcomes when the number of raters is fixed, and more than two outcomes when the number of raters varies. _kap_ (second syntax) and _kappa_ produce the same results; they merely differ in how they expect the data to be organized.

_kap_ assumes that each observation is a subject. _varname_ 1 contains the ratings by the first rater, _varname_ 2 by the second rater, and so on.

_kappa_ also assumes that each observation is a subject. The variables, however, record the frequencies with which ratings were assigned. The first variable records the number of times the first rating was assigned, the second variable records the number of times the second rating was assigned, and so on.

Options

<table>
<thead>
<tr>
<th>Main</th>
</tr>
</thead>
</table>

_tab_ displays a tabulation of the assessments by the two raters.

_wgt(wgtid)_ specifies that _wgtid_ be used to weight disagreements. You can define your own weights by using _kapwgt_; _wgt()_ then specifies the name of the user-defined matrix. For instance, you might define

```
.kapwgt mine 1 \ .8 1 \ 0 .8 1 \ 0 0 .8 1
```

and then

```
.kap rata ratb, wgt(mine)
```

Also, two prerecorded weights are available.

_wgt(w)_ specifies weights \(1 - \frac{|i - j|}{(k - 1)}\), where \(i\) and \(j\) index the rows and columns of the ratings by the two raters and \(k\) is the maximum number of possible ratings.

_wgt(w2)_ specifies weights \(1 - \left(\frac{(i - j)}{(k - 1)}\right)^2\).

_absolute_ is relevant only if _wgt()_ is also specified. The _absolute_ option modifies how \(i\), \(j\), and \(k\) are defined and how corresponding entries are found in a user-defined weighting matrix. When _absolute_ is not specified, \(i\) and \(j\) refer to the row and column index, not to the ratings themselves. Say that the ratings are recorded as \(\{0, 1, 1.5, 2\}\). There are four ratings; \(k = 4\), and \(i\) and \(j\) are still 1, 2, 3, and 4 in the formulas above. Index 3, for instance, corresponds to rating \(= 1.5\). This system is convenient but can, with some data, lead to difficulties.

When _absolute_ is specified, all ratings must be integers, and they must be coded from the set \(\{1, 2, 3, \ldots\}\). Not all values need be used; integer values that do not occur are simply assumed to be unobserved.
Remarks and examples

Remarks are presented under the following headings:

Two raters
More than two raters

The kappa-statistic measure of agreement is scaled to be 0 when the amount of agreement is what would be expected to be observed by chance and 1 when there is perfect agreement. For intermediate values, Landis and Koch (1977a, 165) suggest the following interpretations:

- below 0.0: Poor
- 0.00–0.20: Slight
- 0.21–0.40: Fair
- 0.41–0.60: Moderate
- 0.61–0.80: Substantial
- 0.81–1.00: Almost perfect

Two raters

Example 1

Consider the classification by two radiologists of 85 xeromammograms as normal, benign disease, suspicion of cancer, or cancer (a subset of the data from Boyd et al. [1982] and discussed in the context of kappa in Altman [1991, 403–405]).

```
use http://www.stata-press.com/data/r13/rate2
(Altman p. 403)
tabulate rada radb
```

</tbody>
</table>

| Total | 28 | 38 | 16 | 3  | 85 |

Our dataset contains two variables: `rada`, radiologist A’s assessment, and `radb`, radiologist B’s assessment. Each observation is a patient.

We can obtain the kappa measure of interrater agreement by typing

```
.kap rada radb
```

<table>
<thead>
<tr>
<th>Agreement</th>
<th>Expected Agreement</th>
<th>Kappa</th>
<th>Std. Err.</th>
<th>Z</th>
<th>Prob&gt;Z</th>
</tr>
</thead>
<tbody>
<tr>
<td>63.53%</td>
<td>30.82%</td>
<td>0.4728</td>
<td>0.0694</td>
<td>6.81</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

If each radiologist had made his determination randomly (but with probabilities equal to the overall proportions), we would expect the two radiologists to agree on 30.8% of the patients. In fact, they agreed on 63.5% of the patients, or 47.3% of the way between random agreement and perfect agreement. The amount of agreement indicates that we can reject the hypothesis that they are making their determinations randomly.
Example 2: Weighted kappa, prerecorded weight $w$

There is a difference between two radiologists disagreeing about whether a xeromammogram indicates cancer or the suspicion of cancer and disagreeing about whether it indicates cancer or is normal. The weighted kappa attempts to deal with this. `kap` provides two “prerecorded” weights, $w$ and $w_2$:

```
. kap rada radb, wgt(w)
```

<table>

<td>0.6667</td>
<td>1.0000</td>
<td></td>
</tr>
</tbody>
</table>

```
Expected
Agreement Agreement Kappa Std. Err. Z Prob>Z
```

|   | 86.67% | 69.11% | 0.5684 | 0.0788 | 7.22 | 0.0000 |

The $w$ weights are given by $1 - |i - j|/(k - 1)$, where $i$ and $j$ index the rows of columns of the ratings by the two raters and $k$ is the maximum number of possible ratings. The weighting matrix is printed above the table. Here the rows and columns of the $4 \times 4$ matrix correspond to the ratings normal, benign, suspicious, and cancerous.

A weight of 1 indicates that an observation should count as perfect agreement. The matrix has 1s down the diagonals—when both radiologists make the same assessment, they are in agreement. A weight of, say, 0.6667 means that they are in two-thirds agreement. In our matrix, they get that score if they are “one apart”—one radiologist assesses cancer and the other is merely suspicious, or one is suspicious and the other says benign, and so on. An entry of 0.3333 means that they are in one-third agreement, or, if you prefer, two-thirds disagreement. That is the score attached when they are “two apart”. Finally, they are in complete disagreement when the weight is zero, which happens only when they are three apart—one says cancer and the other says normal.

Example 3: Weighted kappa, prerecorded weight $w_2$

The other prerecorded weight is $w_2$, where the weights are given by $1 - \{(i - j)/(k - 1)\}^2$:

```
. kap rada radb, wgt(w2)
```

<table>
<thead>
<tr>
<th>Ratings weighted by:</th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>1.0000</td>

<td>0.8889</td>
<td></td>
</tr>
<tr>
<td>0.0000</td>
<td>0.5556</td>
<td>0.8889</td>
<td>1.0000</td>
<td></td>
</tr>
</tbody>
</table>

```
Expected
Agreement Agreement Kappa Std. Err. Z Prob>Z
```

|   | 94.77% | 84.09% | 0.6714 | 0.1079 | 6.22 | 0.0000 |

The $w_2$ weight makes the categories even more alike and is probably inappropriate here.
Example 4: Weighted kappa, user-defined weights

In addition to using prerecorded weights, we can define our own weights with the `kapwgt` command. For instance, we might feel that suspicious and cancerous are reasonably similar, that benign and normal are reasonably similar, but that the suspicious/cancerous group is nothing like the benign/normal group:

```
. kapwgt xm 1 .8 1 0 0 1 0 0 .8 1
. kapwgt xm
1.0000
0.8000 1.0000
0.0000 0.0000 1.0000
0.0000 0.0000 0.8000 1.0000
```

We name the weights `xm`, and after the weight name, we enter the lower triangle of the weighting matrix, using \ to separate rows. We have four outcomes, so we continued entering numbers until we had defined the fourth row of the weighting matrix. If we type `kapwgt` followed by a name and nothing else, it shows us the weights recorded under that name. Satisfied that we have entered them correctly, we now use the weights to recalculate kappa:

```
. kap rada radb, wgt(xm)
```

```
Ratings weighted by:
1.0000 0.8000 0.0000 0.0000
0.8000 1.0000 0.0000 0.0000
0.0000 0.0000 1.0000 0.8000
0.0000 0.0000 0.8000 1.0000
```

<table>
<thead>
<tr>
<th>Expected Agreement</th>
<th>Agreement</th>
<th>Kappa</th>
<th>Std. Err.</th>
<th>Z</th>
<th>Prob&gt;Z</th>
</tr>
</thead>
<tbody>
<tr>
<td>80.47%</td>
<td>52.67%</td>
<td>0.5874</td>
<td>0.0865</td>
<td>6.79</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Technical note

In addition to using weights for weighting the differences in categories, you can specify Stata’s traditional weights for weighting the data. In the examples above, we have 85 observations in our dataset—one for each patient. If we only knew the table of outcomes—that there were 21 patients rated normal by both radiologists, etc.—it would be easier to enter the table into Stata and work from it. The easiest way to enter the data is with `tabi`; see [R] tabulate twoway.

```
. tabi 21 12 0 0 \ 4 17 1 0 \ 3 9 15 2 \ 0 0 0 1, replace
```

```
<p>|</p>
<table>
<thead>
<tr>
<th>row</th>
</tr>
</thead>
<tbody>
<tr>
<td>col</td>
</tr>
<tr>
<td>1</td>
</tr>
<tr>
<td>2</td>
</tr>
<tr>
<td>3</td>
</tr>
<tr>
<td>4</td>
</tr>
<tr>
<td>Total</td>
</tr>
<tr>
<td>------</td>
</tr>
<tr>
<td>1</td>
</tr>
<tr>
<td>2</td>
</tr>
<tr>
<td>3</td>
</tr>
<tr>
<td>4</td>
</tr>
<tr>
<td>Total</td>
</tr>
</tbody>
</table>

Pearson chi2(9) = 77.8111 Pr = 0.000
```

tabi reported the Pearson \( \chi^2 \) for this table, but we do not care about it. The important thing is that, with the `replace` option, tabi left the table in memory:
The variable row is radiologist A’s assessment, col is radiologist B’s assessment, and pop is the number so assessed by both. Thus

```
.kap row col [freq=pop]
```

| Agreement | Expected Agreement | Kappa | Std. Err. | Z | Prob>|Z|
|-----------|--------------------|-------|-----------|---|-----|
| 63.53%    | 30.82%             | 0.4728| 0.0694    | 6.81| 0.0000 |

If we are going to keep these data, the names row and col are not indicative of what the data reflect. We could type (see [U] 12.6 Dataset, variable, and value labels)

```
.rename row rada
.rename col radb
.label var rada "Radiologist A’s assessment"
.label var radb "Radiologist B’s assessment"
.label define assess 1 normal 2 benign 3 suspect 4 cancer
.label values rada assess
.label values radb assess
.label data "Altman p. 403"
```

kap’s `tab` option, which can be used with or without weighted data, shows the table of assessments:

```
.kap rada radb [freq=pop], tab
```

<table>
<thead>
<tr>
<th>Radiologist A’s assessment</th>
<th>Radiologist B’s assessment</th>
<th>cancer</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>normal</td>
<td>21</td>
<td>12</td>
<td>0</td>
</tr>
<tr>
<td>benign</td>
<td>4</td>
<td>17</td>
<td>1</td>
</tr>
<tr>
<td>suspect</td>
<td>3</td>
<td>9</td>
<td>15</td>
</tr>
<tr>
<td>cancer</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>Total</td>
<td>28</td>
<td>38</td>
<td>16</td>
</tr>
</tbody>
</table>

| Agreement | Expected Agreement | Kappa | Std. Err. | Z | Prob>|Z|
|-----------|--------------------|-------|-----------|---|-----|
| 63.53%    | 30.82%             | 0.4728| 0.0694    | 6.81| 0.0000 |
Technical note

You have data on individual patients. There are two raters, and the possible ratings are 1, 2, 3, and 4, but neither rater ever used rating 3:

```
. use http://www.stata-press.com/data/r13/rate2no3, clear
. tabulate ratera raterb
```

```
raterb
  ratera     1   2   4  Total
   1       6   4   3   13
   2       5   3   3   11
   4       1   1   26  28
 Total   12   8  32  52
```

Here `kap` would determine that the ratings are from the set \{1, 2, 4\} because those were the only values observed. `kap` would expect a user-defined weighting matrix to be $3 \times 3$, and if it were not, `kap` would issue an error message. In the formula-based weights, the calculation would be based on $i, j = 1, 2, 3$ corresponding to the three observed ratings \{1, 2, 4\}.

Specifying the `absolute` option would clarify that the ratings are 1, 2, 3, and 4; it just so happens that rating 3 was never assigned. If a user-defined weighting matrix were also specified, `kap` would expect it to be $4 \times 4$ or larger (larger because we can think of the ratings being 1, 2, 3, 4, 5, ... and it just so happens that ratings 5, 6, ... were never observed, just as rating 3 was not observed). In the formula-based weights, the calculation would be based on $i, j = 1, 2, 4$.

```
. kap ratera raterb, wgt(w)
```

```
Ratings weighted by:
0.0000  1.0000  0.5000
0.5000  1.0000  0.5000
0.0000  0.5000  1.0000

Expected Agreement Agreement Kappa Std. Err. Z Prob>Z
79.81%  57.17%  0.5285  0.1169  4.52  0.0000
```

```
. kap ratera raterb, wgt(w) absolute
```

```
Ratings weighted by:
0.0000  1.0000  0.6667
0.6667  1.0000  0.3333
0.0000  0.3333  1.0000

Expected Agreement Agreement Kappa Std. Err. Z Prob>Z
81.41%  55.08%  0.5862  0.1209  4.85  0.0000
```

If all conceivable ratings are observed in the data, specifying `absolute` makes no difference. For instance, if rater A assigns ratings \{1, 2, 4\} and rater B assigns \{1, 2, 3, 4\}, the complete set of assigned ratings is \{1, 2, 3, 4\}, the same that `absolute` would specify. Without `absolute`, it makes no difference whether the ratings are coded \{1, 2, 3, 4\}, \{0, 1, 2, 3\}, \{1, 7, 9, 100\}, \{0, 1, 1.5, 2.0\}, or otherwise.
More than two raters

For more than two raters, the mathematics are such that the two raters are not considered unique. For instance, if there are three raters, there is no assumption that the three raters who rate the first subject are the same as the three raters who rate the second. Although we call this the “more than two raters” case, it can be used with two raters when the raters’ identities vary.

The nonunique rater case can be usefully broken down into three subcases: 1) there are two possible ratings, which we will call positive and negative; 2) there are more than two possible ratings, but the number of raters per subject is the same for all subjects; and 3) there are more than two possible ratings, and the number of raters per subject varies. \texttt{kappa} handles all these cases. To emphasize that there is no assumption of constant identity of raters across subjects, the variables specified contain counts of the number of raters rating the subject into a particular category.

\begin{quote}
Jacob Cohen (1923–1998) was born in New York City. After studying psychology at City College of New York and New York University, he worked as a medical psychologist until 1959 when he became a full professor in the Department of Psychology at New York University. He made many contributions to research methods, including the kappa measure. He persistently emphasized the value of multiple regression and the importance of power and of measuring effects rather than testing significance.
\end{quote}

\begin{quote}
\textbf{Example 5: Two ratings}

Fleiss, Levin, and Paik (2003, 612) offers the following hypothetical ratings by different sets of raters on 25 subjects:
\end{quote}

\begin{table}
\centering
\begin{tabular}{cccc}
Subject & No. of raters & No. of pos. ratings & Subject & No. of raters & No. of pos. ratings \\
1 & 2 & 2 & 14 & 4 & 3 \\
2 & 2 & 0 & 15 & 2 & 0 \\
3 & 3 & 2 & 16 & 2 & 2 \\
4 & 4 & 3 & 17 & 3 & 1 \\
5 & 3 & 3 & 18 & 2 & 1 \\
6 & 4 & 1 & 19 & 4 & 1 \\
7 & 3 & 0 & 20 & 5 & 4 \\
8 & 5 & 0 & 21 & 3 & 2 \\
9 & 2 & 0 & 22 & 4 & 0 \\
10 & 4 & 4 & 23 & 3 & 0 \\
11 & 5 & 5 & 24 & 3 & 3 \\
12 & 3 & 3 & 25 & 2 & 2 \\
13 & 4 & 4 \\
\end{tabular}
\end{table}

We have entered these data into Stata, and the variables are called \texttt{subject}, \texttt{raters}, and \texttt{pos}. \texttt{kappa}, however, requires that we specify variables containing the number of positive ratings and negative ratings, that is, \texttt{pos} and \texttt{raters-pos}:

\begin{verbatim}
. use http://www.stata-press.com/data/r13/p612
. gen neg = raters-pos
. kappa pos neg
\end{verbatim}

\begin{table}
\centering
\begin{tabular}{ccc}
Kappa & Z & Prob>Z \\
0.5415 & 5.28 & 0.0000 \\
\end{tabular}
\end{table}
We would have obtained the same results if we had typed `kappa neg pos`.

> **Example 6: More than two ratings, constant number of raters, kappa**

Each of 10 subjects is rated into one of three categories by five raters (Fleiss, Levin, and Paik 2003, 615):

```
. use http://www.stata-press.com/data/r13/p615, clear
. list
```

<table>
<thead>
<tr>
<th>subject</th>
<th>cat1</th>
<th>cat2</th>
<th>cat3</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>4</td>
<td>0</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>0</td>
<td>3</td>
</tr>
<tr>
<td>3</td>
<td>3</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>4</td>
<td>4</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>5</td>
<td>3</td>
<td>2</td>
</tr>
<tr>
<td>6</td>
<td>6</td>
<td>1</td>
<td>4</td>
</tr>
<tr>
<td>7</td>
<td>7</td>
<td>5</td>
<td>0</td>
</tr>
<tr>
<td>8</td>
<td>8</td>
<td>0</td>
<td>4</td>
</tr>
<tr>
<td>9</td>
<td>9</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>10</td>
<td>10</td>
<td>3</td>
<td>0</td>
</tr>
</tbody>
</table>

We obtain the kappa statistic:

```
. kappa cat1-cat3
```

<table>
<thead>
<tr>
<th>Outcome</th>
<th>Kappa</th>
<th>Z</th>
<th>Prob&gt;Z</th>
</tr>
</thead>
<tbody>
<tr>
<td>cat1</td>
<td>0.2917</td>
<td>2.92</td>
<td>0.0018</td>
</tr>
<tr>
<td>cat2</td>
<td>0.6711</td>
<td>6.71</td>
<td>0.0000</td>
</tr>
<tr>
<td>cat3</td>
<td>0.3490</td>
<td>3.49</td>
<td>0.0002</td>
</tr>
<tr>
<td>combined</td>
<td>0.4179</td>
<td>5.83</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

The first part of the output shows the results of calculating kappa for each of the categories separately against an amalgam of the remaining categories. For instance, the `cat1` line is the two-rating kappa, where positive is `cat1` and negative is `cat2` or `cat3`. The test statistic, however, is calculated differently (see *Methods and formulas*). The combined kappa is the appropriately weighted average of the individual kappas. There is considerably less agreement about the rating of subjects into the first category than there is for the second.

> **Example 7: More than two ratings, constant number of raters, kap**

Now suppose that we have the same data as in the previous example but that the data are organized differently:
. use http://www.stata-press.com/data/r13/p615b
. list

<table>
<thead>
<tr>
<th>subject</th>
<th>rater1</th>
<th>rater2</th>
<th>rater3</th>
<th>rater4</th>
<th>rater5</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>1</td>
<td>2</td>
<td>2</td>
<td>2</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>1</td>
<td>1</td>
<td>3</td>
<td>3</td>
</tr>
<tr>
<td>3</td>
<td>3</td>
<td>3</td>
<td>3</td>
<td>3</td>
<td>3</td>
</tr>
<tr>
<td>4</td>
<td>4</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>5</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>3</td>
</tr>
<tr>
<td>6</td>
<td>6</td>
<td>1</td>
<td>2</td>
<td>2</td>
<td>2</td>
</tr>
<tr>
<td>7</td>
<td>7</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>8</td>
<td>8</td>
<td>2</td>
<td>2</td>
<td>2</td>
<td>2</td>
</tr>
<tr>
<td>9</td>
<td>9</td>
<td>1</td>
<td>3</td>
<td>3</td>
<td>3</td>
</tr>
<tr>
<td>10</td>
<td>10</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>3</td>
</tr>
</tbody>
</table>

Here we would use \texttt{kap} rather than \texttt{kappa} because the variables record ratings for each rater.

. kap rater1 rater2 rater3 rater4 rater5
There are 5 raters per subject:

<table>
<thead>
<tr>
<th>Outcome</th>
<th>Kappa</th>
<th>Z</th>
<th>Prob&gt;Z</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0.2917</td>
<td>2.92</td>
<td>0.0018</td>
</tr>
<tr>
<td>2</td>
<td>0.6711</td>
<td>6.71</td>
<td>0.0000</td>
</tr>
<tr>
<td>3</td>
<td>0.3490</td>
<td>3.49</td>
<td>0.0002</td>
</tr>
<tr>
<td>combined</td>
<td>0.4179</td>
<td>5.83</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

It does not matter which rater is which when there are more than two raters.

\section*{Example 8: More than two ratings, varying number of raters, kappa}

In this unfortunate case, kappa can be calculated, but there is no test statistic for testing against $\kappa > 0$. We do nothing differently—\texttt{kappa} calculates the total number of raters for each subject, and, if it is not a constant, \texttt{kappa} suppresses the calculation of test statistics.

. use http://www.stata-press.com/data/r13/rvary
. list

<table>
<thead>
<tr>
<th>subject</th>
<th>cat1</th>
<th>cat2</th>
<th>cat3</th>
</tr>

Note: number of ratings per subject vary; cannot calculate test statistics.
Stored results

\texttt{kap} and \texttt{kappa} store the following in \texttt{r():}

Scalars

\begin{itemize}
\item \texttt{r(N)} — number of subjects (\texttt{kap} only)
\item \texttt{r(prop_o)} — observed proportion of agreement (\texttt{kap} only)
\item \texttt{r(prop_e)} — expected proportion of agreement (\texttt{kap} only)
\item \texttt{r(kappa)} — kappa
\item \texttt{r(z)} — z statistic
\item \texttt{r(se)} — standard error for kappa statistic
\end{itemize}

Methods and formulas

The kappa statistic was first proposed by Cohen (1960). The generalization for weights reflecting the relative seriousness of each possible disagreement is due to Cohen (1968). The analysis-of-variance approach for \(k = 2\) and \(m \geq 2\) is due to Landis and Koch (1977b). See Altman (1991, 403–409) or Dunn (2000, chap. 2) for an introductory treatment and Fleiss, Levin, and Paik (2003, chap. 18) for a more detailed treatment. All formulas below are as presented in Fleiss, Levin, and Paik (2003). Let \(m\) be the number of raters, and let \(k\) be the number of rating outcomes.

Methods and formulas are presented under the following headings:

\begin{itemize}
\item \texttt{kap: m = 2}
\item \texttt{kappa: m > 2, k = 2}
\item \texttt{kappa: m > 2, k > 2}
\end{itemize}

\textbf{kap: m = 2}

Define \(w_{ij}\) \((i = 1, \ldots, k\) and \(j = 1, \ldots, k\)) as the weights for agreement and disagreement (\texttt{wgt()}), or, if the data are not weighted, define \(w_{ii} = 1\) and \(w_{ij} = 0\) for \(i \neq j\). If \texttt{wgt(w)} is specified, \(w_{ij} = 1 - |i - j|/(k - 1)\). If \texttt{wgt(w2)} is specified, \(w_{ij} = 1 - \{(i - j)/(k - 1)\}^2\).

The observed proportion of agreement is

\[ p_o = \sum_{i=1}^{k} \sum_{j=1}^{k} w_{ij} p_{ij} \]

where \(p_{ij}\) is the fraction of ratings \(i\) by the first rater and \(j\) by the second. The expected proportion of agreement is

\[ p_e = \sum_{i=1}^{k} \sum_{j=1}^{k} w_{ij} p_i p_j \]

where \(p_i = \sum_j p_{ij}\) and \(p_j = \sum_i p_{ij}\).

Kappa is given by \(\hat{\kappa} = (p_o - p_e)/(1 - p_e)\).

The standard error of \(\hat{\kappa}\) for testing against 0 is

\[ \hat{s}_0 = \frac{1}{(1 - p_e)\sqrt{n}} \left( \left[ \sum_i \sum_j p_i p_j \{w_{ij} - (\bar{w}_i + \bar{w}_j)\}^2 \right] - p_e^2 \right)^{1/2} \]

where \(n\) is the number of subjects being rated, \(\bar{w}_i = \sum_j p_j w_{ij}\), and \(\bar{w}_j = \sum_i p_i w_{ij}\). The test statistic \(Z = \hat{\kappa}/\hat{s}_0\) is assumed to be distributed \(N(0, 1)\).
**kappa: \( m > 2, k = 2 \)**

Each subject \( i, i = 1, \ldots, n \), is found by \( x_i \) of \( m_i \) raters to be positive (the choice as to what is labeled positive is arbitrary).

The overall proportion of positive ratings is \( \bar{p} = \sum_i x_i / (nm) \), where \( \bar{m} = \sum_i m_i / n \). The between-subjects mean square is (approximately)

\[
B = \frac{1}{n} \sum_i \frac{(x_i - m_i \bar{p})^2}{m_i}
\]

and the within-subject mean square is

\[
W = \frac{1}{n(m - 1)} \sum_i \frac{x_i (m_i - x_i)}{m_i}
\]

Kappa is then defined as

\[
\hat{\kappa} = \frac{B - W}{B + (\bar{m} - 1)W}
\]

The standard error for testing against 0 (Fleiss and Cuzick 1979) is approximately equal to and is calculated as

\[
\hat{s}_0 = \frac{1}{(\bar{m} - 1)\sqrt{n \bar{m} \bar{H}}} \left \{ 2(\bar{m}_H - 1) + \frac{(\bar{m} - \bar{m}_H)(1 - 4pq)}{mpq} \right \}^{1/2}
\]

where \( \bar{m}_H \) is the harmonic mean of \( m_i \) and \( \bar{q} = 1 - \bar{p} \).

The test statistic \( Z = \hat{\kappa} / \hat{s}_0 \) is assumed to be distributed \( N(0, 1) \).

**kappa: \( m > 2, k > 2 \)**

Let \( x_{ij} \) be the number of ratings on subject \( i, i = 1, \ldots, n \), into category \( j, j = 1, \ldots, k \). Define \( \bar{p}_j \) as the overall proportion of ratings in category \( j \), \( \bar{q}_j = 1 - \bar{p}_j \), and let \( \hat{\kappa}_j \) be the kappa statistic given above for \( k = 2 \) when category \( j \) is compared with the amalgam of all other categories. Kappa is

\[
\kappa = \sum_j \frac{\bar{p}_j \bar{q}_j \hat{\kappa}_j}{\sum_j \bar{p}_j \bar{q}_j}
\]

(Landis and Koch 1977b). In the case where the number of raters per subject, \( \sum_j x_{ij} \), is a constant \( m \) for all \( i \), Fleiss, Nee, and Landis (1979) derived the following formulas for the approximate standard errors. The standard error for testing \( \hat{\kappa}_j \) against 0 is

\[
\hat{s}_j = \left \{ \frac{2}{nm(m - 1)} \right \}^{1/2}
\]
and the standard error for testing $\kappa$ is

$$\bar{\kappa} = \frac{\sqrt{2}}{\sum_j \bar{p}_j \bar{q}_j \sqrt{nm(m-1)}} \left\{ \left( \sum_j \bar{p}_j \bar{q}_j \right)^2 - \sum_j \bar{p}_j \bar{q}_j (\bar{q}_j - \bar{p}_j) \right\}^{1/2}$$

Statistics > Nonparametric analysis > Kernel density estimation

Description

kdensity produces kernel density estimates and graphs the result.

Options

\textbf{Main}

\texttt{kernel}(<\texttt{kernel}>): specifies the kernel function for use in calculating the kernel density estimate. The default kernel is the Epanechnikov kernel (\texttt{epanechnikov}).

\texttt{bwidth}(\#): specifies the half-width of the kernel, the width of the density window around each point. If \texttt{bwidth()} is not specified, the “optimal” width is calculated and used. The optimal width is the width that would minimize the mean integrated squared error if the data were Gaussian and a Gaussian kernel were used, so it is not optimal in any global sense. In fact, for multimodal and highly skewed densities, this width is usually too wide and oversmooths the density (Silverman 1992).

\texttt{generate}(\texttt{newvar}_x \texttt{newvar}_d): stores the results of the estimation. \texttt{newvar}_x will contain the points at which the density is estimated. \texttt{newvar}_d will contain the density estimate.

\texttt{n}(\#): specifies the number of points at which the density estimate is to be evaluated. The default is min\((N, 50)\), where \(N\) is the number of observations in memory.

\texttt{at}(\texttt{var}_x): specifies a variable that contains the values at which the density should be estimated. This option allows you to more easily obtain density estimates for different variables or different subsamples of a variable and then overlay the estimated densities for comparison.

\texttt{nograph} suppresses the graph. This option is often used with the \texttt{generate()} option.

\textbf{Kernel plot}

\texttt{cline_options} affect the rendition of the plotted kernel density estimate. See [G-3] \texttt{cline_options}.

\textbf{Density plots}

\texttt{normal} requests that a normal density be overlaid on the density estimate for comparison.

\texttt{normopts}(\texttt{cline_options}) specifies details about the rendition of the normal curve, such as the color and style of line used. See [G-3] \texttt{cline_options}.

\texttt{student}(\#) specifies that a Student’s \(t\) density with \# degrees of freedom be overlaid on the density estimate for comparison.

\texttt{stopts}(\texttt{cline_options}) affects the rendition of the Student’s \(t\) density. See [G-3] \texttt{cline_options}.

\textbf{Add plots}

\texttt{addplot}(\texttt{plot}) provides a way to add other plots to the generated graph. See [G-3] \texttt{addplot_option}.
Remarks and examples

Kernel density estimators approximate the density \( f(x) \) from observations on \( x \). Histograms do this, too, and the histogram itself is a kind of kernel density estimate. The data are divided into nonoverlapping intervals, and counts are made of the number of data points within each interval. Histograms are bar graphs that depict these frequency counts—the bar is centered at the midpoint of each interval—and its height reflects the average number of data points in the interval.

In more general kernel density estimates, the range is still divided into intervals, and estimates of the density at the center of intervals are produced. One difference is that the intervals are allowed to overlap. We can think of sliding the interval—called a window—along the range of the data and collecting the center-point density estimates. The second difference is that, rather than merely counting the number of observations in a window, a kernel density estimator assigns a weight between 0 and 1—based on the distance from the center of the window—and sums the weighted values. The function that determines these weights is called the kernel.

Kernel density estimates have the advantages of being smooth and of being independent of the choice of origin (corresponding to the location of the bins in a histogram).

See Salgado-Ugarte, Shimizu, and Taniuchi (1993) and Fox (1990) for discussions of kernel density estimators that stress their use as exploratory data-analysis tools.

Cox (2007) gives a lucid introductory tutorial on kernel density estimation with several Stata produced examples. He provides tips and tricks for working with skewed or bounded distributions and applying the same techniques to estimate the intensity function of a point process.

Example 1: Histogram and kernel density estimate

Goeden (1978) reports data consisting of 316 length observations of coral trout. We wish to investigate the underlying density of the lengths. To begin on familiar ground, we might draw a histogram. In [R] histogram, we suggest setting the bins to \( \min(\sqrt{n}, 10 \cdot \log_{10} n) \), which for \( n = 316 \) is roughly 18:
The kernel density estimate, on the other hand, is smooth.

```
. kdensity length
```

Kernel density estimators are, however, sensitive to an assumption, just as are histograms. In histograms, we specify a number of bins. For kernel density estimators, we specify a width. In the graph above, we used the default width. `kdensity` is smarter than `twoway histogram` in that its default width is not a fixed constant. Even so, the default width is not necessarily best.

`kdensity` stores the width in the returned scalar `bwidth`, so typing `display r(bwidth)` reveals it. Doing this, we discover that the width is approximately 20.

Widths are similar to the inverse of the number of bins in a histogram in that smaller widths provide more detail. The units of the width are the units of \( x \), the variable being analyzed. The width is specified as a half-width, meaning that the kernel density estimator with half-width 20 corresponds to sliding a window of size 40 across the data.
We can specify half-widths for ourselves by using the `bwidth()` option. Smaller widths do not smooth the density as much:

```
. kdensity length, bwidth(10)
```

![Kernel density estimate with bwidth(10)](image)

```
. kdensity length, bwidth(15)
```

![Kernel density estimate with bwidth(15)](image)

**Example 2: Different kernels can produce different results**

When widths are held constant, different kernels can produce surprisingly different results. This is really an attribute of the kernel and width combination; for a given width, some kernels are more sensitive than others at identifying peaks in the density estimate.

We can see this when using a dataset with lots of peaks. In the automobile dataset, we characterize the density of `weight`, the weight of the vehicles. Below we compare the Epanechnikov and Parzen kernels.
We did not specify a width, so we obtained the default width. That width is not a function of the selected kernel, but of the data. See Methods and formulas for the calculation of the optimal width.

Example 3: Density with overlaid normal density

In examining the density estimates, we may wish to overlay a normal density or a Student’s \( t \) density for comparison. Using automobile weights, we can get an idea of the distance from normality by using the normal option.

. kdensity weight, kernel(epanechnikov) normal
Example 4: Compare two densities

We also may want to compare two or more densities. In this example, we will compare the density estimates of the weights for the foreign and domestic cars.

```
. use http://www.stata-press.com/data/r13/auto, clear
   (1978 Automobile Data)
. kdensity weight, nograph generate(x fx)
. kdensity weight if foreign==0, nograph generate(fx0) at(x)
. kdensity weight if foreign==1, nograph generate(fx1) at(x)
. label var fx0 "Domestic cars"
. label var fx1 "Foreign cars"
. line fx0 fx1 x, sort ytitle(Density)
```

![Graph comparing foreign and domestic car weights](image)

Technical note

Although all the examples we included had densities of less than 1, the density may exceed 1.

The probability density $f(x)$ of a continuous variable, $x$, has the units and dimensions of the reciprocal of $x$. If $x$ is measured in meters, $f(x)$ has units $1$/meter. Thus the density is not measured on a probability scale, so it is possible for $f(x)$ to exceed 1.

To see this, think of a uniform density on the interval 0 to 1. The area under the density curve is 1: this is the product of the density, which is constant at 1, and the range, which is 1. If the variable is then transformed by doubling, the area under the curve remains 1 and is the product of the density, constant at 0.5, and the range, which is 2. Conversely, if the variable is transformed by halving, the area under the curve also remains at 1 and is the product of the density, constant at 2, and the range, which is 0.5. (Strictly, the range is measured in certain units, and the density is measured in the reciprocal of those units, so the units cancel on multiplication.)
stored results

kdensity stores the following in r():

Scalars
- r(bwidth) kernel bandwidth
- r(n) number of points at which the estimate was evaluated
- r(scale) density bin width

Macros
- r(kernel) name of kernel

methods and formulas

A kernel density estimate is formed by summing the weighted values calculated with the kernel function $K$, as in

$$\hat{f}_K = \frac{1}{qh} \sum_{i=1}^{n} w_i K \left( \frac{x - X_i}{h} \right)$$

where $q = \sum_i w_i$ if weights are frequency weights (fweight) or analytic weights (aweight), and $q = 1$ if weights are importance weights (iweights). Analytic weights are rescaled so that $\sum_i w_i = n$ (see [U] 11 Language syntax). If weights are not used, then $w_i = 1$, for $i = 1, \ldots, n$. kdensity includes seven different kernel functions. The Epanechnikov is the default function if no other kernel is specified and is the most efficient in minimizing the mean integrated squared error.

<table>
<thead>
<tr>
<th>Kernel</th>
<th>Formula</th>
</tr>
</thead>
</table>
| Biweight  | $K[z] = \begin{cases} 
\frac{15}{16} (1 - z^2)^2 & \text{if } |z| < 1 \\
0 & \text{otherwise} 
\end{cases}$ |
| Cosine    | $K[z] = \begin{cases}

0 & \text{otherwise} 
\end{cases}$ |
| Epan2     | $K[z] = \begin{cases} 
\frac{3}{4} (1 - z^2) & \text{if } |z| < 1 \\
0 & \text{otherwise} 
\end{cases}$ |
| Gaussian  | $K[z] = \frac{1}{\sqrt{2\pi}} e^{-z^2/2}$ |
| Parzen    | $K[z] = \begin{cases} 
\frac{4}{3} - 8z^2 + 8|z|^3 & \text{if } |z| \leq 1/2 \\
8(1 - |z|)^3 / 3 & \text{if } 1/2 < |z| \leq 1 \\
0 & \text{otherwise} 
\end{cases}$ |
| Rectangular | $K[z] = \begin{cases} 
1/2 & \text{if } |z| < 1 \\
0 & \text{otherwise} 
\end{cases}$ |
| Triangular | $K[z] = \begin{cases} 
1 - |z| & \text{if } |z| < 1 \\
0 & \text{otherwise} 
\end{cases}$ |

From the definitions given in the table, we can see that the choice of $h$ will drive how many values are included in estimating the density at each point. This value is called the window width or bandwidth. If the window width is not specified, it is determined as...
\[ m = \min\left(\sqrt{\text{variance}_x}, \frac{\text{interquartile range}_x}{1.349}\right) \]

\[ h = \frac{0.9m}{n^{1/5}} \]

where \( x \) is the variable for which we wish to estimate the kernel and \( n \) is the number of observations.

Most researchers agree that the choice of kernel is not as important as the choice of bandwidth. There is a great deal of literature on choosing bandwidths under various conditions; see, for example, Parzen (1962) or Tapia and Thompson (1978). Also see Newton (1988) for a comparison with sample spectral density estimation in time-series applications.

Acknowledgments

We gratefully acknowledge the previous work by Isaías H. Salgado-Ugarte of Universidad Nacional Autónoma de México, and Makoto Shimizu and Toru Taniuchi of the University of Tokyo; see Salgado-Ugarte, Shimizu, and Taniuchi (1993). Their article provides a good overview of the subject of univariate kernel density estimation and presents arguments for its use in exploratory data analysis.

[R] *histogram* — Histograms for continuous and categorical variables
ksmirnov — Kolmogorov–Smirnov equality-of-distributions test

Syntax

One-sample Kolmogorov–Smirnov test

```
ksmirnov varname = exp [if] [in]
```

Two-sample Kolmogorov–Smirnov test

```
ksmirnov varname [if] [in], by(groupvar) [ exact ]
```

Menu

Statistics > Nonparametric analysis > Tests of hypotheses > Kolmogorov-Smirnov test

Description

ksmirnov performs one- and two-sample Kolmogorov–Smirnov tests of the equality of distributions. In the first syntax, varname is the variable whose distribution is being tested, and exp must evaluate to the corresponding (theoretical) cumulative. In the second syntax, groupvar must take on two distinct values. The distribution of varname for the first value of groupvar is compared with that of the second value.

When testing for normality, please see [R] sktest and [R] swilk.

Options for two-sample test

by(groupvar) is required. It specifies a binary variable that identifies the two groups.

exact specifies that the exact p-value be computed. This may take a long time if n > 50.

Remarks and examples

> Example 1: Two-sample test

Say that we have data on x that resulted from two different experiments, labeled as group==1 and group==2. Our data contain

1012
We wish to use the two-sample Kolmogorov–Smirnov test to determine if there are any differences in the distribution of \( x \) for these two groups:

```
ksmirnov x, by(group)
```

Two-sample Kolmogorov-Smirnov test for equality of distribution functions

<table>
<thead>
<tr>
<th>Smaller group</th>
<th>D</th>
<th>P-value</th>
<th>Corrected</th>
</tr>
</thead>
<tbody>
<tr>
<td>1:</td>
<td>0.5000</td>
<td>0.424</td>
<td></td>
</tr>
<tr>
<td>2:</td>
<td>-0.1667</td>
<td>0.909</td>
<td></td>
</tr>
<tr>
<td>Combined K-S:</td>
<td>0.5000</td>
<td>0.785</td>
<td>0.735</td>
</tr>
</tbody>
</table>

The first line tests the hypothesis that \( x \) for group 1 contains smaller values than for group 2. The largest difference between the distribution functions is 0.5. The approximate \( p \)-value for this is 0.424, which is not significant.

The second line tests the hypothesis that \( x \) for group 1 contains larger values than for group 2. The largest difference between the distribution functions in this direction is 0.1667. The approximate \( p \)-value for this small difference is 0.909.

Finally, the approximate \( p \)-value for the combined test is 0.785, corrected to 0.735. The \( p \)-values \( ksmirnov \) calculates are based on the asymptotic distributions derived by Smirnov (1933). These approximations are not good for small samples (\( n < 50 \)). They are too conservative—real \( p \)-values tend to be substantially smaller. We have also included a less conservative approximation for the nondirectional hypothesis based on an empirical continuity correction—the 0.735 reported in the third column.

That number, too, is only an approximation. An exact value can be calculated using the `exact` option:

```
ksmirnov x, by(group) exact
```

Two-sample Kolmogorov-Smirnov test for equality of distribution functions

<table>
<thead>
<tr>
<th>Smaller group</th>
<th>D</th>
<th>P-value</th>
<th>Exact</th>
</tr>
</thead>
<tbody>
<tr>
<td>1:</td>
<td>0.5000</td>
<td>0.424</td>
<td></td>
</tr>
<tr>
<td>2:</td>
<td>-0.1667</td>
<td>0.909</td>
<td></td>
</tr>
<tr>
<td>Combined K-S:</td>
<td>0.5000</td>
<td>0.785</td>
<td>0.657</td>
</tr>
</tbody>
</table>

Example 2: One-sample test

Let’s now test whether \( x \) in the example above is distributed normally. Kolmogorov–Smirnov is not a particularly powerful test in testing for normality, and we do not endorse such use of it; see [R] `sktest` and [R] `swilk` for better tests.
In any case, we will test against a normal distribution with the same mean and standard deviation:

\[
\text{. summarize x}
\]

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>7</td>
<td>4.571429</td>
<td>3.457222</td>
<td>0</td>
<td>10</td>
</tr>
</tbody>
</table>

\[
\text{. ksmirnov x = normal((x-4.571429)/3.457222)}
\]

One-sample Kolmogorov-Smirnov test against theoretical distribution

\[
\text{normal((x-4.571429)/3.457222)}
\]

<table>
<thead>
<tr>
<th>Smaller group</th>
<th>D</th>
<th>P-value</th>
<th>Corrected</th>
</tr>
</thead>
<tbody>
<tr>
<td>x:</td>
<td>0.1650</td>
<td>0.683</td>
<td></td>
</tr>
<tr>
<td>Cumulative:</td>
<td>-0.1250</td>
<td>0.803</td>
<td></td>
</tr>
<tr>
<td>Combined K-S:</td>
<td>0.1650</td>
<td>0.991 0.978</td>
<td></td>
</tr>
</tbody>
</table>

Because Stata has no way of knowing that we based this calculation on the calculated mean and standard deviation of \( x \), the test statistics will be slightly conservative in addition to being approximations. Nevertheless, they clearly indicate that the data cannot be distinguished from normally distributed data.

\[
\text{Stored results}

Macros

- \( r(group1) \) = name of group from line 1
- \( r(group2) \) = name of group from line 2

Methods and formulas

In general, the Kolmogorov–Smirnov test (Kolmogorov 1933; Smirnov 1933; also see Conover [1999], 428–465) is not very powerful against differences in the tails of distributions. In return for this, it is fairly powerful for alternative hypotheses that involve lumpiness or clustering in the data.

The directional hypotheses are evaluated with the statistics

\[
D^+ = \max_x \left\{ F(x) - G(x) \right\}
\]

\[
D^- = \min_x \left\{ F(x) - G(x) \right\}
\]

where \( F(x) \) and \( G(x) \) are the empirical distribution functions for the sample being compared. The combined statistic is

\[
D = \max \left( |D^+|, |D^-| \right)
\]

The \( p \)-value for this statistic may be obtained by evaluating the asymptotic limiting distribution. Let \( m \) be the sample size for the first sample, and let \( n \) be the sample size for the second sample. Smirnov (1933) shows that
\[
\lim_{m,n \to \infty} \Pr\left\{ \sqrt{\frac{mn}{m+n}} D_{m,n} \leq z \right\} = 1 - 2 \sum_{i=1}^{\infty} (-1)^{i-1} \exp \left( -2i^2 z^2 \right)
\]

The first five terms form the approximation \(P_a\) used by Stata. The exact \(p\)-value is calculated by a counting algorithm; see Gibbons and Chakraborti (2011, 236–238). A corrected \(p\)-value was obtained by modifying the asymptotic \(p\)-value by using a numerical approximation technique:

\[
Z = \Phi^{-1}(P_a) + 1.04/\min(m, n) + 2.09/\max(m, n) - 1.35/\sqrt{mn/(m+n)}
\]

\(p\)-value = \(\Phi(Z)\)

where \(\Phi(\cdot)\) is the cumulative normal distribution.

Andrei Nikolayevich Kolmogorov (1903–1987), of Russia, was one of the great mathematicians of the twentieth century, making outstanding contributions in many different branches, including set theory, measure theory, probability and statistics, approximation theory, functional analysis, classical dynamics, and theory of turbulence. He was a faculty member at Moscow State University for more than 60 years.

Nikolai Vasilevich Smirnov (1900–1966) was a Russian statistician whose work included contributions in nonparametric statistics, order statistics, and goodness of fit. After army service and the study of philosophy and philology, he turned to mathematics and eventually rose to be head of mathematical statistics at the Steklov Mathematical Institute in Moscow.

Title

**kwallis — Kruskal–Wallis equality-of-populations rank test**

**Syntax**

```stata
kwallis varname [if] [in], by(groupvar)
```

**Menu**

Statistics > Nonparametric analysis > Tests of hypotheses > Kruskal-Wallis rank test

**Description**

`kwallis` tests the hypothesis that several samples are from the same population. In the syntax diagram above, `varname` refers to the variable recording the outcome, and `groupvar` refers to the variable denoting the population. `by()` is required.

**Option**

`by(groupvar)` is required. It specifies a variable that identifies the groups.

**Remarks and examples**

> Example 1

We have data on the 50 states. The data contain the median age of the population, `medage`, and the region of the country, `region`, for each state. We wish to test for the equality of the median age distribution across all four regions simultaneously:

```stata
. use http://www.stata-press.com/data/r13/census
(1980 Census data by state)
. kwallis medage, by(region)
Kruskal-Wallis equality-of-populations rank test
```

<table>
<thead>
<tr>
<th>region</th>
<th>Obs</th>
<th>Rank Sum</th>
</tr>
</thead>
<tbody>
<tr>
<td>NE</td>
<td>9</td>
<td>376.50</td>
</tr>
<tr>
<td>N Cntrl</td>
<td>12</td>
<td>294.00</td>
</tr>
<tr>
<td>South</td>
<td>16</td>
<td>398.00</td>
</tr>
<tr>
<td>West</td>
<td>13</td>
<td>206.50</td>
</tr>
</tbody>
</table>

chi-squared = 17.041 with 3 d.f.
probability = 0.0007

chi-squared with ties = 17.062 with 3 d.f.
probability = 0.0007
From the output, we see that we can reject the hypothesis that the populations are the same at any level below 0.07%.

**Stored results**

`kwallis` stores the following in `r()`:

Scalars
- `r(df)` degrees of freedom
- `r(chi2)` $\chi^2$
- `r(chi2_adj)` $\chi^2$ adjusted for ties

**Methods and formulas**

The Kruskal–Wallis test (Kruskal and Wallis 1952, 1953; also see Altman [1991, 213–215]; Conover [1999, 288–297]; and Riffenburgh [2012, sec. 11.6]) is a multiple-sample generalization of the two-sample Wilcoxon (also called Mann–Whitney) rank sum test (Wilcoxon 1945; Mann and Whitney 1947). Samples of sizes $n_j$, $j = 1, \ldots, m$, are combined and ranked in ascending order of magnitude. Tied values are assigned the average ranks. Let $n$ denote the overall sample size, and let $R_j = \sum_{i=1}^{n_j} R(X_{ji})$ denote the sum of the ranks for the $j$th sample. The Kruskal–Wallis one-way analysis-of-variance test, $H$, is defined as

$$H = \frac{1}{S^2} \left\{ \sum_{j=1}^{m} \frac{R_j^2}{n_j} - \frac{n(n+1)^2}{4} \right\}$$

where

$$S^2 = \frac{1}{n-1} \left\{ \sum_{\text{all ranks}} R(X_{ji})^2 - \frac{n(n+1)^2}{4} \right\}$$

If there are no ties, this equation simplifies to

$$H = \frac{12}{n(n+1)} \sum_{j=1}^{m} \frac{R_j^2}{n_j} - 3(n+1)$$

The sampling distribution of $H$ is approximately $\chi^2$ with $m - 1$ degrees of freedom.

**William Henry Kruskal** (1919–2005) was born in New York City. He studied mathematics and statistics at Antioch College, Harvard, and Columbia, and joined the University of Chicago in 1951. He made many outstanding contributions to linear models, nonparametric statistics, government statistics, and the history and methodology of statistics.

**Wilson Allen Wallis** (1912–1998) was born in Philadelphia. He studied psychology and economics at the Universities of Minnesota and Chicago and at Columbia. He taught at Yale, Stanford, and Chicago, before moving as president (later chancellor) to the University of Rochester in 1962. He also served in several Republican administrations. Wallis served as editor of the *Journal of the American Statistical Association*, coauthored a popular introduction to statistics, and contributed to nonparametric statistics.

ladder — Ladder of powers

Syntax

Ladder of powers

\[ \text{ladder } \varname [ \text{if} ] [ \text{in} ] [ , \text{generate(newvar) noadjust} ] \]

Ladder-of-powers histograms

\[ \text{gladder } \varname [ \text{if} ] [ \text{in} ] [ , \text{histogram_options combine_options} ] \]

Ladder-of-powers quantile–normal plots

\[ \text{qladder } \varname [ \text{if} ] [ \text{in} ] [ , \text{qnorm_options combine_options} ] \]

by is allowed with \text{ladder}; see \text{[D] by}.

Menu

ladder
Statistics > Summaries, tables, and tests > Distributional plots and tests > Ladder of powers

gladder
Statistics > Summaries, tables, and tests > Distributional plots and tests > Ladder-of-powers histograms

qladder
Statistics > Summaries, tables, and tests > Distributional plots and tests > Ladder-of-powers quantile-normal plots

Description

\text{ladder} searches a subset of the ladder of powers (Tukey 1977) for a transform that converts \varname into a normally distributed variable. \text{sktest} tests for normality; see \text{[R] sktest}. Also see \text{[R] boxcox}.

\text{gladder} displays nine histograms of transforms of \varname according to the ladder of powers. \text{gladder} is useful pedagogically, but we do not advise looking at histograms for research work; \text{ladder} or \text{qnorm} (see \text{[R] diagnostic plots}) is preferred.

\text{qladder} displays the quantiles of transforms of \varname according to the ladder of powers against the quantiles of a normal distribution.
Options for ladder

`generate(newvar)` saves the transformed values corresponding to the minimum chi-squared value from the table. We do not recommend using `generate()` because it is literal in interpreting the minimum, thus ignoring nearly equal but perhaps more interpretable transforms.

`noadjust` is the `noadjust` option to `sktest`; see `[R] sktest`.

Options for gladder

`histogram_options` affect the rendition of the histograms across all relevant transformations; see `[R] histogram`. Here the `normal` option is assumed, so you must supply the `nonormal` option to suppress the overlaid normal density. Also, `gladder` does not allow the `width(#)` option of `histogram`.

`combine_options` are any of the options documented in `[G-2] graph combine`. These include options for titling the graph (see `[G-3] title_options`) and for saving the graph to disk (see `[G-3] saving_option`).

Options for qladder

`qnorm_options` affect the rendition of the quantile–normal plots across all relevant transformations. See `[R] diagnostic plots`.

`combine_options` are any of the options documented in `[G-2] graph combine`. These include options for titling the graph (see `[G-3] title_options`) and for saving the graph to disk (see `[G-3] saving_option`).

Remarks and examples

Example 1: ladder

We have data on the mileage rating of 74 automobiles and wish to find a transform that makes the variable normally distributed:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. ladder mpg
```

<table>
<thead>
<tr>
<th>Transformation</th>
<th>formula</th>
<th>chi2(2)</th>
<th>P(chi2)</th>
</tr>
</thead>
<tbody>
<tr>
<td>cubic</td>
<td>mpg^3</td>
<td>43.59</td>
<td>0.000</td>
</tr>
<tr>
<td>square</td>
<td>mpg^2</td>
<td>27.03</td>
<td>0.000</td>
</tr>
<tr>
<td>identity</td>
<td>mpg</td>
<td>10.95</td>
<td>0.004</td>
</tr>
<tr>
<td>square root</td>
<td>sqrt(mpg)</td>
<td>4.94</td>
<td>0.084</td>
</tr>
<tr>
<td>log</td>
<td>log(mpg)</td>
<td>0.87</td>
<td>0.647</td>
</tr>
<tr>
<td>1/(square root)</td>
<td>1/sqrt(mpg)</td>
<td>0.20</td>
<td>0.905</td>
</tr>
<tr>
<td>inverse</td>
<td>1/mpg</td>
<td>2.36</td>
<td>0.307</td>
</tr>
<tr>
<td>1/square</td>
<td>1/(mpg^2)</td>
<td>11.99</td>
<td>0.002</td>
</tr>
<tr>
<td>1/cubic</td>
<td>1/(mpg^3)</td>
<td>24.30</td>
<td>0.000</td>
</tr>
</tbody>
</table>

If we had typed `ladder mpg, gen(mpgx)`, the variable `mpgx` containing $1/\sqrt{\text{mpg}}$ would have been automatically generated for us. This is the perfect example of why you should not, in general, specify the `generate()` option. We also cannot reject the hypothesis that the inverse of `mpg` is normally distributed and that $1/\text{mpg}$—gallons per mile—has a better interpretation. It is a measure of energy consumption.
Example 2: gladder

gladder explores the same transforms as ladder but presents results graphically:

```
.gladder mpg, fraction
```

Histograms by transformation

Technical note

gladder is useful pedagogically, but be careful when using it for research work, especially with many observations. For instance, consider the following data on the average July temperature in degrees Fahrenheit for 954 U.S. cities:

```
.use http://www.stata-press.com/data/r13/citytemp
(City Temperature Data)
.ladder tempjuly
```

<table>
<thead>
<tr>
<th>Transformation</th>
<th>formula</th>
<th>chi2(2)</th>
<th>P(chi2)</th>
</tr>
</thead>
<tbody>
<tr>
<td>cubic</td>
<td>tempjuly^3</td>
<td>47.49</td>
<td>0.000</td>
</tr>
<tr>
<td>square</td>
<td>tempjuly^2</td>
<td>19.70</td>
<td>0.000</td>
</tr>
<tr>
<td>identity</td>
<td>tempjuly</td>
<td>3.83</td>
<td>0.147</td>
</tr>
<tr>
<td>square root</td>
<td>sqrt(tempjuly)</td>
<td>1.83</td>
<td>0.400</td>
</tr>
<tr>
<td>log</td>
<td>log(tempjuly)</td>
<td>5.40</td>
<td>0.067</td>
</tr>
<tr>
<td>1/(square root)</td>
<td>1/sqrt(tempjuly)</td>
<td>13.72</td>
<td>0.001</td>
</tr>
<tr>
<td>inverse</td>
<td>1/tempjuly</td>
<td>26.36</td>
<td>0.000</td>
</tr>
<tr>
<td>1/square</td>
<td>1/(tempjuly^2)</td>
<td>64.43</td>
<td>0.000</td>
</tr>
<tr>
<td>1/cubic</td>
<td>1/(tempjuly^3)</td>
<td>.</td>
<td>0.000</td>
</tr>
</tbody>
</table>

The period in the last line indicates that the $\chi^2$ is very large; see [R] sktest.
From the table, we see that there is certainly a difference in normality between the square and square-root transform. If, however, you can see the difference between the transforms in the diagram below, you have better eyes than we do:

```
. gladder tempjuly, ltitle("") ylabel(none) xlabel(none)
```

![Histograms by transformation](image)

**Average July temperature**

**Example 3: qladder**

A better graph for seeing normality is the quantile–normal graph, which can be produced by `qladder`. 

---

**ladder — Ladder of powers**

- Cubic
- Square
- Identity
- Square-root
- Log
- Inverse
- 1/Square
- 1/Cubic

---

**Histograms by transformation**
This graph shows that for the square transform, the upper tail—and only the upper tail—diverges from what would be expected. This divergence is detected by `sktest` (see [R] `sktest`) as a problem with skewness, as we would learn from using `sktest` to examine `tempjuly` squared and square rooted.
Stored results

`ladder` stores the following in r():

Scalars

- `r(N)` number of observations
- `r(invcube)` χ² for inverse-cubic transformation
- `r(P_invcube)` significance level for inverse-cubic transformation
- `r(invsq)` χ² for inverse-square transformation
- `r(P_invsq)` significance level for inverse-square transformation
- `r(inv)` χ² for inverse transformation
- `r(P_inv)` significance level for inverse transformation
- `r(invsqrt)` χ² for inverse-root transformation
- `r(P_invsqrt)` significance level for inverse-root transformation
- `r(log)` χ² for log transformation
- `r(P_log)` significance level for log transformation
- `r(sqrt)` χ² for square-root transformation
- `r(P_sqrt)` significance level for square-root transformation
- `r(ident)` χ² for untransformed data
- `r(P_ident)` significance level for untransformed data
- `r(square)` χ² for square transformation
- `r(P_square)` significance level for square transformation
- `r(cube)` χ² for cubic transformation
- `r(P_cube)` significance level for cubic transformation

Methods and formulas

For `ladder`, results are as reported by `sktest`; see [R] `sktest`. If `generate()` is specified, the transform with the minimum χ² value is chosen.

`gladder` sets the number of bins to \( \min(\sqrt{n}, 10 \log_{10} n) \), rounded to the closest integer, where \( n \) is the number of unique values of `varname`. See [R] `histogram` for a discussion of the optimal number of bins.

Also see Findley (1990) for a ladder-of-powers variable transformation program that produces one-way graphs with overlaid box plots, in addition to histograms with overlaid normals. Buchner and Findley (1990) discuss ladder-of-powers transformations as one aspect of preliminary data analysis. Also see Hamilton (1992, 18–23) and Hamilton (2013, 129–132).

Acknowledgment

`qladder` was written by Jeroen Weesie of the Department of Sociology at Utrecht University, The Netherlands.

**Title**

*level — Set default confidence level*

### Syntax

```
set level # [, permanently]
```

### Description

`set level` specifies the default confidence level for confidence intervals for all commands that report confidence intervals. The initial value is 95, meaning 95% confidence intervals. # may be between 10.00 and 99.99, and # can have at most two digits after the decimal point.

### Option

`permanently` specifies that, in addition to making the change right now, the level setting be remembered and become the default setting when you invoke Stata.

### Remarks and examples

To change the level of confidence intervals reported by a particular command, you need not reset the default confidence level. All commands that report confidence intervals have a `level(#)` option. When you do not specify the option, the confidence intervals are calculated for the default level set by `set level`, or for 95% if you have not reset `set level`.

#### Example 1

We use the `ci` command to obtain the confidence interval for the mean of `mpg`:

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. ci mpg
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6725511</td>
<td>19.9569 22.63769</td>
</tr>
</tbody>
</table>

To obtain 90% confidence intervals, we would type

```
. ci mpg, level(90)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[90% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6725511</td>
<td>20.17683 22.41776</td>
</tr>
</tbody>
</table>

or

```
. set level 90
. ci mpg
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[90% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6725511</td>
<td>20.17683 22.41776</td>
</tr>
</tbody>
</table>

1026
If we opt for the second alternative, the next time that we fit a model (say, with `regress`), 90% confidence intervals will be reported. If we wanted 95% confidence intervals, we could specify `level(95)` on the estimation command, or we could reset the default by typing `set level 95`.

The current setting of `level()` is stored as the c-class value `c(level)`; see [P] `creturn`.

</tbody>
</table>

1. $2,147,483,647$ is a theoretical maximum; memory availability will certainly impose a smaller maximum.

2. The maximum length of the contents of a macro are fixed in Stata/IC and settable in Stata/SE and Stata/MP. The currently set maximum length is recorded in `c(macrolen)`; type `display c(macrolen)`. The maximum length can be changed with `set maxvar`. If you set `maxvar` to a larger value, the maximum length increases; if you set `maxvar` to a smaller value, the maximum length decreases. The relationship between them is $\text{maximum length} = 33 \times \text{maxvar} + 200$.

3. In Mata, matrices are limited only by the amount of memory on your computer.
Matrix size

See [R] matsize.

Determining which flavor of Stata you are running

Type

```
   . about
```

The response will be Stata/MP, Stata/SE, Stata/IC, or Small Stata. Other information is also shown, including your serial number. See [R] about.

Syntax

\[ \text{lincom } \exp \left[ , \text{options} \right] \]

\begin{tabular}{ll}
\textit{options} & Description \\
\hline 
\textit{eform} & generic label; \( \exp(\hat{b}) \)  \\
or & odds ratio  \\
h\text{r} & hazard ratio  \\
shr & subhazard ratio  \\
irr & incidence-rate ratio  \\
rrr & relative-risk ratio  \\
level(#) & set confidence level; default is \texttt{level(95)}  \\
display\_options & control column formats  \\
df(#) & use \( t \) distribution with \# degrees of freedom for computing \( p \)-values and confidence intervals  \\
\end{tabular}

\( \exp \) is any linear combination of coefficients that is a valid syntax for \texttt{test}; see [\texttt{R} \texttt{test}]. \( \exp \) must not contain an equal sign.

\texttt{df(#) does not appear in the dialog box.}

Menu

Statistics > Postestimation > Linear combinations of estimates

Description

\texttt{lincom} computes point estimates, standard errors, \( t \) or \( z \) statistics, \( p \)-values, and confidence intervals for linear combinations of coefficients after any estimation command. Results can optionally be displayed as odds ratios, hazard ratios, incidence-rate ratios, or relative-risk ratios.

\texttt{lincom} can be used with \texttt{svy} estimation results; see [\texttt{SVY}] \texttt{svy postestimation}.

Options

\texttt{eform}, \texttt{or}, \texttt{hr}, \texttt{shr}, \texttt{irr}, and \texttt{rrr} all report coefficient estimates as \( \exp(\hat{\beta}) \) rather than \( \hat{\beta} \). Standard errors and confidence intervals are similarly transformed. \texttt{or} is the default after \texttt{logistic}. The only difference in these options is how the output is labeled.
### Option Label Explanation Example commands

<table>
<thead>

<td>RRR</td>
<td>Relative-risk ratio</td>
<td>mlogit</td>
</tr>
</tbody>
</table>

exp may not contain any additive constants when you use the eform, or, hr, irr, or rrr option.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

display_options: cformat(%,fmt), pformat(%,fmt), and sformat(%,fmt); see [R] estimation options.

The following option is available with lincom but is not shown in the dialog box:

df(#) specifies that the t distribution with # degrees of freedom be used for computing p-values and confidence intervals. The default is to use e(df_r) degrees of freedom or the standard normal distribution if e(df_r) is missing.

## Remarks and examples

Remarks are presented under the following headings:

Using lincom

Odds ratios and incidence-rate ratios

Multiple-equation models

### Using lincom

After fitting a model and obtaining estimates for coefficients $\beta_1, \beta_2, \ldots, \beta_k$, you may want to view estimates for linear combinations of the $\beta_i$, such as $\beta_1 - \beta_2$. lincom can display estimates for any linear combination of the form $c_0 + c_1\beta_1 + c_2\beta_2 + \cdots + c_k\beta_k$.

lincom works after any estimation command for which test works. Any valid expression for test syntax I (see [R] test) is a valid expression for lincom.

lincom is useful for viewing odds ratios, hazard ratios, etc., for one group (that is, one set of covariates) relative to another group (that is, another set of covariates). See the examples below.
Example 1

We perform a linear regression:

```
. use http://www.stata-press.com/data/r13/regress
. regress y x1 x2 x3
```

```
Source | SS df MS Number of obs = 148
--------+---------------------------------------------------------------
Model | 3259.3561 3 1086.45203 Prob > F = 0.0000
       | 1627.56282 144 11.3025196 R-squared = 0.6670
       | 4886.91892 147 33.2443464 Adj R-squared = 0.6600
       | 1627.56282 144 11.3025196 Root MSE = 3.3619
--------+---------------------------------------------------------------
        | y      Coef. Std. Err. t P>|t| [95% Conf. Interval]
x1     | 1.457113 1.07461 1.36 0.177 -.666934 3.581161
x2     | 2.221682 .8610358 2.58 0.011 .5197797 3.923583
x3     | -.006139 .0005543 -11.08 0.000 -.0072345 -.0050435
_cons  | 36.10135 4.382693 8.24 0.000 27.43863 44.76407
--------+---------------------------------------------------------------
```

To see the difference of the coefficients of x2 and x1, we type

```
. lincom x2 - x1
   ( 1) - x1 + x2 = 0
```

```
       | y      Coef. Std. Err. t P>|t| [95% Conf. Interval]
(1)    | .7645682 .9950282 0.77 0.444 -1.20218 2.731316
```

The expression can be any linear combination.

```
. lincom 3*x1 + 500*x3
   ( 1) 3*x1 + 500*x3 = 0
```

```
       | y      Coef. Std. Err. t P>|t| [95% Conf. Interval]
(1)    | 1.301825 3.396624 0.38 0.702 -5.411858 8.015507
```

Nonlinear expressions are not allowed.

```
. lincom x2/x1
   not possible with test
r(131);
```

For information about estimating nonlinear expressions, see [R] `nlcom`.

Technical note

`lincom` uses the same shorthands for coefficients as does `test` (see [R] `test`). When you type `x1`, for instance, `lincom` knows that you mean the coefficient of `x1`. The formal syntax for referencing this coefficient is actually `_b[x1]`, or alternatively, `_coef[x1]`. So, more formally, in the last example we could have typed

```
. lincom 3*_b[x1] + 500*_b[x3]
(output omitted)
```
Odds ratios and incidence-rate ratios

After logistic regression, the *or* option can be specified with **lincom** to display odds ratios for any effect. Incidence-rate ratios after commands such as **poisson** can be similarly obtained by specifying the **irr** option.

> **Example 2**

Consider the low birthweight dataset from Hosmer, Lemeshow, and Sturdivant (2013, 24). We fit a logistic regression model of low birthweight (variable *low*) on the following variables:

<table>
<thead>
<tr>
<th>Variable</th>
<th>Description</th>
<th>Coding</th>
</tr>
</thead>
<tbody>
<tr>
<td>age</td>
<td>age in years</td>
<td></td>
</tr>
<tr>
<td>race</td>
<td>race</td>
<td></td>
</tr>
<tr>
<td>smoke</td>
<td>smoking status</td>
<td>1 if smoker, 0 if nonsmoker</td>
</tr>
<tr>
<td>ht</td>
<td>history of hypertension</td>
<td>1 if yes, 0 if no</td>
</tr>
<tr>
<td>ui</td>
<td>uterine irritability</td>
<td>1 if yes, 0 if no</td>
</tr>
<tr>
<td>lwd</td>
<td>maternal weight before pregnancy</td>
<td>1 if weight &lt; 110 lb., 0 otherwise</td>
</tr>
<tr>
<td>ptd</td>
<td>history of premature labor</td>
<td>1 if yes, 0 if no</td>
</tr>
<tr>
<td>c.age##lwd</td>
<td>age main effects, lwd main effects, and their interaction</td>
<td></td>
</tr>
<tr>
<td>smoke##lwd</td>
<td>smoke main effects, lwd main effects, and their interaction</td>
<td></td>
</tr>
</tbody>
</table>

We first fit a model without the interaction terms by using **logit**.

```
. use http://www.stata-press.com/data/r13/lbw3
(Hosmer & Lemeshow data)
. logit low age lwd i.race smoke ptd ht ui
Iteration 0: log likelihood = -117.336
Iteration 1: log likelihood = -99.3982
Iteration 2: log likelihood = -98.780418
Iteration 3: log likelihood = -98.777998
Iteration 4: log likelihood = -98.777998
Logistic regression Number of obs = 189
LR chi2(8) = 37.12
Prob > chi2 = 0.0000
Log likelihood = -98.777998 Pseudo R2 = 0.1582
```

```
  | Coef.  Std. Err.     z  P>|z|     [95% Conf. Interval]  
---|--------|-----------------|---|-----------------|------------------|
  low |       |
 age | -.0464796  .0373888  -1.24  0.214  -.1197603  .0268011 |
 lwd | .8420615  .4055338   2.08  0.038  .0472299  1.636893 |
 race |       |
  black | 1.073456  .5150753   2.08  0.037   .0639273  2.082985 |
  other | .815367  .4452979   1.83  0.067  -.0574008  1.688135 |
 smoke |       |
 smoke | .8071996  .404446   2.00  0.046  .0145001  1.599899 |
 ptd | 1.281678  .4621157   2.77  0.006   .3759478  2.187408 |
 ht | 1.435227  .6482699   2.21  0.027  1.646414  2.705813 |
 ui | .6576256  .4666192   1.41  0.159  -.2569313  1.572182 |
 _cons | -1.216781  .9556797  -1.27  0.203  -.3089878  .656317 |
```
To get the odds ratio for black smokers relative to white nonsmokers (the reference group), we type

```
. lincom 2.race + smoke, or
( 1) [low]2.race + [low]smoke = 0
```

| low | Odds Ratio | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|-----|------------|-----------|-------|------|----------------------|
| (1) | 6.557805   | 4.744692  | 2.60  | 0.009| 1.588176 27.07811    |

`lincom` computed $\exp(\beta_{2.race} + \beta_{smoke}) = 6.56$. To see the odds ratio for white smokers relative to black nonsmokers, we type

```
. lincom smoke - 2.race, or
( 1) - [low]2.race + [low]smoke = 0
```

| low | Odds Ratio | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|-----|------------|-----------|-------|------|----------------------|
| (1) | .7662425   | .4430176  | -0.46 | 0.645| .2467334 2.379603    |

Now let’s add the interaction terms to the model (Hosmer and Lemeshow 1989, table 4.10). This time, we will use `logistic` rather than `logit`. By default, `logistic` displays odds ratios.

```
. logistic low i.race ht ui ptd c.age##lwd smoke##lwd
```

Logistic regression
Number of obs = 189
LR chi2(10) = 42.66
Prob > chi2 = 0.0000
Log likelihood = -96.00616 Pseudo R2 = 0.1818

| low | Odds Ratio | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|-----|------------|-----------|-------|------|----------------------|
| race |           |           |       |      |                      |
| black | 2.95383    | 1.532789  | 2.09  | 0.037| 1.068277 8.167465    |

| smoker | 3.168096   | 1.452378  | 2.52  | 0.012| 1.289956 7.78076     |
| smoke#lwd |           |           |       |      |                      |
| smoker 1 | .2447849   | .2003996  | -1.72 | 0.086| .0491956 1.217988    |
| _cons | .599443    | .6519163  | -0.47 | 0.638| .0711271 5.051971    |

Hosmer and Lemeshow (1989, table 4.13) consider the effects of smoking ($\text{smoke} = 1$) and low maternal weight before pregnancy ($\text{lwd} = 1$). The effect of smoking among non–low-weight mothers ($\text{lwd} = 0$) is given by the odds ratio 3.17 for $\text{smoke}$ in the `logistic` output. The effect of smoking among low-weight mothers is given by
We did not have to specify the `or` option. After `logistic`, `lincom` assumes `or` by default.

The effect of low weight (\(lwd = 1\)) is more complicated because we fit an \(\text{age} \times lwd\) interaction. We must specify the age of mothers for the effect. The effect among 30-year-old nonsmokers is given by

\[
\text{lincom 1.lwd + 30*1.lwd#c.age}
\]

(1) \([\text{low}]1.lwd + 30*[\text{low}]1.lwd#c.age = 0\)

| low | Odds Ratio | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|-----|------------|-----------|------|------|---------------------|
| (1) | 14.7669    | 13.5669   | 2.93 | 0.003| 2.439264 89.39633   |

`lincom` computed \(\exp(\beta_{1.lwd} + 30\beta_{\text{age}lwd}) = 14.8\). It may seem odd that we entered it as `1.lwd + 30*1.lwd#c.age`, but remember that these terms are just `lincom`'s (and `test`'s) shorthands for \(_b[1.lwd]\) and \(_b[1.lwd#c.age]\). We could have typed

\[
\text{lincom _b[1.lwd] + 30*_b[1.lwd#c.age]}
\]

(1) \([\text{low}]1.lwd + 30*[\text{low}]1.lwd#c.age = 0\)

| low | Odds Ratio | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|-----|------------|-----------|------|------|---------------------|
| (1) | 14.7669    | 13.5669   | 2.93 | 0.003| 2.439264 89.39633   |

**Multiple-equation models**

`lincom` also works with multiple-equation models. The only difference is how you refer to the coefficients. Recall that for multiple-equation models, coefficients are referenced using the syntax

\([eqno]\text{varname}\)

where `eqno` is the equation number or equation name and `varname` is the corresponding variable name for the coefficient; see [U] 13.5 Accessing coefficients and standard errors and [R] test for details.
Example 3

Let’s consider example 4 from [R] `mlogit` (Tarlov et al. 1989; Wells et al. 1989).

```
. use http://www.stata-press.com/data/r13/sysdsn1
(Health insurance data)
. mlogit insure age male nonwhite i.site, nolog
Multinomial logistic regression    Number of obs =      615
LR chi2(10) =    42.99
Prob > chi2 =    0.0000
Log likelihood = -534.36165    Pseudo R2 =    0.0387

           Coef.   Std. Err.      z    P>|z|     [95% Conf. Interval]
------------------------------------------------------------------------------

Syntax

\texttt{linktest \ [if] \ [in] \ [ , cmd\_options ]}

When \texttt{if} and \texttt{in} are not specified, the link test is performed on the same sample as the previous estimation.

Menu

Statistics > Postestimation > Tests > Specification link test for single-equation models

Description

\texttt{linktest} performs a link test for model specification after any single-equation estimation command, such as \texttt{logistic, regress, stcox}, etc.

Option

\texttt{cmd\_options} must be the same options specified with the underlying estimation command, except the \texttt{display\_options} may differ.

Remarks and examples

The form of the link test implemented here is based on an idea of Tukey \cite{1949}, which was further described by Pregibon \cite{1980}, elaborating on work in his unpublished thesis \cite{1979}. See \textit{Methods and formulas} below for more details.

Example 1

We want to explain the mileage ratings of cars in our automobile dataset by using the weight, engine displacement, and whether the car is manufactured outside the United States:
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress mpg weight displ foreign

<table>
<thead>
<tr>
<th>Source</th>

| _cons    | 41.84795  | 2.350704  | 17.80 | 0.000 | 37.15962 46.53628 |

On the basis of the $R^2$, we are reasonably pleased with this model.

If our model really is specified correctly, then if we were to regress mpg on the prediction and the prediction squared, the prediction squared would have no explanatory power. This is what linktest does:

. linktest

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>1670.71514</td>
<td>2</td>
<td>835.357572</td>

</tr>
<tr>
<td>Total</td>
<td>2443.45946</td>
<td>73</td>
<td>33.4720474</td>
</tr>
</tbody>
</table>

Number of obs = 74
F( 2, 71) = 76.75
Prob > F = 0.0000
R-squared = 0.6837
Adj R-squared = 0.6748
Root MSE = 3.299

| mpg   | Coef. | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|-------|-------|-----------|-------|-----|----------------------|
| _hat  | -.4127198 | .6577736 | -0.63 | 0.532 | -1.724283 .8988434 |
| _hatsq | .0338198 | .015624 | 2.16 | 0.034 | .0026664 .0649732 |
| _cons | 14.00705  | 6.713276 | 2.09 | 0.041 | .6211539 27.39294 |

We find that the prediction squared does have explanatory power, so our specification is not as good as we thought.

Although linktest is formally a test of the specification of the dependent variable, it is often interpreted as a test that, conditional on the specification, the independent variables are specified incorrectly. We will follow that interpretation and now include weight squared in our model:
. regress mpg weight c.weight#c.weight displ foreign

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>1699.02634</td>
<td>4</td>
<td>424.75684</td>
<td>F( 4, 69) = 39.37</td>
</tr>
<tr>
<td>Residual</td>
<td>744.433124</td>
<td>69</td>
<td>10.788859</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Total</td>
<td>2443.45946</td>
<td>73</td>
<td>33.472074</td>
<td>R-squared = 0.6953</td>
</tr>
</tbody>
</table>

Adj R-squared = 0.6777

Root MSE = 3.2846

| mpg       | Coef. | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|-----------|-------|-----------|------|-----|----------------------|
| weight    | -.0173257 | .0040488 | -4.28 | 0.000 | -.0254028 -.0092486 |
| c.weight# | 1.87e-06  | 6.89e-07  | 2.71  | 0.008 | 4.93e-07 3.24e-06  |
| c.weight  | -.0101625 | .0106236  | -0.96 | 0.342 | -.031356  .011031 |
| displacement | -.0101625  | .0106236  | -0.96 | 0.342 | -.031356  .011031 |
| foreign   | -2.560016  | 1.123506  | -2.28 | 0.026 | -4.801349 -.318632 |
| _cons     | 58.23575  | 6.449882  | 9.03  | 0.000 | 45.36859  71.10291 |

Now we perform the link test on our new model:

. linktest

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>1699.39489</td>
<td>2</td>
<td>849.69745</td>
<td>F( 2, 71) = 81.08</td>
</tr>
<tr>
<td>Residual</td>
<td>744.06457</td>
<td>71</td>
<td>10.47979</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Total</td>
<td>2443.45946</td>
<td>73</td>
<td>33.472074</td>
<td>R-squared = 0.6955</td>
</tr>
</tbody>
</table>

Adj R-squared = 0.6869

Root MSE = 3.2372

| mpg       | Coef. | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|-----------|-------|-----------|------|-----|----------------------|
| _hat      | 1.141987 | .7612218 | 1.50  | 0.138 | -.3758456 2.659821  |
| _hatsq    | -.0031916 | .0170194 | -0.19 | 0.852 | -.0371272 .0307441 |
| _cons     | -1.50305  | 8.196444 | -0.18 | 0.855 | -17.84629 14.84019 |

We now pass the link test.

Example 2

Above we followed a standard misinterpretation of the link test—when we discovered a problem, we focused on the explanatory variables of our model. We might consider varying exactly what the link test tests. The link test told us that our dependent variable was misspecified. For those with an engineering background, mpg is indeed a strange measure. It would make more sense to model energy consumption—gallons per mile—in terms of weight and displacement:
The link test can be used with any single-equation estimation procedure, not solely regression. Let's turn our problem around and attempt to explain whether a car is manufactured outside the United States by its mileage rating and weight. To save paper, we will specify `logit`’s `nolog` option, which suppresses the iteration log:

```plaintext
.logit foreign mpg weight, nolog
```

Logistic regression

```
Number of obs = 74
LR chi2(2) = 35.72
Prob > chi2 = 0.0000
Log likelihood = -27.175156  Pseudo R2 = 0.3966
```

| foreign | Coef.  | Std. Err. | z     | P>|z|   | [95% Conf. Interval] |
|---------|--------|-----------|-------|-------|---------------------|
| mpg     | -.1685869 | .0919175  | -1.83 | 0.067 | -.3487418 .011568  |
| weight  | -.0039067  | .0010116  | -3.86 | 0.000 | -.0058894 -.001924 |
| _cons   | 13.70837   | 4.518709  | 3.03  | 0.002 | 4.851859 22.56487 |

Specifying the model in terms of gallons per mile also solves the specification problem and results in a more parsimonious specification.
When we run `linktest` after `logit`, the result is another logit specification:

```
. linktest, nolog
```

```
Logistic regression
Number of obs = 74
LR chi2(2) = 36.83
Prob > chi2 = 0.0000
Log likelihood = -26.615714 Pseudo R2 = 0.4090

foreign Coef. Std. Err. z P>|z| [95% Conf. Interval]
_hat  .8438531 .2738759 3.08 0.002 .3070661 1.38064
_hatsq -.1559115 .1568642 -0.99 0.320 -.4633596 .1515366
_cons .2630557 .4299598 0.61 0.541 -.57965 1.105761
```

The link test reveals no problems with our specification.

If there had been a problem, we would have been virtually forced to accept the misinterpretation of the link test—we would have reconsidered our specification of the independent variables. When using `logit`, we have no control over the specification of the dependent variable other than to change likelihood functions.

We admit to having seen a dataset once for which the link test rejected the logit specification. We did change the likelihood function, refitting the model using `probit`, and satisfied the link test. Probit has thinner tails than logit. In general, however, you will not be so lucky.

Technical note

You should specify the same options with `linktest` that you do with the estimation command, although you do not have to follow this advice as literally as we did in the preceding example. `logit`’s `nolog` option merely suppresses a part of the output, not what is estimated. We specified `nolog` both times to save space.

If you are testing a tobit model, you must specify the censoring points just as you do with the `tobit` command.

If you are not sure which options are important, duplicate exactly what you specified on the estimation command.

If you do not specify `if exp` or `in range` with `linktest`, Stata will by default perform the link test on the same sample as the previous estimation. Suppose that you omitted some data when performing your estimation, but want to calculate the link test on all the data, which you might do if you believe the model is appropriate for all the data. You would type `linktest if e(sample) < .` to do this.

Stored results

`linktest` stores the following in `r()`:

Scalars
- `r(t)` $t$ statistic on `_hatsq`
- `r(df)` degrees of freedom

`linktest` is not an estimation command in the sense that it leaves previous estimation results unchanged. For instance, after running a regression and performing the link test, typing `regress` without arguments after the link test still replays the original regression.
For integrating an estimation command with `linktest`, `linktest` assumes that the name of the estimation command is stored in `e(cmd)` and that the name of the dependent variable is stored in `e(depvar)`. After estimation, it assumes that the number of degrees of freedom for the \( t \) test is given by `e(df_m)` if the macro is defined.

If the estimation command reports \( z \) statistics instead of \( t \) statistics, `linktest` will also report \( z \) statistics. The \( z \) statistic, however, is still returned in `r(t)`, and `r(df)` is set to a missing value.

**Methods and formulas**

The link test is based on the idea that if a regression or regression-like equation is properly specified, you should be able to find no additional independent variables that are significant except by chance. One kind of specification error is called a link error. In regression, this means that the dependent variable needs a transformation or “link” function to properly relate to the independent variables. The idea of a link test is to add an independent variable to the equation that is especially likely to be significant if there is a link error.

Let 

\[
y = f(X\beta)
\]

be the model and \( \hat{\beta} \) be the parameter estimates. `linktest` calculates

\[
_{\text{hat}} = X\hat{\beta}
\]

and

\[
_{\text{hatsq}} = _{\text{hat}}^2
\]

The model is then refit with these two variables, and the test is based on the significance of \(_{\text{hatsq}}\). This is the form suggested by Pregibon (1979) based on an idea of Tukey (1949). Pregibon (1980) suggests a slightly different method that has come to be known as “Pregibon’s goodness-of-link test”. We prefer the older version because it is universally applicable, straightforward, and a good second-order approximation. It can be applied to any single-equation estimation technique, whereas Pregibon’s more recent tests are estimation-technique specific.

</table>

**Menu**

**lnskew0**

Data > Create or change data > Other variable-creation commands > Zero-skewness log transform

**bcskew0**

Data > Create or change data > Other variable-creation commands > Box-Cox transform

**Description**

**lnskew0** creates \( \newvar = \ln(\pm \exp - k) \), choosing \( k \) and the sign of \( \exp \) so that the skewness of \( \newvar \) is zero.

**bcskew0** creates \( \newvar = (\exp^\lambda - 1)/\lambda \), the Box–Cox power transformation (Box and Cox 1964), choosing \( \lambda \) so that the skewness of \( \newvar \) is zero. \( \exp \) must be strictly positive. Also see [R] boxcox for maximum likelihood estimation of \( \lambda \).

**Options**

**Main**

delta(#) specifies the increment used for calculating the derivative of the skewness function with respect to \( k \) (lnskew0) or \( \lambda \) (bcskew0). The default values are 0.02 for lnskew0 and 0.01 for bcskew0.
zero(#) specifies a value for skewness to determine convergence that is small enough to be considered zero and is, by default, 0.001.

level(#) specifies the confidence level for the confidence interval for $k$ (lnskew0) or $\lambda$ (bcskew0). The confidence interval is calculated only if level() is specified. # is specified as an integer; 95 means 95% confidence intervals. The level() option is honored only if the number of observations exceeds 7.

Remarks and examples

Example 1: lnskew0

Using our automobile dataset (see [U] 1.2.2 Example datasets), we want to generate a new variable equal to $\ln(mpg - k)$ to be approximately normally distributed. mpg records the miles per gallon for each of our cars. One feature of the normal distribution is that it has skewness 0.

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. lnskew0 lnmpg = mpg
    k [95% Conf. Interval] Skewness
     ln(mpg-k) 5.383659 (not calculated) -7.05e-06
```

This created the new variable \texttt{lnmpg} = \texttt{ln(mpg - 5.384)}:

```
. describe lnmpg
    storage  display  value
    variable name  type  format  label  variable label
    lnmpg  float  %9.0g  ln(mpg-5.383659)
```

Because we did not specify the level() option, no confidence interval was calculated. At the outset, we could have typed

```
. use http://www.stata-press.com/data/r13/auto, clear
   (Automobile Data)
. lnskew0 lnmpg = mpg, level(95)
    k [95% Conf. Interval] Skewness
     ln(mpg-k) 5.383659 -17.12339 9.892416 -7.05e-06
```

The confidence interval is calculated under the assumption that $\ln(mpg - k)$ really does have a normal distribution. It would be perfectly reasonable to use \texttt{lnskew0}, even if we did not believe that the transformed variable would have a normal distribution—if we literally wanted the zero-skewness transform—although, then the confidence interval would be an approximation of unknown quality to the true confidence interval. If we now wanted to test the believability of the confidence interval, we could also test our new variable \texttt{lnmpg} by using \texttt{swilk} (see [R] swilk) with the \texttt{lnnormal} option.

Technical note

\texttt{lnskew0} and \texttt{bcskew0} report the resulting skewness of the variable merely to reassure you of the accuracy of its results. In our example above, \texttt{lnskew0} found $k$ such that the resulting skewness was $-7 \times 10^{-6}$, a number close enough to zero for all practical purposes. If we wanted to make it even smaller, we could specify the \texttt{zero()} option. Typing \texttt{lnskew0 new=mpg, zero(1e-8)} changes the estimated $k$ to 5.383552 from 5.383659 and reduces the calculated skewness to $-2 \times 10^{-11}$. 

When you request a confidence interval, \texttt{lnskew0} may report the lower confidence interval as ‘.’, which should be taken as indicating the lower confidence limit \( k_L = -\infty \). (This cannot happen with \texttt{bcskew0}.)

As an example, consider a sample of size \( n \) on \( x \) and assume that the skewness of \( x \) is positive, but not significantly so, at the desired significance level—say, 5%. Then no matter how large and negative you make \( k_L \), there is no value extreme enough to make the skewness of \( \ln(x - k_L) \) equal the corresponding percentile (97.5 for a 95% confidence interval) of the distribution of skewness in a normal distribution of the same sample size. You cannot do this because the distribution of \( \ln(x - k_L) \) tends to that of \( x \)—apart from location and scale shift—as \( x \to \infty \). This “problem” never applies to the upper confidence limit, \( k_U \), because the skewness of \( \ln(x - k_U) \) tends to \(-\infty\) as \( k \) tends upward to the minimum value of \( x \).

Example 2: \texttt{bcskew0}

In example 1, using \texttt{lnskew0} with a variable such as \texttt{mpg} is probably undesirable. \texttt{mpg} has a natural zero, and we are shifting that zero arbitrarily. On the other hand, use of \texttt{lnskew0} with a variable such as temperature measured in Fahrenheit or Celsius would be more appropriate, as the zero is indeed arbitrary.

For a variable like \texttt{mpg}, it makes more sense to use the Box–Cox power transform (Box and Cox 1964):

\[
y^{(\lambda)} = \frac{y^\lambda - 1}{\lambda}
\]

\( \lambda \) is free to take on any value, but \( y^{(1)} = y - 1, y^{(0)} = \ln(y) \), and \( y^{(-1)} = 1 - 1/y \).

\texttt{bcskew0} works like \texttt{lnskew0}:

\begin{verbatim}
. bcskew0 bcmpg = mpg, level(95)
\end{verbatim}

<table>

<tbody>
<tr>
<td>(mpg^L-1)/L</td>
<td>-.3673283</td>
<td>-1.212752</td>
<td>.4339645</td>
</tr>
</tbody>
</table>

The 95% confidence interval includes \( \lambda = -1 \) (\( \lambda \) is labeled L in the output), which has a rather more pleasing interpretation—gallons per mile—than \( (\text{mpg}^{0.3673} - 1)/(-0.3673) \). The confidence interval, however, is calculated assuming that the power transformed variable is normally distributed. It makes perfect sense to use \texttt{bcskew0}, even when you do not believe that the transformed variable will be normally distributed, but then the confidence interval is an approximation of unknown quality. If you believe that the transformed data are normally distributed, you can alternatively use \texttt{boxcox} to estimate \( \lambda \); see \texttt{[R] boxcox}.

\section*{Stored results}

\texttt{lnskew0} and \texttt{bcskew0} store the following in \texttt{r(}()):

\textbf{Scalars}

\begin{itemize}
  \item \texttt{r(gamma)} \quad k (\texttt{lnskew0})
  \item \texttt{r(lambda)} \quad \lambda (\texttt{bcskew0})
  \item \texttt{r(lb)} \quad lower bound of confidence interval
  \item \texttt{r(ub)} \quad upper bound of confidence interval
  \item \texttt{r(skewness)} \quad resulting skewness of transformed variable
\end{itemize}
Methods and formulas

Skewness is as calculated by `summarize`; see [R] `summarize`. Newton’s method with numeric, uncentered derivatives is used to estimate $k$ (lnskew0) and $\lambda$ (bcskew0). For lnskew0, the initial value is chosen so that the minimum of $x - k$ is 1, and thus $\ln(x - k)$ is 0. bcskew0 starts with $\lambda = 1$.

Acknowledgment

lnskew0 and bcskew0 were written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model*.

**Syntax**

Report status of log file

```plaintext
log
log query [logname | _all]
```

Open log file

```plaintext
log using filename [, append replace [text | smcl] name(logname)]
```

Close log

```plaintext
log close [logname | _all]
```

Temporarily suspend logging or resume logging

```plaintext
log {off | on} [logname]
```

Report status of command log file

```plaintext
cmdlog
```

Open command log file

```plaintext
cmdlog using filename [, append replace]
```

Close command log, temporarily suspend logging, or resume logging

```plaintext
cmdlog {close | on | off}
```

Set default format for logs

```plaintext
set logtype {text | smcl} [, permanently]
```

Specify screen width

```plaintext
set linesize #
```

In addition to using the `log` command, you may access the capabilities of `log` by selecting **File > Log** from the menu and choosing one of the options in the list.
**Description**

`log` allows you to make a full record of your Stata session. A log is a file containing what you type and Stata’s output. You may start multiple log files at the same time, and you may refer to them with a `logname`. If you do not specify a `logname`, Stata will use the name `<unnamed>`.

`cmdlog` allows you to make a record of what you type during your Stata session. A command log contains only what you type, so it is a subset of a full log.

You can make full logs, command logs, or both simultaneously. Neither is produced until you tell Stata to start logging.

Command logs are always text files, making them easy to convert into do-files. (In this respect, it would make more sense if the default extension of a command log file was `.do` because command logs are do-files. The default is `.txt`, not `.do`, however, to keep you from accidentally overwriting your important do-files.)

Full logs are recorded in one of two formats: Stata Markup and Control Language (SMCL) or plain text. The default is SMCL, but you can use `set logtype` to change that, or you can specify an option to state the format you wish. We recommend SMCL because it preserves fonts and colors. SMCL logs can be converted to text or to other formats by using the `translate` command; see [R] `translate`. You can also use `translate` to produce printable versions of SMCL logs. SMCL logs can be viewed and printed from the Viewer, as can any text file; see [R] `view`.

When using multiple log files, you may have up to five SMCL logs and five text logs open at the same time.

`log` or `cmdlog`, typed without arguments, reports the status of logging. `log query`, when passed an optional `logname`, reports the status of that log.

`log using` and `cmdlog using` open a log file. `log close` and `cmdlog close` close the file. Between times, `log off` and `cmdlog off`, and `log on` and `cmdlog on`, can temporarily suspend and resume logging.

If `filename` is specified without an extension, one of the suffixes `.smcl`, `.log`, or `.txt` is added. The extension `.smcl` or `.log` is added by `log`, depending on whether the file format is SMCL or text. The extension `.txt` is added by `cmdlog`. If `filename` contains embedded spaces, remember to enclose it in double quotes.

`set logtype` specifies the default format in which full logs are to be recorded. Initially, full logs are recorded in SMCL format.

`set linesize` specifies the maximum width, in characters, of Stata output. Most commands in Stata do not respect `linesize`, because it is not important for most commands. Most users never need to `set linesize`, because it will automatically be reset if you resize your Results window. This is also why there is no `permanently` option allowed with `set linesize`. `set linesize` is for use with commands such as `list` and `display` and is typically used by programmers who wish the output of those commands to be wider or narrower than the current width of the Results window.
Options for use with both log and cmdlog

append specifies that results be appended to an existing file. If the file does not already exist, a new file is created.

replace specifies that filename, if it already exists, be overwritten. When you do not specify either replace or append, the file is assumed to be new. If the specified file already exists, an error message is issued and logging is not started.

Options for use with log

text and smcl specify the format in which the log is to be recorded. The default is complicated to describe but is what you would expect:

If you specify the file as filename.smcl, the default is to write the log in SMCL format (regardless of the value of set logtype).
If you specify the file as filename.log, the default is to write the log in text format (regardless of the value of set logtype).
If you type filename without an extension and specify neither the smcl option nor the text option, the default is to write the file according to the value of set logtype. If you have not set logtype, then the default is SMCL. Also, the filename you specified will be fixed to read filename.smcl if a SMCL log is being created or filename.log if a text log is being created.
If you specify either the text or smcl option, then what you specify determines how the log is written. If filename was specified without an extension, the appropriate extension is added for you.

If you open multiple log files, you may choose a different format for each file.

ame(logname) specifies an optional name you may use to refer to the log while it is open. You can start multiple log files, give each a different logname, and then close, temporarily suspend, or resume them each individually.

Option for use with set logtype

permanently specifies that, in addition to making the change right now, the logtype setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

For a detailed explanation of logs, see [U] 15 Saving and printing output—log files.

When you open a full log, the default is to show the name of the file and a time and date stamp:

```
    . log using myfile
    name: <unnamed>
    log: C:\data\proj1\myfile.smcl
    log type: smcl
    opened on: 12 Jan 2013, 12:28:23
```

The above information will appear in the log. If you do not want this information to appear, precede the command by quietly:

```
    . quietly log using myfile
```

quietly will not suppress any error messages or anything else you need to know.
Similarly, when you close a full log, the default is to show the full information,

```
log close
```

and that information will also appear in the log. If you want to suppress that, type `quietly log close`.

## Stored results

`log` and `cmdlog` store the following in `r()`:

### Macros

- `r(name)`  
  `logname`
- `r(filename)`  
  name of file
- `r(status)`  
  on or off
- `r(type)`  
  smcl or text

`log query _all` stores the following in `r()`:

### Scalars

- `r(numlogs)`  
  number of open log files

For each open log file, `log query _all` also stores

- `r(name#)`  
  `logname`
- `r(filename#)`  
  name of file
- `r(status#)`  
  on or off
- `r(type#)`  
  smcl or text

where `#` varies between 1 and the value of `r(numlogs)`. Be aware that `#` will not necessarily represent the order in which the log files were first opened, nor will it necessarily remain constant for a given log file upon multiple calls to `log query`.

<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**options**

**Model**

- `noconstant` suppress constant term
- `offset(varname)` include `varname` in model with coefficient constrained to 1
- `asis` retain perfect predictor variables
- `constraints(constraints)` apply specified linear constraints
- `collinear` keep collinear variables

**SE/Robust**

- `vce(vcetype)` `vcetype` may be `oim`, `robust`, `cluster clustvar`, `bootstrap`, or `jackknife`

**Reporting**

- `level(#)` set confidence level; default is `level(95)`
- `coef` report estimated coefficients
- `nocnsreport` do not display constraints
- `display_options` control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

**Maximization**

- `maximize_options` control the maximization process; seldom used
- `coeflegend` display legend instead of statistics

`indepvars` may contain factor variables; see [U] 11.4.3 Factor variables.
`depvar` and `indepvars` may contain time-series operators; see [U] 11.4.4 Time-series varlists.
`bootstrap`, `by`, `fp`, `jackknife`, `mfp`, `mi estimate`, `nestreg`, `rolling`, `statsby`, `stepwise`, and `svy` are allowed; see [U] 11.1.10 Prefix commands.
`vce(bootstrap)` and `vce(jackknife)` are not allowed with the `mi estimate` prefix; see [MI] mi estimate.
Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap.
`vce()` and weights are not allowed with the `svy` prefix; see [SVY] svy.
`fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 weight.
`coeflegend` does not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

1055
logistic fits a logistic regression model of \textit{depvar} on \textit{indepvars}, where \textit{depvar} is a 0/1 variable (or, more precisely, a 0/non-0 variable). Without arguments, \textit{logistic} redisplay the last \textit{logistic} estimates. \textit{logistic} displays estimates as odds ratios; to view coefficients, type \textit{logit} after running \textit{logistic}. To obtain odds ratios for any covariate pattern relative to another, see \cite{R lincom}.

The following option is available with \textit{logistic} but is not shown in the dialog box:
\textit{coeflegend}; see \cite{R estimation options}. 

\textbf{Options}

\begin{itemize}
  \item \texttt{Model}:
    \begin{itemize}
    \item \texttt{noconstant}, \texttt{offset(\textit{varname})}, \texttt{constraints(\textit{constraints})}, \texttt{collinear}; see \cite{R estimation options}.
    \end{itemize}
  \item \texttt{asis} forces retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see \cite{R probit}.
  \item \texttt{SE/Robust}:
    \begin{itemize}
    \item \texttt{vce(\textit{vcetype})} specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\texttt{oim}), that are robust to some kinds of misspecification (\texttt{robust}), that allow for intragroup correlation (\texttt{cluster clustvar}), and that use bootstrap or jackknife methods (\texttt{bootstrap}, \texttt{jackknife}); see \cite{R vce option}.
    \end{itemize}
  \item \texttt{Reporting}:
    \begin{itemize}
    \item \texttt{level(\#)}; see \cite{R estimation options}.
    \end{itemize}
  \item \texttt{Maximization}:
    \begin{itemize}
    \item \texttt{maximize} options: \texttt{dif\_ficult}, \texttt{technique(\textit{algorithm}\_\texttt{spec})}, \texttt{iterate(\#)}, \texttt{[no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(\#), ltolerance(\#), nrtolerance(\#), nonrtolerance}, and \texttt{from(\textit{init}\_\texttt{specs})}; see \cite{R maximize}. These options are seldom used.
    \end{itemize}
\end{itemize}

The following option is available with \textit{logistic} but is not shown in the dialog box:
\textit{coeflegend}; see \cite{R estimation options}.
Remarks and examples

Remarks are presented under the following headings:

logistic and logit
Robust estimate of variance
Video examples

logistic and logit

logistic provides an alternative and preferred way to fit maximum-likelihood logit models, the other choice being logit ([R] logit).

First, let’s dispose of some confusing terminology. We use the words logit and logistic to mean the same thing: maximum likelihood estimation. To some, one or the other of these words connotes transforming the dependent variable and using weighted least squares to fit the model, but that is not how we use either word here. Thus the logit and logistic commands produce the same results.

The logistic command is generally preferred to the logit command because logistic presents the estimates in terms of odds ratios rather than coefficients. To some people, this may seem disadvantageous, but you can type logit without arguments after logistic to see the underlying coefficients. You should be cautious when interpreting the odds ratio of the constant term. Usually, this odds ratio represents the baseline odds of the model when all predictor variables are set to zero. However, you must verify that a zero value for all predictor variables in the model actually makes sense before continuing with this interpretation.

Nevertheless, [R] logit is still worth reading because logistic shares the same features as logit, including omitting variables due to collinearity or one-way causation.

For an introduction to logistic regression, see Lemeshow and Hosmer (2005), Pagano and Gauvreau (2000, 470–487), or Pampel (2000); for a complete but nonmathematical treatment, see Kleinbaum and Klein (2010); and for a thorough discussion, see Hosmer, Lemeshow, and Sturdivant (2013). See Gould (2000) for a discussion of the interpretation of logistic regression. See Dupont (2009) or Hilbe (2009) for a discussion of logistic regression with examples using Stata. For a discussion using Stata with an emphasis on model specification, see Vittinghoff et al. (2012).

Stata has a variety of commands for performing estimation when the dependent variable is dichotomous or polytomous. See Long and Freese (2014) for a book devoted to fitting these models with Stata. Here is a list of some estimation commands that may be of interest. See help estimation commands for a complete list of all of Stata’s estimation commands.

Example 1

Consider the following dataset from a study of risk factors associated with low birthweight described in Hosmer, Lemeshow, and Sturdivant (2013, 24).

```
. use http://www.stata-press.com/data/r13/lbw
(Hosmer & Lemeshow data)
. describe
Contains data from http://www.stata-press.com/data/r13/lbw.dta
    obs:    189  Hosmer & Lemeshow data
    vars:    11  15 Jan 2013 05:01
    size: 2,646

storage  display value
variable name   type format label      variable label
id     int %8.0g   identification code
low    byte %8.0g birthweight<2500g
age    byte %8.0g age of mother
lwt    int %8.0g weight at last menstrual period
race   byte %8.0g race
smoke  byte %8.0g smoked during pregnancy
ptl    byte %8.0g premature labor history (count)
ht     byte %8.0g has history of hypertension
ui     byte %8.0g presence, uterine irritability
ftv    byte %8.0g number of visits to physician during 1st trimester
bwt    int %8.0g birthweight (grams)
```

Sorted by:

We want to investigate the causes of low birthweight. Here `race` is a categorical variable indicating whether a person is white (`race = 1`), black (`race = 2`), or some other race (`race = 3`). We want indicator (dummy) variables for `race` included in the regression, so we will use factor variables.

```
. logistic low age lwt i.race smoke ptl ht ui
Logistic regression               Number of obs =    189
                                  LR chi2(8) =  33.22
                                  Prob > chi2 =  0.0001
Log likelihood = -100.724        Pseudo R2 =  0.1416

  low | Odds Ratio   Std. Err.      z    P>|z|     [95% Conf. Interval]
-----+------------------------------------------------------------------
  age  |   .9732636   .0354759    -0.74   0.457     .9061578    1.046339
 lwt   |   .9849634   .0068217    -2.19   0.029     .9716834    .9984249
 race  |       2.36  1.039949 2.196 0.050   1.001356     5.600207
  black|   3.534767   1.860737    2.40   0.016    1.259736    9.918406
  other|   2.368079   1.039949    1.96   0.050    1.001356    5.600207
 smoke|   2.517698   1.00916    2.30   0.021    1.147676    5.231622
  ptl  |   1.719161   .5952579    1.56   0.118    .8721455    3.388787
   ht  |   6.249602   4.322408    2.66   0.008    1.611152   24.241996
   ui  |   2.351285   .9808153    2.35   0.019    .8677528    5.2534
  _cons|   1.586014   1.910496    0.38   0.702    .1496092   16.81342
```

The odds ratios are for a one-unit change in the variable. If we wanted the odds ratio for `age` to be in terms of 4-year intervals, we would type
. gen age4 = age/4
. logistic low age4 lwt i.race smoke ptl ht ui
(output omitted)

After `logistic`, we can type `logit` to see the model in terms of coefficients and standard errors:

```
. logit
Logistic regression
Number of obs = 189
LR chi2(8) = 33.22
Prob > chi2 = 0.0001
Log likelihood = -100.724 Pseudo R2 = 0.1416

| low | Coef. | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|-----|-------|-----------|-------|------|---------------------|
| age4| -.1084012 | .1458017 | -0.74 | 0.457 | -.3941673 .1773649 |
| lwt | -.0151508  | .0069259 | -2.19 | 0.029 | -.0287253 -.0015763 |
| black | 1.262647 | .5264101 | 2.40  | 0.016 | .2309024 2.294392 |
| other | .8620792  | .4391532 | 1.96  | 0.050 | .0013548 1.722804 |
| smoke | .9233448  | .4008266 | 2.30  | 0.021 | .137739 1.708951 |
| ptl | .5418366 | .346249  | 1.56  | 0.118 | -.136799 1.220472 |
| ht | 1.832518 | .6916292 | 2.65  | 0.008 | .4769494 3.188086 |
| ui | .7585135  | .4593768 | 1.65  | 0.099 | -.1418484 1.658875 |
| _cons | .4612239 | 1.20459  | 0.38  | 0.702 | -1.899729 2.822176 |
```

If we wanted to see the `logistic` output again, we would type `logistic` without arguments.

Example 2

We can specify the confidence interval for the odds ratios with the `level()` option, and we can do this either at estimation time or when replaying the model. For instance, to see our first model in example 1 with narrower, 90% confidence intervals, we might type

```
. logistic, level(90)
Logistic regression
Number of obs = 189
LR chi2(8) = 33.22
Prob > chi2 = 0.0001
Log likelihood = -100.724 Pseudo R2 = 0.1416

| low | Odds Ratio | Std. Err. | z     | P>|z| | [90% Conf. Interval] |
|-----|------------|-----------|-------|------|---------------------|
| age4| .8972675   | .1308231 | -0.74 | 0.457 | .7059409 1.140448 |
| lwt | .9849634   | .0068217 | -2.19 | 0.029 | .9738063 .9962483 |
| black | 3.534767 | 1.860737 | 2.40  | 0.016 | 1.487028 8.402379 |

```
Robust estimate of variance

If you specify `vce(robust)`, Stata reports the robust estimate of variance described in [U] 20.21 Obtaining robust variance estimates. Here is the model previously fit with the robust estimate of variance:

```
. logistic low age lwt i.race smoke ptl ht ui, vce(robust)
Logistic regression
Number of obs = 189
Wald chi2(8) = 29.02
Prob > chi2 = 0.0003
Log pseudolikelihood = -100.724 Pseudo R2 = 0.1416

Robust
Odds Ratio Std. Err. z P>|z| [95% Conf. Interval]
age .9732636 .0329376 -0.80 0.423 .9108015 1.040009
lwt .9849634 .0070209 -2.13 0.034 .9712984 .9988206
race
  black 3.534767 1.793616 2.49 0.013 1.307504 9.556051

_cons
```

Also you can specify `vce(cluster clustvar)` and then, within cluster, relax the assumption of independence. To illustrate this, we have made some fictional additions to the low-birthweight data.

Say that these data are not a random sample of mothers but instead are a random sample of mothers from a random sample of hospitals. In fact, that may be true—we do not know the history of these data.

Hospitals specialize, and it would not be too incorrect to say that some hospitals specialize in more difficult cases. We are going to show two extremes. In one, all hospitals are alike, but we are going to estimate under the possibility that they might differ. In the other, hospitals are strikingly different. In both cases, we assume that patients are drawn from 20 hospitals.

In both examples, we will fit the same model, and we will type the same command to fit it. Below are the same data we have been using but with a new variable, `hospid`, that identifies from which of the 20 hospitals each patient was drawn (and which we have made up):
. use http://www.stata-press.com/data/r13/hospid1, clear
. logistic low age lwt i.race smoke ptl ht ui, vce(cluster hospid)

Logistic regression

| Odds Ratio | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|------------|-----------|------|------|----------------------|
| low        |           |      |      |                      |
| age        | .9732636  | .0397476 | -0.66 | 0.507  | .898396  | 1.05437 |
| lwt        | .9849634  | .0057101 | -2.61 | 0.009  | .9738352 | .9962187 |
| race       |           |      |      |                      |
| black      | 3.534767  | 2.013285 | 2.22  | 0.027  | 1.157563 | 10.79386 |
| other      | 2.368079  | .8451325 | 2.42  | 0.016  | 1.176562 | 4.766257 |
| smoke      |           |      |      |                      |
| ptl        | 1.719161  | .6676221 | 1.40  | 0.163  | .8030814 | 3.680219 |
| ht         | 6.249602  | 4.066275 | 2.82  | 0.005  | 1.74591  | 22.37086 |
| ui         | 2.1351    | 1.093144 | 1.48  | 0.138  | .7827337 | 5.824014 |
| _cons      | 1.586014  | 1.661913 | 0.44  | 0.660  | .2034094 | 12.36639 |

The standard errors are similar to the standard errors we have previously obtained, whether we used the robust or conventional estimators. In this example, we invented the hospital IDs randomly.

Here are the results of the estimation with the same data but with a different set of hospital IDs:

. use http://www.stata-press.com/data/r13/hospid2
. logistic low age lwt i.race smoke ptl ht ui, vce(cluster hospid)

Logistic regression

| Odds Ratio | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |

Note the strikingly larger standard errors. What happened? In these data, women most likely to have low-birthweight babies are sent to certain hospitals, and the decision on likeliness is based not just on age, smoking history, etc., but on other things that doctors can see but that are not recorded in our data. Thus merely because a woman is at one of the centers identifies her to be more likely to have a low-birthweight baby.
Video examples

Logistic regression, part 1: Binary predictors
Logistic regression, part 2: Continuous predictors
Logistic regression, part 3: Factor variables

Stored results

logistic stores the following in e():

Scalars

- `e(N)` number of observations
- `e(N_cds)` number of completely determined successes
- `e(N_cdf)` number of completely determined failures
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(r2_p)` pseudo-$R^2$-squared
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$ significance of model test
- `e(p)` significance of model test
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

Macros

- `e(cmd)` logistic
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(offset)` linear offset variable
- `e(chi2type)` Wald or LR; type of model $\chi^2$ test
- `e(vce)` vcetype specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` max or min; whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of ml method
- `e(user)` name of likelihood-evaluator program
- `e(properties)` b V
- `e(estat_cmd)` program used to implement estat
- `e(predict)` program used to implement predict
- `e(marginsnotok)` predictions disallowed by margins
- `e(asbalanced)` factor variables fvset as asbalanced
- `e(asobserved)` factor variables fvset as asobserved
Methods and formulas

Define \( x_j \) as the (row) vector of independent variables, augmented by 1, and \( b \) as the corresponding estimated parameter (column) vector. The logistic regression model is fit by `logit`; see \([R] \) \texttt{logit} for details of estimation.

The odds ratio corresponding to the \( i \)th coefficient is \( \psi_i = \exp(b_i) \). The standard error of the odds ratio is \( s_i^\psi = \psi_is_i \), where \( s_i \) is the standard error of \( b_i \) estimated by `logit`.

Define \( I_j = x_jb \) as the predicted index of the \( j \)th observation. The predicted probability of a positive outcome is

\[
p_j = \frac{\exp(I_j)}{1 + \exp(I_j)}
\]

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See \([P] \) \texttt{_robust}, particularly Maximum likelihood estimators and Methods and formulas.

`logistic` also supports estimation with survey data. For details on VCEs with survey data, see \([SVY] \) variance estimation.

## Description

The following postestimation commands are of special interest after `logistic`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat classification</code></td>
<td>report various summary statistics, including the classification table</td>
</tr>
<tr>
<td><code>estat gof</code></td>
<td>Pearson or Hosmer–Lemeshow goodness-of-fit test</td>
</tr>
<tr>
<td><code>lroc</code></td>
<td>compute area under ROC curve and graph the curve</td>
</tr>
<tr>
<td><code>lsens</code></td>
<td>graph sensitivity and specificity versus probability cutoff</td>
</tr>
</tbody>
</table>

These commands are not appropriate after the `svy` prefix.

The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>contrast</code></td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td><code>estat ic</code></td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td><code>estat summarize</code></td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>forecast</code></td>
<td>dynamic forecasts and simulations</td>
</tr>
<tr>
<td><code>lincom</code></td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td><code>linktest</code></td>
<td>link test for model specification</td>
</tr>
<tr>
<td><code>lrtest</code></td>
<td>likelihood-ratio test</td>
</tr>
<tr>
<td><code>margins</code></td>
<td>marginal means, predictive margins, marginal effects, and average marginal effects</td>
</tr>
<tr>
<td><code>marginsplot</code></td>
<td>graph the results from margins (profile plots, interaction plots, etc.)</td>
</tr>
<tr>
<td><code>nlcom</code></td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td><code>predict</code></td>
<td>predictions, residuals, influence statistics, and other diagnostic measures</td>
</tr>
<tr>
<td><code>predictnl</code></td>
<td>point estimates, standard errors, testing, and inference for generalized predictions</td>
</tr>
<tr>
<td><code>pwcompare</code></td>
<td>pairwise comparisons of estimates</td>
</tr>
<tr>
<td><code>suest</code></td>
<td>seemingly unrelated estimation</td>
</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

1. `forecast` is not appropriate with `mi` or `svy` estimation results.
2. `lrtest` is not appropriate with `svy` estimation results.
Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset rules asif]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>

</tr>
</tbody>
</table>

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when `if e(sample)` is not specified.

pr, xb, stdp, and score are the only options allowed with svy estimation results.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

pr, the default, calculates the probability of a positive outcome.

xb calculates the linear prediction.

stdp calculates the standard error of the linear prediction.

dbeta calculates the Pregibon (1981) $\Delta \hat{\beta}$ influence statistic, a standardized measure of the difference in the coefficient vector that is due to deletion of the observation along with all others that share the same covariate pattern. In Hosmer, Lemeshow, and Sturdivant (2013, 154–155) jargon, this statistic is $M$-asymptotic; that is, it is adjusted for the number of observations that share the same covariate pattern.

deviance calculates the deviance residual.

dx2 calculates the Hosmer, Lemeshow, and Sturdivant (2013, 191) $\Delta \chi^2$ influence statistic, reflecting the decrease in the Pearson $\chi^2$ that is due to the deletion of the observation and all others that share the same covariate pattern.

ddeviance calculates the Hosmer, Lemeshow, and Sturdivant (2013, 191) $\Delta D$ influence statistic, which is the change in the deviance residual that is due to deletion of the observation and all others that share the same covariate pattern.
hat calculates the Pregibon (1981) leverage or the diagonal elements of the hat matrix adjusted for the number of observations that share the same covariate pattern.

number numbers the covariate patterns—observations with the same covariate pattern have the same number. Observations not used in estimation have number set to missing. The first covariate pattern is numbered 1, the second 2, and so on.

residuals calculates the Pearson residual as given by Hosmer, Lemeshow, and Sturdivant (2013, 155) and adjusted for the number of observations that share the same covariate pattern.

rstandard calculates the standardized Pearson residual as given by Hosmer, Lemeshow, and Sturdivant (2013, 191) and adjusted for the number of observations that share the same covariate pattern.

score calculates the equation-level score, $\partial \ln L / \partial (x_j \beta)$.

Options

-nooffset- is relevant only if you specified offset(varname) for logistic. It modifies the calculations made by predict so that they ignore the offset variable; the linear prediction is treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_j$.

rules requests that Stata use any rules that were used to identify the model when making the prediction. By default, Stata calculates missing for excluded observations. See example 1 in [R] logit postestimation.

asif requests that Stata ignore the rules and the exclusion criteria and calculate predictions for all observations possible by using the estimated parameter from the model. See example 1 in [R] logit postestimation.

Remarks and examples

predict is used after logistic to obtain predicted probabilities, residuals, and influence statistics for the estimation sample. The suggested diagnostic graphs below are from Hosmer, Lemeshow, and Sturdivant (2013), where they are more elaborately explained. Also see Collett (2003, 129–168) for a thorough discussion of model checking.

Remarks are presented under the following headings:

 predict without options
 predict with the xb and stdp options
 predict with the residuals option
 predict with the number option
 predict with the deviance option
 predict with the rstandard option
 predict with the hat option
 predict with the dx2 option
 predict with the ddeviance option
 predict with the dbeta option

predict without options

Typing predict newvar after estimation calculates the predicted probability of a positive outcome.

In example 1 of [R] logistic, we ran the model logistic low age lwt i.race smoke ptl ht ui. We obtain the predicted probabilities of a positive outcome by typing

`. use http://www.stata-press.com/data/r13/lbw`
predict with the xb and stdp options

predict with the xb option calculates the linear combination \( x_j \beta \), where \( x_j \) are the independent variables in the \( j \)th observation and \( \beta \) is the estimated parameter vector. This is sometimes known as the index function because the cumulative distribution function indexed at this value is the probability of a positive outcome.

With the stdp option, predict calculates the standard error of the prediction, which is not adjusted for replicated covariate patterns in the data. The influence statistics described below are adjusted for replicated covariate patterns in the data.

predict with the residuals option

predict can calculate more than predicted probabilities. The Pearson residual is defined as the square root of the contribution of the covariate pattern to the Pearson \( \chi^2 \) goodness-of-fit statistic, signed according to whether the observed number of positive responses within the covariate pattern is less than or greater than expected. For instance,

```
. predict r, residuals
. summarize r, detail
```

We notice the prevalence of a few large positive residuals:
Covariate patterns play an important role in logistic regression. Two observations are said to share the same covariate pattern if the independent variables for the two observations are identical. Although we might think of having individual observations, the statistical information in the sample can be summarized by the covariate patterns, the number of observations with that covariate pattern, and the number of positive outcomes within the pattern. Depending on the model, the number of covariate patterns can approach or be equal to the number of observations, or it can be considerably less.

Stata calculates all the residual and diagnostic statistics in terms of covariate patterns, not observations. That is, all observations with the same covariate pattern are given the same residual and diagnostic statistics. Hosmer, Lemeshow, and Sturdivant (2013, 154–155) argue that such “M-asymptotic” statistics are more useful than “N-asymptotic” statistics.

To understand the difference, think of an observed positive outcome with predicted probability of 0.8. Taking the observation in isolation, the residual must be positive—we expected 0.8 positive responses and observed 1. This may indeed be the correct residual, but not necessarily. Under the M-asymptotic definition, we ask how many successes we observed across all observations with this covariate pattern. If that number were, say, six, and there were a total of 10 observations with this covariate pattern, then the residual is negative for the covariate pattern—we expected eight positive outcomes but observed six. predict makes this kind of calculation and then attaches the same residual to all observations in the covariate pattern.

Occasionally, you might want to find all observations sharing a covariate pattern. number allows you to do this:

```
. predict pattern, number
. summarize pattern
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>pattern</td>
<td>189</td>
<td>89.2328</td>
<td>53.16573</td>
<td>1</td>
<td>182</td>
</tr>
</tbody>
</table>

We previously fit the model `logistic low age lwt i.race smoke ptl ht ui` over 189 observations. There are 182 covariate patterns in our data.

### predict with the deviance option

The deviance residual is defined as the square root of the contribution to the likelihood-ratio test statistic of a saturated model versus the fitted model. It has slightly different properties from the Pearson residual (see Hosmer, Lemeshow, and Sturdivant [2013, 155–157]):

```
. predict d, deviance
. summarize d, detail
```

<table>

</tr>
</tbody>
</table>
predict with the rstandard option

Pearson residuals do not have a standard deviation equal to 1. `rstandard` generates Pearson residuals normalized to have an expected standard deviation equal to 1.

```stata
. predict rs, rstandard
. summarize r rs
    Variable |     Obs  Mean Std. Dev.    Min   Max
-------------|--------|--------|-----------------|---------|---------|
          r |   189  -.02423  .997096  -2.2839  3.1268
          rs|   189  -.02791  1.02641   -2.45  3.15
```

Remember that we previously created `r` containing the (unstandardized) Pearson residuals. In these data, whether we use standardized or unstandardized residuals does not matter much.

predict with the hat option

`hat` calculates the leverage of a covariate pattern—a scaled measure of distance in terms of the independent variables. Large values indicate covariate patterns far from the average covariate pattern that can have a large effect on the fitted model even if the corresponding residual is small. Consider the following graph:

```stata
. predict h, hat
. scatter h r, xline(0)
```

The points to the left of the vertical line are observed negative outcomes; here our data contain almost as many covariate patterns as observations, so most covariate patterns are unique. In such unique patterns, we observe either 0 or 1 success and expect $p$, thus forcing the sign of the residual. If we had fewer covariate patterns—if we did not have continuous variables in our model—there would be no such interpretation, and we would not have drawn the vertical line at 0.
Points on the left and right edges of the graph represent large residuals—covariate patterns that are not fit well by our model. Points at the top of our graph represent high leverage patterns. When analyzing the influence of observations on the model, we are most interested in patterns with high leverage and small residuals—patterns that might otherwise escape our attention.

predict with the \texttt{dx2} option

There are many ways to measure influence, and \texttt{hat} is one example. \texttt{dx2} measures the decrease in the Pearson $\chi^2$ goodness-of-fit statistic that would be caused by deleting an observation (and all others sharing the covariate pattern):

\begin{verbatim}
    . predict dx2, dx2
    . scatter dx2 p
\end{verbatim}

Paraphrasing Hosmer, Lemeshow, and Sturdivant (2013, 195–197), the points going from the top left to the bottom right correspond to covariate patterns with the number of positive outcomes equal to the number in the group; the points on the other curve correspond to 0 positive outcomes. In our data, most of the covariate patterns are unique, so the points tend to lie along one or the other curves; the points that are off the curves correspond to the few repeated covariate patterns in our data in which all the outcomes are not the same.

We examine this graph for large values of \texttt{dx2}—there are two at the top left.

predict with the \texttt{ddeviance} option

Another measure of influence is the change in the deviance residuals due to deletion of a covariate pattern:

\begin{verbatim}
    . predict dd, ddeviance
\end{verbatim}

As with \texttt{dx2}, we typically graph \texttt{ddeviance} against the probability of a positive outcome. We direct you to Hosmer, Lemeshow, and Sturdivant (2013, 195) for an example and for the interpretation of this graph.
predict with the dbeta option

One of the more direct measures of influence of interest to model fitters is the Pregibon (1981) dbeta measure, a measure of the change in the coefficient vector that would be caused by deleting an observation (and all others sharing the covariate pattern):

```
  . predict db, dbeta
  . scatter db p
```

One observation has a large effect on the estimated coefficients. We can easily find this point:

```
  . sort db
  . list in 1
```

<table>

</tbody>
</table>

Pr(low) vs. Pregibon's dbeta
Hosmer, Lemeshow, and Sturdivant (2013, 196) suggest a graph that combines two of the influence measures:

```
. scatter dx2 p [w=db], title("Symbol size proportional to dBeta") mfcolor(none)
(analytic weights assumed)
(analytic weights assumed)
```

![Graph showing Symbol size proportional to dBeta](image)

We can easily spot the most influential points by the `dbeta` and `dx2` measures.

**Methods and formulas**

Let $j$ index observations. Define $M_j$ for each observation as the total number of observations sharing $j$'s covariate pattern. Define $Y_j$ as the total number of positive responses among observations sharing $j$'s covariate pattern.

The Pearson residual for the $j$th observation is defined as

$$
r_j = \frac{Y_j - M_j p_j}{\sqrt{M_j p_j (1 - p_j)}}
$$

For $M_j > 1$, the deviance residual $d_j$ is defined as

$$
d_j = \pm \left( 2 \left[ Y_j \ln \left( \frac{Y_j}{M_j p_j} \right) + (M_j - Y_j) \ln \left( \frac{M_j - Y_j}{M_j (1 - p_j)} \right) \right] \right)^{1/2}
$$

where the sign is the same as the sign of $(Y_j - M_j p_j)$. In the limiting cases, the deviance residual is given by

$$
d_j = \begin{cases}
-\sqrt{2M_j |\ln(1 - p_j)|} & \text{if } Y_j = 0 \\
\sqrt{2M_j \ln p_j} & \text{if } Y_j = M_j
\end{cases}
$$

The unadjusted diagonal elements of the hat matrix $h_{Uj}$ are given by $h_{Uj} = (XVX')_{jj}$, where $V$ is the estimated covariance matrix of parameters. The adjusted diagonal elements $h_j$ created by `hat` are then $h_j = M_j p_j (1 - p_j) h_{Uj}$.
The standardized Pearson residual $r_{Sj}$ is $r_j / \sqrt{1 - h_j}$.

The Pregibon (1981) $\Delta \hat{\beta}_j$ influence statistic is

$$\Delta \hat{\beta}_j = \frac{r_j^2 h_j}{(1 - h_j)^2}$$

The corresponding change in the Pearson $\chi^2$ is $r_{Sj}^2$. The corresponding change in the deviance residual is $\Delta D_j = d_j^2 / (1 - h_j)$.

Syntax

```
logit depvar [indepvars] [if] [in] [weight] [ , options ]
```

**options**

**Model**
- `noconstant` suppress constant term
- `offset(varname)` include `varname` in model with coefficient constrained to 1
- `asis` retain perfect predictor variables
- `constraints(constraints)` apply specified linear constraints
- `collinear` keep collinear variables

**SE/Robust**
- `vce(vcetype)` `vcetype` may be `oim`, `robust`, `cluster clustvar`, `bootstrap`, or `jackknife`

**Reporting**
- `level(#)` set confidence level; default is `level(95)`
- `nocnsreport` do not display constraints
- `display_options` control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

**Maximization**
- `maximize_options` control the maximization process; seldom used
- `nocoef` do not display coefficient table; seldom used
- `coeflegend` display legend instead of statistics

**Also see**
- [U] 11.4.3 Factor variables.
- `indeps` may contain factor variables; see [U] 11.4.3 Factor variables.
- `depvar` and `indeps` may contain time-series operators; see [U] 11.4.4 Time-series varlists.
- `bootstrap`, `by`, `fp`, `jackknife`, `mfp`, `mi estimate`, `nestreg`, `rolling`, `statsby`, `stepwise`, and `svy` are allowed; see [U] 11.1.10 Prefix commands.
- `vce(bootstrap)` and `vce(jackknife)` are not allowed with the `mi estimate` prefix; see [MI] mi estimate.
- Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap.
- `vce()`, `nocoef`, and weights are not allowed with the `svy` prefix; see [SVY] svy.
- `fweight`, `iweight`, and `pweight` are allowed; see [U] 11.1.6 weight.
- `nocoef` and `coeflegend` do not appear in the dialog box.
- See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
**logit — Logistic regression, reporting coefficients**

**Menu**
Statistics > Binary outcomes > Logistic regression

**Description**

`logit` fits a logit model for a binary response by maximum likelihood; it models the probability of a positive outcome given a set of regressors. `depvar` equal to nonzero and nonmissing (typically `depvar` equal to one) indicates a positive outcome, whereas `depvar` equal to zero indicates a negative outcome.

Also see [R] logistic; logistic displays estimates as odds ratios. Many users prefer the logistic command to logit. Results are the same regardless of which you use—both are the maximum-likelihood estimator. Several auxiliary commands that can be run after `logit`, `probit`, or logistic estimation are described in [R] logistic postestimation. A list of related estimation commands is given in [R] logistic.

If estimating on grouped data, see [R] glogit.

**Options**

**Model**

- `noconstant`, `offset(varname)`, `constraints(constraints)`, `collinear`; see [R] estimation options.

- `asis` forces retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see [R] probit.

**SE/Robust**

- `vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

**Reporting**

- `level(#)`; see [R] estimation options.

- `nocnsreport`; see [R] estimation options.

**display_options**: `nomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] estimation options.

**Maximization**

- `maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and from(init_specs); see [R] maximize. These options are seldom used.
The following options are available with `logit` but are not shown in the dialog box:

- `nocoef` specifies that the coefficient table not be displayed. This option is sometimes used by program writers but is of no use interactively.
- `coeflegend`; see [R] estimation options.

### Remarks and examples

Remarks are presented under the following headings:

- **Basic usage**
- **Model identification**

#### Basic usage

`logit` fits maximum likelihood models with dichotomous dependent (left-hand-side) variables coded as 0/1 (or, more precisely, coded as 0 and not-0).

#### Example 1

We have data on the make, weight, and mileage rating of 22 foreign and 52 domestic automobiles. We wish to fit a logit model explaining whether a car is foreign on the basis of its weight and mileage. Here is an overview of our data:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. keep make mpg weight foreign
. describe
```

Contains data from `http://www.stata-press.com/data/r13/auto.dta`

<table>

</table>

(2 unique values)

foreign is labeled and all values are documented in the label.
The variable `foreign` takes on two unique values, 0 and 1. The value 0 denotes a domestic car, and 1 denotes a foreign car.

The model that we wish to fit is

$$\Pr(\text{foreign} = 1) = F(\beta_0 + \beta_1 \text{weight} + \beta_2 \text{mpg})$$

where $F(z) = e^z/(1 + e^z)$ is the cumulative logistic distribution.

To fit this model, we type

```plaintext
.logit foreign weight mpg
```

```plaintext
Iteration 0: log likelihood = -45.03321
Iteration 1: log likelihood = -29.238536
Iteration 2: log likelihood = -27.244139
Iteration 3: log likelihood = -27.175277
Iteration 4: log likelihood = -27.175156
Iteration 5: log likelihood = -27.175156
```

Logistic regression

|                  | Coef.    | Std. Err. | z     | P>|z|   | [95% Conf. Interval] |
|------------------|----------|-----------|-------|-------|----------------------|
| foreign          |          |           |       |       |                      |
| weight           | -.0039067| .0010116  | -3.86 | 0.000 | -.0058894 -.001924  |
| mpg              | -.1685869| .0919175  | -1.83 | 0.067 | -.3487418 .011568   |
| _cons            | 13.70837 | 4.518709  | 3.03  | 0.002 | 4.851859 22.56487   |

We find that heavier cars are less likely to be foreign and that cars yielding better gas mileage are also less likely to be foreign, at least holding the weight of the car constant.

Technical note

Stata interprets a value of 0 as a negative outcome (failure) and treats all other values (except missing) as positive outcomes (successes). Thus if your dependent variable takes on the values 0 and 1, then 0 is interpreted as failure and 1 as success. If your dependent variable takes on the values 0, 1, and 2, then 0 is still interpreted as failure, but both 1 and 2 are treated as successes.

If you prefer a more formal mathematical statement, when you type `logit y x`, Stata fits the model

$$\Pr(y_j \neq 0 | x_j) = \frac{\exp(x_j\beta)}{1 + \exp(x_j\beta)}$$

Model identification

The `logit` command has one more feature, and it is probably the most useful. `logit` automatically checks the model for identification and, if it is underidentified, drops whatever variables and observations are necessary for estimation to proceed. (`logistic`, `probit`, and `ivprobit` do this as well.)
Example 2

Have you ever fit a logit model where one or more of your independent variables perfectly predicted one or the other outcome?

For instance, consider the following data:

<table>
<thead>
<tr>
<th>Outcome y</th>
<th>Independent variable x</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
</tr>
</tbody>
</table>

Say that we wish to predict the outcome on the basis of the independent variable. The outcome is always zero whenever the independent variable is one. In our data, \( \Pr(y = 0 \mid x = 1) = 1 \), which means that the logit coefficient on \( x \) must be minus infinity with a corresponding infinite standard error. At this point, you may suspect that we have a problem.

Unfortunately, not all such problems are so easily detected, especially if you have a lot of independent variables in your model. If you have ever had such difficulties, you have experienced one of the more unpleasant aspects of computer optimization. The computer has no idea that it is trying to solve for an infinite coefficient as it begins its iterative process. All it knows is that at each step, making the coefficient a little bigger, or a little smaller, works wonders. It continues on its merry way until either 1) the whole thing comes crashing to the ground when a numerical overflow error occurs or 2) it reaches some predetermined cutoff that stops the process. In the meantime, you have been waiting. The estimates that you finally receive, if you receive any at all, may be nothing more than numerical roundoff.

Stata watches for these sorts of problems, alerts us, fixes them, and properly fits the model.

Let’s return to our automobile data. Among the variables we have in the data is one called repair, which takes on three values. A value of 1 indicates that the car has a poor repair record, 2 indicates an average record, and 3 indicates a better-than-average record. Here is a tabulation of our data:

```
. use http://www.stata-press.com/data/r13/repair, clear
   (1978 Automobile Data)
. tabulate foreign repair

<table>
<thead>
<tr>
<th>Car type</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Domestic</td>
<td>10</td>
<td>27</td>
<td>9</td>
<td>46</td>
</tr>
<tr>
<td>Foreign</td>
<td>0</td>
<td>3</td>
<td>9</td>
<td>12</td>
</tr>
<tr>
<td>Total</td>
<td>10</td>
<td>30</td>
<td>18</td>
<td>58</td>
</tr>
</tbody>
</table>
```

All the cars with poor repair records (\( \text{repair} = 1 \)) are domestic. If we were to attempt to predict foreign on the basis of the repair records, the predicted probability for the \( \text{repair} = 1 \) category would have to be zero. This in turn means that the logit coefficient must be minus infinity, and that would set most computer programs buzzing.
Let’s try Stata on this problem.

```
logit foreign b3.repair
```

```
 Iteration 0: log likelihood = -26.992087
 Iteration 1: log likelihood = -22.483187
 Iteration 2: log likelihood = -22.230498
 Iteration 3: log likelihood = -22.229139
 Iteration 4: log likelihood = -22.229138
```

Logistic regression

<table>
<thead>
<tr>
<th></th>
<th>Number of obs = 48</th>
</tr>
</thead>
<tbody>
<tr>
<td>LR chi2(1)</td>
<td>9.53</td>
</tr>
<tr>
<td>Prob &gt; chi2</td>
<td>0.0020</td>
</tr>
<tr>
<td>Log likelihood</td>
<td>-22.229138</td>
</tr>
<tr>
<td>Pseudo R2</td>
<td>0.1765</td>
</tr>
</tbody>
</table>

|   | Coef.  | Std. Err. | z     | P>|z| | 95% Conf. Interval |
|---|--------|-----------|-------|------|-------------------|
| repair | 0 (empty) |           |       |      |                   |
| 1  | -2.197225 | .7698003  | -2.85 | 0.004 | -3.706005 to -.688436 |
| 2  | -1.98e-16 | .4714045  | -0.00 | 1.000 | -.9239359 to .9239359 |
| _cons | -1.98e-16 | .4714045  | -0.00 | 1.000 | -.9239359 to .9239359 |

Remember that all the cars with poor repair records (repair = 1) are domestic, so the model cannot be fit, or at least it cannot be fit if we restrict ourselves to finite coefficients. Stata noted that fact “note: 1.repair !=0 predicts failure perfectly”. This is Stata’s mathematically precise way of saying what we said in English. When repair is 1, the car is domestic.

Stata then went on to say “1.repair dropped and 10 obs not used”. This is Stata eliminating the problem. First 1.repair had to be removed from the model because it would have an infinite coefficient. Then the 10 observations that led to the problem had to be eliminated, as well, so as not to bias the remaining coefficients in the model. The 10 observations that are not used are the 10 domestic cars that have poor repair records.

Stata then fit what was left of the model, using the remaining observations. Because no observations remained for cars with poor repair records, Stata reports “(empty)” in the row for repair = 1.

Technical note

Stata is pretty smart about catching problems like this. It will catch “one-way causation by a dummy variable”, as we demonstrated above.

Stata also watches for “two-way causation”, that is, a variable that perfectly determines the outcome, both successes and failures. Here Stata says, “so-and-so predicts outcome perfectly” and stops. Statistics dictates that no model can be fit.

Stata also checks your data for collinear variables; it will say, “so-and-so omitted because of collinearity”. No observations need to be eliminated in this case, and model fitting will proceed without the offending variable.

It will also catch a subtle problem that can arise with continuous data. For instance, if we were estimating the chances of surviving the first year after an operation, and if we included in our model age, and if all the persons over 65 died within the year, Stata would say, “age > 65 predicts failure perfectly”. It would then inform us about the fix-up it takes and fit what can be fit of our model.
logit (and logistic, probit, and ivprobit) will also occasionally display messages such as

Note: 4 failures and 0 successes completely determined.

There are two causes for a message like this. The first—and most unlikely—case occurs when a continuous variable (or a combination of a continuous variable with other continuous or dummy variables) is simply a great predictor of the dependent variable. Consider Stata’s auto.dta dataset with 6 observations removed.

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. drop if foreign==0 & gear_ratio > 3.1
(6 observations deleted)
. logit foreign mpg weight gear_ratio, nolog
Logistic regression                           Number of obs   =      68
LR chi2(3)         =   72.64
Prob > chi2        =   0.0000
Log likelihood     = -6.4874814      Pseudo R2        =   0.8484

foreign             Coef.   Std. Err.      z    P>|z|     [95% Conf. Interval]
------------------------------------------------------------------
  mpg                -.4944907   .2655508    -1.86   0.063    -1.014961   .0259792
  weight             -.0060919   .0031011    -1.96   0.049    -.0121698   -.000014
  gear_ratio         15.70509    8.166234     1.92   0.054    -.300436   31.71061
  _cons             -21.39527   25.41486    -0.84   0.400   -71.20747    28.41694

Note: 4 failures and 0 successes completely determined.
```

There are no missing standard errors in the output. If you receive the “completely determined” message and have one or more missing standard errors in your output, see the second case discussed below.

Note gear_ratio’s large coefficient. logit thought that the 4 observations with the smallest predicted probabilities were essentially predicted perfectly.

```
. predict p
   (option pr assumed; Pr(foreign))
. sort p
. list p in 1/4

         p
   1.  1.34e-10
   2.   6.26e-09
   3.   7.84e-09
   4.   1.49e-08
```

If this happens to you, you do not have to do anything. Computationally, the model is sound. The second case discussed below requires careful examination.

The second case occurs when the independent terms are all dummy variables or continuous ones with repeated values (for example, age). Here one or more of the estimated coefficients will have missing standard errors. For example, consider this dataset consisting of 5 observations.
. use http://www.stata-press.com/data/r13/logitxmpl, clear

|_cons | -18.3704  | 1.414214   |   -12.99| 0.000 | -21.14221            -15.5986 |

Note: 2 failures and 0 successes completely determined.

convergence not achieved

r(430);

Three things are happening here. First, `logit` iterates almost forever and then declares nonconvergence. Second, `logit` can fit the outcome (y = 0) for the covariate pattern x1 = 0 and x2 = 0 (that is, the first two observations) perfectly. This observation is the “2 failures and 0 successes completely determined”. Third, if this observation is dropped, then x1, x2, and the constant are collinear.

This is the cause of the nonconvergence, the message “completely determined”, and the missing standard errors. It happens when you have a covariate pattern (or patterns) with only one outcome and there is collinearity when the observations corresponding to this covariate pattern are dropped.

If this happens to you, confirm the causes. First, identify the covariate pattern with only one outcome. (For your data, replace x1 and x2 with the independent variables of your model.)
If successes were completely determined, that means that there are predicted probabilities that are almost 1. If failures were completely determined, that means that there are predicted probabilities that are almost 0. The latter is the case here, so we locate the corresponding value of `pattern`:

```
tabulate pattern if p < 1e-7
```

<table>
<thead>
<tr>
<th>group(x1 x2)</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>2</td>
<td>100.00</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>2</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>
```

Once we omit this covariate pattern from the estimation sample, `logit` can deal with the collinearity:

```
logit y x1 x2 if pattern != 1, nolog
```

| y              | Coef. | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|----------------|-------|-----------|-------|------|----------------------|
| x1             | 0     | 2         | 0.00  | 1.000| -3.919928 3.919928   |
| x2 (omitted)   |       |           |       |      |                      |
| _cons          | 0     | 1.414214  | 0.00  | 1.000| -2.771808 2.771808   |
```

We omit the collinear variable. Then we must decide whether to include or omit the observations with `pattern = 1`. We could include them,

```
logit y x1, nolog
```

| y              | Coef. | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|----------------|-------|-----------|-------|------|----------------------|
| x1             | 1.098612 | 1.825742 | 0.60  | 0.547| -2.479776 4.677001   |
| _cons          | -1.098612| 1.154701  | -0.95 | 0.341| -3.361784 1.164559   |
or exclude them,

```
. logit y x1 if pattern != 1, nolog
```

| _cons | 0    | 1.414214  | 0.00 | 1.000 | -2.771808 2.771808 |

If the covariate pattern that predicts outcome perfectly is meaningful, you may want to exclude these observations from the model. Here you would report that covariate pattern such and such predicted outcome perfectly and that the best model for the rest of the data is . . . . But, more likely, the perfect prediction was simply the result of having too many predictors in the model. Then you would omit the extraneous variables from further consideration and report the best model for all the data.

### Stored results

logit stores the following in e():

Scalars

- `e(N)` number of observations
- `e(N_cds)` number of completely determined successes
- `e(N_cdf)` number of completely determined failures
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(r2_p)` pseudo-$R^2$-squared
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(p)` significance of model test
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise
logit — Logistic regression, reporting coefficients

Macros

- `e(cmd)` logit
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(offset)` linear offset variable
- `e(chi2type)` Wald or LR; type of model $\chi^2$ test
- `e(vcetype)` vcetype specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` max or min; whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of ml method
- `e(user)` name of likelihood-evaluator program
- `e(technique)` maximization technique
- `e(properties)` b V
- `e(estat_cmd)` program used to implement `estat`
- `e(predict)` program used to implement `predict`
- `e(marginsnotok)` predictions disallowed by `margins`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

Matrices

- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(ilog)` iteration log (up to 20 iterations)
- `e(gradient)` gradient vector
- `e(mns)` vector of means of the independent variables
- `e(rules)` information about perfect predictors
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

Functions

- `e(sample)` marks estimation sample

Methods and formulas

Cramer (2003, chap. 9) surveys the prehistory and history of the logit model. The word “logit” was coined by Berkson (1944) and is analogous to the word “probit”. For an introduction to probit and logit, see, for example, Aldrich and Nelson (1984), Cameron and Trivedi (2010), Greene (2012), Jones (2007), Long (1997), Long and Freese (2014), Pampel (2000), or Powers and Xie (2008).

The likelihood function for logit is

$$\ln L = \sum_{j \in S} w_j \ln F(x_j b) + \sum_{j \not\in S} w_j \ln \{1 - F(x_j b)\}$$
where S is the set of all observations j, such that y_j \neq 0, F(z) = e^z / (1 + e^z), and w_j denotes the optional weights. lnL is maximized as described in [R] maximize.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using vce(robust) and vce(cluster clustvar), respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas. The scores are calculated as u_j = \{1 - F(x_jb)\}x_j for the positive outcomes and −F(x_jb)x_j for the negative outcomes.

logit also supports estimation with survey data. For details on VCEs with survey data, see [SVY] variance estimation.

Joseph Berkson (1899–1982) was born in New York City and studied at the College of the City of New York, Columbia, and Johns Hopkins, earning both an MD and a doctorate in statistics. He then worked at Johns Hopkins before moving to the Mayo Clinic in 1931 as a biostatistician. Among many other contributions, his most influential one drew upon a long-sustained interest in the logistic function, especially his 1944 paper on bioassay, in which he introduced the term “logit”. Berkson was a frequent participant in controversy—sometimes humorous, sometimes bitter—on subjects such as the evidence for links between smoking and various diseases and the relative merits of probit and logit methods and of different calculation methods.

[U] 20 Estimation and postestimation commands
Description

The following postestimation commands are of special interest after `logit`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat</code> classification</td>
<td>report various summary statistics, including the classification table</td>
</tr>
<tr>
<td><code>estat</code> gof</td>
<td>Pearson or Hosmer–Lemeshow goodness-of-fit test</td>
</tr>
<tr>
<td><code>lroc</code></td>
<td>compute area under ROC curve and graph the curve</td>
</tr>
<tr>
<td><code>lsens</code></td>
<td>graph sensitivity and specificity versus probability cutoff</td>
</tr>
</tbody>
</table>

These commands are not appropriate after the `svy` prefix.

The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>contrast</code></td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td><code>estat</code> ic</td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td><code>estat</code> summarize</td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td><code>estat</code> vce</td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>forecast</code>¹</td>
<td>dynamic forecasts and simulations</td>
</tr>
<tr>
<td><code>lincom</code></td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td><code>linktest</code></td>
<td>link test for model specification</td>
</tr>
<tr>
<td><code>lrtest</code>²</td>
<td>likelihood-ratio test</td>
</tr>
<tr>
<td><code>margins</code></td>
<td>marginal means, predictive margins, marginal effects, and average marginal effects</td>
</tr>
<tr>
<td><code>marginsplot</code></td>
<td>graph the results from margins (profile plots, interaction plots, etc.)</td>
</tr>
<tr>
<td><code>nlcom</code></td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td><code>predict</code></td>
<td>predictions, residuals, influence statistics, and other diagnostic measures</td>
</tr>
<tr>
<td><code>predictnl</code></td>
<td>point estimates, standard errors, testing, and inference for generalized predictions</td>
</tr>
<tr>
<td><code>pwcompare</code></td>
<td>pairwise comparisons of estimates</td>
</tr>
<tr>
<td><code>suest</code></td>
<td>seemingly unrelated estimation</td>
</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

¹ `forecast` is not appropriate with `mi` or `svy` estimation results.
² `lrtest` is not appropriate with `svy` estimation results.
Syntax for predict

```
predict [type] newvar [if] [in] [ , statistic nooffset rules asif ]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>probability of a positive outcome; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the prediction</td>
</tr>
<tr>
<td>*dbeta</td>
<td>Pregibon (1981) $\Delta \hat{\beta}$ influence statistic</td>
</tr>
<tr>
<td>*deviance</td>
<td>deviance residual</td>
</tr>
<tr>
<td>*dx2</td>
<td>Hosmer, Lemeshow, and Sturdivant (2013) $\Delta \chi^2$ influence statistic</td>
</tr>
<tr>
<td>*ddeviance</td>
<td>Hosmer, Lemeshow, and Sturdivant (2013) $\Delta D$ influence statistic</td>
</tr>
<tr>
<td>*hat</td>
<td>Pregibon (1981) leverage</td>

<td>Pearson residuals; adjusted for number sharing covariate pattern</td>
</tr>
<tr>
<td>*rstandard</td>
<td>standardized Pearson residuals; adjusted for number sharing covariate pattern</td>
</tr>
<tr>
<td>score</td>
<td>first derivative of the log likelihood with respect to $x_j \beta$</td>
</tr>
</tbody>
</table>

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when `if e(sample)` is not specified.

pr, xb, stdp, and score are the only options allowed with `svy` estimation results.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

- **pr**, the default, calculates the probability of a positive outcome.
- **xb** calculates the linear prediction.
- **stdp** calculates the standard error of the linear prediction.
- **dbeta** calculates the Pregibon (1981) $\Delta \hat{\beta}$ influence statistic, a standardized measure of the difference in the coefficient vector that is due to deletion of the observation along with all others that share the same covariate pattern. In Hosmer, Lemeshow, and Sturdivant (2013, 154–155) jargon, this statistic is $M$-asymptotic; that is, it is adjusted for the number of observations that share the same covariate pattern.
- **deviance** calculates the deviance residual.
- **dx2** calculates the Hosmer, Lemeshow, and Sturdivant (2013, 191) $\Delta \chi^2$ influence statistic, reflecting the decrease in the Pearson $\chi^2$ that is due to deletion of the observation and all others that share the same covariate pattern.
- **ddeviance** calculates the Hosmer, Lemeshow, and Sturdivant (2013, 191) $\Delta D$ influence statistic, which is the change in the deviance residual that is due to deletion of the observation and all others that share the same covariate pattern.
hat calculates the Pregibon (1981) leverage or the diagonal elements of the hat matrix adjusted for the number of observations that share the same covariate pattern.

number numbers the covariate patterns—observations with the same covariate pattern have the same number. Observations not used in estimation have number set to missing. The first covariate pattern is numbered 1, the second 2, and so on.

residuals calculates the Pearson residual as given by Hosmer, Lemeshow, and Sturdivant (2013, 155) and adjusted for the number of observations that share the same covariate pattern.

rstandard calculates the standardized Pearson residual as given by Hosmer, Lemeshow, and Sturdivant (2013, 191) and adjusted for the number of observations that share the same covariate pattern.

score calculates the equation-level score, \( \partial \ln L / \partial (x_j \beta) \).

Options

nooffset is relevant only if you specified offset(varname) for logit. It modifies the calculations made by predict so that they ignore the offset variable; the linear prediction is treated as \( x_j \beta \) rather than as \( x_j \beta + \text{offset}_j \).

rules requests that Stata use any rules that were used to identify the model when making the prediction. By default, Stata calculates missing for excluded observations.

asif requests that Stata ignore the rules and exclusion criteria and calculate predictions for all observations possible by using the estimated parameter from the model.

Remarks and examples

Once you have fit a logit model, you can obtain the predicted probabilities by using the predict command for both the estimation sample and other samples; see [U] 20 Estimation and postestimation commands and [R] predict. Here we will make only a few more comments.

predict without arguments calculates the predicted probability of a positive outcome, that is, \( \Pr(y_j = 1) = F(x_j \beta) \). With the xb option, predict calculates the linear combination \( x_j \beta \), where \( x_j \) are the independent variables in the \( j \)th observation and \( \beta \) is the estimated parameter vector. This is sometimes known as the index function because the cumulative distribution function indexed at this value is the probability of a positive outcome.

In both cases, Stata remembers any rules used to identify the model and calculates missing for excluded observations, unless rules or asif is specified. For information about the other statistics available after predict, see [R] logistic postestimation.

Example 1: Predicted probabilities

In example 2 of [R] logit, we fit the logit model logit foreign b3.repair. To obtain predicted probabilities, type

```
. use http://www.stata-press.com/data/r13/repair
(1978 Automobile Data)
. logit foreign b3.repair
note: 1.repair != 0 predicts failure perfectly
1.repair dropped and 10 obs not used
(output omitted)
. predict p
(option pr assumed; Pr(foreign))
(10 missing values generated)
```
Stata remembers any rules used to identify the model and sets predictions to missing for any excluded observations. `logit` dropped the variable `1.repair` from our model and excluded 10 observations. Thus when we typed `predict p`, those same 10 observations were again excluded, and their predictions were set to missing.

`predict`’s `rules` option uses the rules in the prediction. During estimation, we were told “1.repair != 0 predicts failure perfectly”, so the rule is that when 1.repair is not zero, we should predict 0 probability of success or a positive outcome:

```
. predict p2, rules
(option pr assumed; Pr(foreign))
. summarize foreign p p2
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>58</td>
<td>.2068966</td>
<td>.4086186</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>p</td>
<td>48</td>
<td>.25</td>
<td>.1956984</td>
<td>.1</td>
<td>.5</td>
</tr>
<tr>
<td>p2</td>
<td>58</td>
<td>.2068966</td>
<td>.2016268</td>
<td>0</td>
<td>.5</td>
</tr>
</tbody>
</table>

`predict`’s `asif` option ignores the rules and exclusion criteria and calculates predictions for all observations possible by using the estimated parameters from the model:

```
. predict p3, asif
(option pr assumed; Pr(foreign))
. summarize foreign p p2 p3
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>58</td>
<td>.2068966</td>
<td>.4086186</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>p</td>
<td>48</td>
<td>.25</td>
<td>.1956984</td>
<td>.1</td>
<td>.5</td>
</tr>
<tr>
<td>p2</td>
<td>58</td>
<td>.2068966</td>
<td>.2016268</td>
<td>0</td>
<td>.5</td>
</tr>
<tr>
<td>p3</td>
<td>58</td>
<td>.2931035</td>
<td>.2016268</td>
<td>.1</td>
<td>.5</td>
</tr>
</tbody>
</table>

Which is right? What `predict` does by default is the most conservative approach. If many observations had been excluded because of a simple rule, we could be reasonably certain that the `rules` prediction is correct. The `asif` prediction is correct only if the exclusion is a fluke, and we would be willing to exclude the variable from the analysis anyway. Then, however, we would refit the model to include the excluded observations.

Example 2: Predictive margins

We can use the command `margins, contrast` after `logit` to make comparisons on the probability scale. Let’s fit a model predicting low birthweight from characteristics of the mother:

```
. use http://www.stata-press.com/data/r13/lbw, clear
```
. logit low age i.race i.smoke ptl i.ht i.ui
Iteration 0:  log likelihood = -117.336
Iteration 1:  log likelihood = -103.81846
Iteration 2:  log likelihood = -103.40486
Iteration 3:  log likelihood = -103.40384
Iteration 4:  log likelihood = -103.40384

Logistic regression  Number of obs = 189
LR chi2(7) = 27.86
Prob > chi2 = 0.0002
Log likelihood = -103.40384  Pseudo R2 = 0.1187

| low   | Coef.  | Std. Err. | z     | P>|z|   | [95% Conf. Interval] |
|-------|--------|-----------|-------|-------|----------------------|
| age   | -0.0403293 | 0.0357127  | -1.13 | 0.259 | -0.1103249 - 0.0296663 |
| race  |        |           |       |       |                      |
| black | 1.009436 | 0.5025122  | 2.01  | 0.045 | 0.0245302 1.994342   |
| other | 1.001908 | 0.4248342  | 2.36  | 0.018 | 0.1692485 1.834568   |
| smoke |        |           |       |       |                      |
| smoker| 0.9631876 | 0.3904357  | 2.47  | 0.014 | 0.1979477 1.728427   |
| ptl   | 0.6288678 | 0.3399067  | 1.85  | 0.064 | -0.0373371 1.295073  |
| 1.ht  | 1.358142  | 0.6289555  | 2.16  | 0.031 | 0.125412 2.590872    |
| 1.ui  | 0.8001832 | 0.4572306  | 1.75  | 0.080 | -0.0959724 1.696339  |
| _cons | -1.184127 | 0.9187461  | -1.29 | 0.197 | -2.984837 0.6165818  |

The coefficients are log odds-ratios: conditional on the other predictors, smoking during pregnancy is associated with an increase of 0.96 in the log odds-ratios of low birthweight. The model is linear in the log odds-scale, so the estimate of 0.96 has the same interpretation, whatever the values of the other predictors might be. We could convert 0.96 to an odds ratio by replaying the results with logit, or.

But what if we want to talk about the probability of low birthweight, and not the odds? Then we will need the command margins, contrast. We will use the r. contrast operator to compare each level of smoke with a reference level. (smoke has only two levels, so there will be only one comparison: a comparison of smokers with nonsmokers.)

. margins r.smoke, contrast
Contrasts of predictive margins
Model VCE : OIM
Expression : Pr(low), predict()

<table>
<thead>
<tr>
<th>df</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>chi2</td>
<td>6.32</td>
<td>0.0119</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Delta-method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Contrast</td>
</tr>
<tr>
<td>smoke</td>
</tr>
<tr>
<td>(smoker vs nonsmoker)</td>
</tr>
</tbody>
</table>

We see that maternal smoking is associated with an 18.3% increase in the probability of low birthweight. (We received a contrast in the probability scale because predicted probabilities are the default when margins is used after logit.)
The contrast of 18.3% is a difference of margins that are computed by averaging over the predictions for observations in the estimation sample. If the values of the other predictors were different, the contrast for \textit{smoke} would be different, too. Let’s estimate the contrast for 25-year-old mothers:

\begin{verbatim}
. margins r.smoke, contrast at(age=25)
Contras tof predictive margins
Model VCE : OIM
Expression : Pr(low), predict()
at : age = 25

<table>
<thead>
<tr>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>smoke</td>
<td>1</td>
<td>6.19</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Delta-method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Contrast</td>
</tr>
<tr>
<td>smoke</td>
</tr>
</tbody>
</table>

\end{verbatim}

Specifying a maternal \textit{age} of 25 changed the contrast to 18.1%. Our contrast of probabilities changed because the \textit{logit} model is nonlinear in the probability scale. A contrast of log odds-ratios would not have changed.

\section*{Methods and formulas}

Syntax

loneway response_var group_var [if] [in] [weight] [, options]

options Description

Main

mean expected value of $F$ distribution; default is 1
median median of $F$ distribution; default is 1
exact exact confidence intervals (groups must be equal with no weights)
level(#) set confidence level; default is level(95)

by is allowed; see [D] by.
aweights are allowed; see [U] 11.1.6 weight.

Menu

Statistics > Linear models and related > ANOVA/MANOVA > Large one-way ANOVA

Description

loneway fits one-way analysis-of-variance (ANOVA) models on datasets with many levels of group_var and presents different ancillary statistics from oneway (see [R] oneway):

<table>

Options

mean specifies that the expected value of the $F_{k-1,N-k}$ distribution be used as the reference point $F_m$ in the estimation of $\rho$ instead of the default value of 1.
median specifies that the median of the $F_{k-1,N-k}$ distribution be used as the reference point $F_m$ in the estimation of $\rho$ instead of the default value of 1.

exact requests that exact confidence intervals be computed, as opposed to the default asymptotic confidence intervals. This option is allowed only if the groups are equal in size and weights are not used.

level(#) specifies the confidence level, as a percentage, for confidence intervals of the coefficients. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

### Remarks and examples

Remarks are presented under the following headings:

- The one-way ANOVA model
- R-squared
- The random-effects ANOVA model
- Intraclass correlation
- Estimated reliability of the group-averaged score

### The one-way ANOVA model

#### Example 1

loneway’s output looks like that of oneway, except that loneway presents more information at the end. Using our automobile dataset, we have created a (numeric) variable called manufacturer_grp identifying the manufacturer of each car, and within each manufacturer we have retained a maximum of four models, selecting those with the lowest mpg. We can compute the intraclass correlation of mpg for all manufacturers with at least four models as follows:

```stata
. use http://www.stata-press.com/data/r13/auto7
(1978 Automobile Data)
. loneway mpg manufacturer_grp if nummake == 4
```

![One-way Analysis of Variance for mpg: Mileage (mpg)](image)

In addition to the standard one-way ANOVA output, loneway produces the $R$-squared, the estimated standard deviation of the group effect, the estimated standard deviation within group, the intragroup correlation, the estimated reliability of the group-averaged mean, and, for unweighted data, the asymptotic standard error and confidence interval for the intragroup correlation.
The $R^2$-squared is, of course, simply the underlying $R^2$ for a regression of response\_var on the levels of group\_var, or mpg on the various manufacturers here.

The random-effects ANOVA model

`loneway` assumes that we observe a variable, $y_{ij}$, measured for $n_i$ elements within $k$ groups or classes such that

$$y_{ij} = \mu + \alpha_i + \epsilon_{ij}, \quad i = 1, 2, \ldots, k, \quad j = 1, 2, \ldots, n_i$$

and $\alpha_i$ and $\epsilon_{ij}$ are independent zero-mean random variables with variance $\sigma^2_\alpha$ and $\sigma^2_\epsilon$, respectively. This is the random-effects ANOVA model, also known as the components-of-variance model, in which it is typically assumed that the $y_{ij}$ are normally distributed.

The interpretation with respect to our example is that the observed value of our response variable, mpg, is created in two steps. First, the $i$th manufacturer is chosen, and a value, $\alpha_i$, is determined—the typical mpg for that manufacturer less the overall mpg $\mu$. Then a deviation, $\epsilon_{ij}$, is chosen for the $j$th model within this manufacturer. This is how much that particular automobile differs from the typical mpg value for models from this manufacturer.

For our sample of 36 car models, the estimated standard deviations are $\sigma_\alpha = 3.8$ and $\sigma_\epsilon = 4.6$. Thus a little more than half of the variation in mpg between cars is attributable to the car model, with the rest attributable to differences between manufacturers. These standard deviations differ from those that would be produced by a (standard) fixed-effects regression in that the regression would require the sum within each manufacturer of the $\epsilon_{ij}$, $\epsilon_i$, for the $i$th manufacturer, to be zero, whereas these estimates merely impose the constraint that the sum is expected to be zero.

Intraclass correlation

There are various estimators of the intraclass correlation, such as the pairwise estimator, which is defined as the Pearson product-moment correlation computed over all possible pairs of observations that can be constructed within groups. For a discussion of various estimators, see Donner (1986). `loneway` computes what is termed the analysis of variance, or ANOVA, estimator. This intraclass correlation is the theoretical upper bound on the variation in response\_var that is explainable by group\_var, of which $R^2$-squared is an overestimate because of the serendipity of fitting. This correlation is comparable to an $R^2$-squared—you do not have to square it.

In our example, the intra-manu correlation, the correlation of mpg within manufacturer, is 0.40. Because aweights were not used and the default correlation was computed (that is, the mean and median options were not specified), `loneway` also provided the asymptotic confidence interval and standard error of the intraclass correlation estimate.

Estimated reliability of the group-averaged score

The estimated reliability of the group-averaged score or mean has an interpretation similar to that of the intragroup correlation; it is a comparable number if we average response\_var by group\_var, or mpg by manu in our example. It is the theoretical upper bound of a regression of manufacturer-averaged mpg on characteristics of manufacturers. Why would we want to collapse our 36-observation dataset into a 9-observation dataset of manufacturer averages? Because the 36 observations might be a mirage. When General Motors builds cars, do they sometimes put a Pontiac label and sometimes a Chevrolet label on them, so that it appears in our data as if we have two cars when we really have
only one, replicated? If that were the case, and if it were the case for many other manufacturers, then we would be forced to admit that we do not have data on 36 cars; we instead have data on nine manufacturer-averaged characteristics.

### Stored results

`loneway` stores the following in `r()`:

<table>
<thead>

</tbody>
</table>

### Methods and formulas

The mean squares in the `loneway`’s ANOVA table are computed as

\[ MS_\alpha = \sum_i w_i (\bar{y}_i - \bar{y}.)^2 / (k - 1) \]

and

\[ MS_\epsilon = \sum_i \sum_j w_{ij} (y_{ij} - \bar{y}_i)^2 / (N - k) \]

in which

\[ w_i = \sum_j w_{ij} \quad w. = \sum_i w_i \quad \bar{y}_i = \sum_j w_{ij} y_{ij} / w_i \quad \text{and} \quad \bar{y}. = \sum_i w_i \bar{y}_i / w. \]

The corresponding expected values of these mean squares are

\[ E(MS_\alpha) = \sigma_\alpha^2 + g \sigma_\alpha^2 \quad \text{and} \quad E(MS_\epsilon) = \sigma_\epsilon^2 \]

in which

\[ g = \frac{w. - \sum_i w_i^2 / w.}{k - 1} \]

In the unweighted case, we get

\[ g = \frac{N - \sum_i n_i^2 / N}{k - 1} \]

As expected, \( g = m \) for the case of no weights and equal group sizes in the data, that is, \( n_i = m \) for all \( i \). Replacing the expected values with the observed values and solving yields the ANOVA estimates of \( \sigma_\alpha^2 \) and \( \sigma_\epsilon^2 \). Substituting these into the definition of the intraclass correlation

\[ \rho = \frac{\sigma_\alpha^2}{\sigma_\alpha^2 + \sigma_\epsilon^2} \]

yields the ANOVA estimator of the intraclass correlation:

\[ \rho_A = \frac{F_{obs} - 1}{F_{obs} - 1 + g} \]
\( F_{\text{obs}} \) is the observed value of the \( F \) statistic from the ANOVA table. For no weights and equal \( n_i, \rho_A = \text{roh} \), which is the intragroup correlation defined by Kish (1965). Two slightly different estimators are available through the \textit{mean} and \textit{median} options (Gleason 1997). If either of these options is specified, the estimate of \( \rho \) becomes

\[
\rho = \frac{F_{\text{obs}} - F_m}{F_{\text{obs}} + (g-1)F_m}
\]

For the \textit{mean} option, \( F_m = E(F_{k-1,N-K}) = (N-k)/(N-k-2) \), that is, the expected value of the ANOVA table’s \( F \) statistic. For the \textit{median} option, \( F_m \) is simply the median of the \( F \) statistic. Setting \( F_m \) to 1 gives \( \rho_A \), so for large samples, these different point estimators are essentially the same. Also, because the intraclass correlation of the random-effects model is by definition nonnegative, for any of the three possible point estimators, \( \rho \) is truncated to zero if \( F_{\text{obs}} \) is less than \( F_m \).

For no weighting, interval estimators for \( \rho_A \) are computed. If the groups are equal sized (all \( n_i \) equal) and the \textit{exact} option is specified, the following exact (assuming that the \( y_{ij} \) are normally distributed) 100(1 - \( \alpha \))% confidence interval is computed:

\[
\left\{ \frac{F_{\text{obs}} - F_m F_u}{F_{\text{obs}} + (g-1)F_m F_u}, \frac{F_{\text{obs}} - F_m F_l}{F_{\text{obs}} + (g-1)F_m F_l} \right\}
\]

with \( F_m = 1, F_l = F_{\alpha/2,k-1,N-k}, \) and \( F_u = F_{1-\alpha/2,k-1,N-k} \). \( F_{k-1,N-k}, F_{k-1,N-k} \) being the cumulative distribution function for the \( F \) distribution with \( k-1 \) and \( N-k \) degrees of freedom. If \textit{mean} or \textit{median} is specified, \( F_m \) is defined as above. If the groups are equal sized and \textit{exact} is not specified, the following asymptotic 100(1 - \( \alpha \))% confidence interval for \( \rho_A \) is computed,

\[
\left[ \rho_A - z_{\alpha/2} \sqrt{V(\rho_A)}, \rho_A + z_{\alpha/2} \sqrt{V(\rho_A)} \right]
\]

where \( z_{\alpha/2} \) is the 100(1 - \( \alpha/2 \)) percentile of the standard normal distribution and \( \sqrt{V(\rho_A)} \) is the asymptotic standard error of \( \rho \) defined below. This confidence interval is also available for unequal groups. It is not applicable and, therefore, not computed for the estimates of \( \rho \) provided by the \textit{mean} and \textit{median} options. Again, because the intraclass coefficient is nonnegative, if the lower bound is negative for either confidence interval, it is truncated to zero. As might be expected, the coverage probability of a truncated interval is higher than its nominal value.

The asymptotic standard error of \( \rho_A \), assuming that the \( y_{ij} \) are normally distributed, is also computed when appropriate, namely, for unweighted data and when \( \rho_A \) is computed (neither the \textit{mean} option nor the \textit{median} option is specified):

\[
V(\rho_A) = \frac{2(1-\rho)^2}{g^2} (A + B + C)
\]

with

\[
A = \frac{(1+\rho(g-1))^2}{N-k}
\]

\[
B = \frac{(1-\rho)(1+\rho(2g-1))}{k-1}
\]

\[
C = \rho^2\left\{ \sum n_i^2 - 2N^{-1} \sum n_i^3 + N^{-2}(\sum n_i^2)^2 \right\}/(k-1)^2
\]

and \( \rho_A \) is substituted for \( \rho \) (Donner 1986).
The estimated reliability of the group-averaged score, known as the Spearman–Brown prediction formula in the psychometric literature (Winer, Brown, and Michels 1991, 1014), is

\[ \rho_t = \frac{t \rho}{1 + (t - 1) \rho} \]

for group size \( t \). \texttt{loneway} computes \( \rho_t \) for \( t = g \).

The estimated standard deviation of the group effect is \( \sigma_\alpha = \sqrt{(MS_\alpha - MS_\epsilon)/g} \). This deviation comes from the assumption that an observation is derived by adding a group effect to a within-group effect.

The estimated standard deviation within group is the square root of the mean square due to error, or \( \sqrt{MS_\epsilon} \).

**Acknowledgment**

We thank John Gleason of Syracuse University (retired) for his contributions to improving \texttt{loneway}.

Menu

Statistics > Nonparametric analysis > Lowess smoothing

Description

lowess carries out a locally weighted regression of yvar on xvar, displays the graph, and optionally saves the smoothed variable.

Warning: lowess is computationally intensive and may therefore take a long time to run on a slow computer. Lowess calculations on 1,000 observations, for instance, require performing 1,000 regressions.
Options

Main

**mean** specifies running-mean smoothing; the default is running-line least-squares smoothing.

**noweight** prevents the use of Cleveland’s (1979) tricube weighting function; the default is to use the weighting function.

**bwidth(#)** specifies the bandwidth. Centered subsets of $bwidth() \times N$ observations are used for calculating smoothed values for each point in the data except for the end points, where smaller, uncentered subsets are used. The greater the $bwidth()$, the greater the smoothing. The default is 0.8.

**logit** transforms the smoothed $yvar$ into logits. Predicted values less than 0.0001 or greater than 0.9999 are set to $1/N$ and $1 - 1/N$, respectively, before taking logits.

**adjust** adjusts the mean of the smoothed $yvar$ to equal the mean of $yvar$ by multiplying by an appropriate factor. This option is useful when smoothing binary (0/1) data.

**nograph** suppresses displaying the graph.

**generate**(newvar) creates newvar containing the smoothed values of $yvar$.

Plot

**marker_options** affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] *marker_options*.

**marker_label_options** specify if and how the markers are to be labeled; see [G-3] *marker_label_options*.

Smoothed line

**lineopts(cline_options)** affects the rendition of the lowess-smoothed line; see [G-3] *cline_options*.

Add plots

**addplot(plot)** provides a way to add other plots to the generated graph; see [G-3] *addplot_option*.

Y axis, X axis, Titles, Legend, Overall, By

**twoway_options** are any of the options documented in [G-3] *twoway_options*. These include options for titling the graph (see [G-3] *title_options*), options for saving the graph to disk (see [G-3] *saving_option*), and the by() option (see [G-3] *by_option*).

Remarks and examples

By default, *lowess* provides locally weighted scatterplot smoothing. The basic idea is to create a new variable (newvar) that, for each $yvar$ $y_i$, contains the corresponding smoothed value. The smoothed values are obtained by running a regression of $yvar$ on $xvar$ by using only the data $(x_i, y_i)$ and a few of the data near this point. In *lowess*, the regression is weighted so that the central point $(x_i, y_i)$ gets the highest weight and points that are farther away (based on the distance $|x_j - x_i|$) receive less weight. The estimated regression line is then used to predict the smoothed value $\hat{y_i}$ for $y_i$ only. The procedure is repeated to obtain the remaining smoothed values, which means that a separate weighted regression is performed for every point in the data.

Lowess is a desirable smoother because of its locality—it tends to follow the data. Polynomial smoothing methods, for instance, are global in that what happens on the extreme left of a scatterplot can affect the fitted values on the extreme right.
Example 1

The amount of smoothing is affected by `bwidth(#)`.
You are warned to experiment with different values.
For instance,

```stata
. use http://www.stata-press.com/data/r13/lowess1
(example data for lowess)
. lowess h1 depth
```

![Lowess smoother](image1)

Now compare that with

```stata
. lowess h1 depth, bwidth(.4)
```

![Lowess smoother](image2)

In the first case, the default bandwidth of 0.8 is used,
meaning that 80% of the data are used in smoothing each point.
In the second case, we explicitly specified a bandwidth of 0.4.
Smaller bandwidths follow the original data more closely.
Example 2

Two `lowess` options are especially useful with binary (0/1) data: `adjust` and `logit`. `adjust` adjusts the resulting curve (by multiplication) so that the mean of the smoothed values is equal to the mean of the unsmoothed values. `logit` specifies that the smoothed curve be in terms of the log of the odds ratio:

```
.use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
.lowess foreign mpg, ylabel(0 "Domestic" 1 "Foreign") jitter(5) adjust
```

![](image1)

```
.lowess foreign mpg, logit yline(0)
```

![](image2)

With binary data, if you do not use the `logit` option, it is a good idea to specify `graph`'s `jitter()` option; see [G-2] `graph twoway scatter`. Because the underlying data (whether the car was manufactured outside the United States here) take on only two values, raw data points are more likely to be on top of each other, thus making it impossible to tell how many points there are. `graph`'s `jitter()` option adds some noise to the data to shift the points around. This noise affects only the location of points on the graph, not the lowess curve.
When you specify the logit option, the display of the raw data is suppressed.

Technical note

`lowess` can be used for more than just lowess smoothing. Lowess can be usefully thought of as a combination of two smoothing concepts: the use of predicted values from regression (rather than means) for imputing a smoothed value and the use of the tricube weighting function (rather than a constant weighting function). `lowess` allows you to combine these concepts freely. You can use line smoothing without weighting (specify `noweight`), mean smoothing with tricube weighting (specify `mean`), or mean smoothing without weighting (specify `mean` and `noweight`).

Methods and formulas

Let $y_i$ and $x_i$ be the two variables, and assume that the data are ordered so that $x_i \leq x_{i+1}$ for $i = 1, \ldots, N - 1$. For each $y_i$, a smoothed value $y_i^s$ is calculated.

The subset used in calculating $y_i^s$ is indices $i_- = \max(1, i - k)$ through $i_+ = \min(i + k, N)$, where $k = \lfloor (N \times \text{width} - 0.5)/2 \rfloor$. The weights for each of the observations between $j = i_-, \ldots, i_+$ are either 1 (`noweight`) or the tricube (default),

$$w_j = \left\{1 - \left( \frac{|x_j - x_i|}{\Delta} \right)^3 \right\}^3$$

where $\Delta = 1.0001 \max(x_{i+} - x_i, x_i - x_{i-})$. The smoothed value $y_i^s$ is then the (weighted) mean or the (weighted) regression prediction at $x_i$.

Acknowledgment

`lowess` is a modified version of a command originally written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model*.

**Menu**

Statistics > Nonparametric analysis > Local polynomial smoothing

**Description**

lpoly performs a kernel-weighted local polynomial regression of *yvar* on *xvar* and displays a graph of the smoothed values with (optional) confidence bands.

**Options**

**Main**

kernel(*kernel*) specifies the kernel function for use in calculating the weighted local polynomial estimate. The default is kernel(epanechnikov).

bwidth(# | *varname*) specifies the half-width of the kernel—the width of the smoothing window around each point. If bwidth() is not specified, a rule-of-thumb (ROT) bandwidth estimator is calculated and used. A local variable bandwidth may be specified in *varname*, in conjunction with an explicit smoothing grid using the at() option.

degree(#) specifies the degree of the polynomial to be used in the smoothing. The default is degree(0), meaning local-mean smoothing.

generate([ *newvar*_x ] *newvar*_s) stores the smoothing grid in *newvar*_x and the smoothed values in *newvar*_s. If at() is not specified, then both *newvar*_x and *newvar*_s must be specified. Otherwise, only *newvar*_s is to be specified.

n(#) specifies the number of points at which the smooth is to be calculated. The default is min(\(N, 50\)), where \(N\) is the number of observations.

at(*varname*) specifies a variable that contains the values at which the smooth should be calculated.

By default, the smoothing is done on an equally spaced grid, but you can use at() to instead perform the smoothing at the observed *x*’s, for example. This option also allows you to more easily obtain smooths for different variables or different subsamples of a variable and then overlay the estimates for comparison.

nograph suppresses drawing the graph of the estimated smooth. This option is often used with the generate() option.
noscatter suppresses superimposing a scatterplot of the observed data over the smooth. This option is useful when the number of resulting points would be so large as to clutter the graph.

\[ \text{SE/CI} \]

\text{ci} plots confidence bands, using the confidence level specified in level().

\text{level(\#)} specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

\text{se(newvar)} stores the estimates of the standard errors in newvar. This option requires specifying generate() or at().

\text{pwidth(\#)} specifies the pilot bandwidth to be used for standard-error computations. The default is chosen to be 1.5 times the value of the ROT bandwidth selector. If you specify pwidth() without specifying se() or ci, then the ci option is assumed.

\text{var(\# \mid varname)} specifies an estimate of a constant residual variance or a variable containing estimates of the residual variances at each grid point required for standard-error computation. By default, the residual variance at each smoothing point is estimated by the normalized weighted residual sum of squares obtained from locally fitting a polynomial of order \( p + 2 \), where \( p \) is the degree specified in degree(). \text{var(varname)} is allowed only if at() is specified. If you specify var() without specifying se() or ci, then the ci option is assumed.

\text{Scatterplot}

\text{marker_options} affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.

\text{marker_label_options} specify if and how the markers are to be labeled; see [G-3] marker_label_options.

\text{Smoothed line}

\text{lineopts(cline_options)} affects the rendition of the smoothed line; see [G-3] cline_options.

\text{CI plot}

\text{ciopts(cline_options)} affects the rendition of the confidence bands; see [G-3] cline_options.

\text{Add plots}

\text{addplot(plot)} provides a way to add other plots to the generated graph; see [G-3] addplot_option.

\text{Y axis, X axis, Titles, Legend, Overall}

\text{twoway_options} are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

\text{Remarks and examples}

Remarks are presented under the following headings:

- Introduction
- Local polynomial smoothing
- Choice of a bandwidth
- Confidence bands
Introduction

The last 25 years or so has seen a significant outgrowth in the literature on scatterplot smoothing, otherwise known as univariate nonparametric regression. Of most appeal is the idea of making no assumptions about the functional form for the expected value of a response given a regressor, but instead allowing the data to “speak for themselves”. Various methods and estimators fall into the category of nonparametric regression, including local mean smoothing as described independently by Nadaraya (1964) and Watson (1964), the Gasser and Müller (1979) estimator, locally weighted scatterplot smoothing (LOWESS) as described by Cleveland (1979), wavelets (for example, Donoho [1995]), and splines (Eubank 1999), to name a few. Much of the vast literature focuses on automating the amount of smoothing to be performed and dealing with the bias/variance tradeoff inherent to this type of estimation. For example, for Nadaraya–Watson the amount of smoothing is controlled by choosing a bandwidth.

Smoothing via local polynomials is by no means a new idea but instead one that has been rediscovered in recent years in articles such as Fan (1992). A natural extension of the local mean smoothing of Nadaraya–Watson, local polynomial regression involves fitting the response to a polynomial form of the regressor via locally weighted least squares. Higher-order polynomials have better bias properties than the zero-degree local polynomials of the Nadaraya–Watson estimator; in general, higher-order polynomials do not require bias adjustment at the boundary of the regression space. For a definitive reference on local polynomial smoothing, see Fan and Gijbels (1996).

Local polynomial smoothing

Consider a set of scatterplot data \{ (x_1, y_1), \ldots, (x_n, y_n) \} from the model

\[ y_i = m(x_i) + \sigma(x_i) \epsilon_i \quad (1) \]

for some unknown mean and variance functions \( m(\cdot) \) and \( \sigma^2(\cdot) \), and symmetric errors \( \epsilon_i \) with \( E(\epsilon_i) = 0 \) and \( Var(\epsilon_i) = 1 \). The goal is to estimate \( m(x_0) = E[Y|X=x_0] \), making no assumption about the functional form of \( m(\cdot) \).

lpoly estimates \( m(x_0) \) as the constant term (intercept) of a regression, weighted by the kernel function specified in \texttt{kernel()} of \texttt{yvar} on the polynomial terms \((xvar-x_0), (xvar-x_0)^2, \ldots, (xvar-x_0)^p\) for each smoothing point \( x_0 \). The degree of the polynomial, \( p \), is specified in \texttt{degree()}, the amount of smoothing is controlled by the bandwidth specified in \texttt{bwidth()}, and the chosen kernel function is specified in \texttt{kernel()}.

Example 1

Consider the motorcycle data as examined (among other places) in Fan and Gijbels (1996). The data consist of 133 observations and measure the acceleration (\texttt{accel} measured in grams [g]) of a dummy’s head during impact over time (\texttt{time} measured in milliseconds). For these data, we use \texttt{lpoly} to fit a local cubic polynomial with the default bandwidth (obtained using the \texttt{ROT} method) and the default Epanechnikov kernel.
. use http://www.stata-press.com/data/r13/motorcycle
(Motorcycle data from Fan & Gijbels (1996))
. lpoly accel time, degree(3)

The default bandwidth and kernel settings do not provide a satisfactory fit in this example. To improve the fit, we can either supply a different bandwidth by using the `bwidth()` option or specify a different kernel by using the `kernel()` option. For example, using the alternative Epanechnikov kernel, `kernel(epan2)`, below provides a better fit for these data.

. lpoly accel time, degree(3) kernel(epan2)

Technical note

lpoly allows specifying in `degree()` both odd and even orders of the polynomial to be used for the smoothing. However, the odd-order, $2k + 1$, polynomial approximations are preferable. They have
an extra parameter compared with the even-order, $2k$, approximations, which leads to a significant bias reduction and there is no increase of variability associated with adding this extra parameter. Using an odd order when estimating the regression function is therefore usually sufficient. For a more thorough discussion, see Fan and Gijbels (1996).

**Choice of a bandwidth**

The choice of a bandwidth is crucial for many smoothing techniques, including local polynomial smoothing. In general, using a large bandwidth gives smooths with a large bias, whereas a small bandwidth may result in highly variable smoothed values. Various techniques exist for optimal bandwidth selection. By default, `lpoly` uses the ROT method to estimate the bandwidth used for the smoothing; see *Methods and formulas* for details.

**Example 2**

Using the `motorcycle` data, we demonstrate how a local linear polynomial fit changes using different bandwidths.

```
. lpoly accel time, degree(1) kernel(epan2) bwidth(1) generate(at smooth1)
> nograph
. lpoly accel time, degree(1) kernel(epan2) bwidth(7) at(at) generate(smooth2)
> nograph
. label variable smooth1 "smooth: width = 1"
. label variable smooth2 "smooth: width = 7"
. lpoly accel time, degree(1) kernel(epan2) at(at) addplot(line smooth* at)
> legend(label(2 "smooth: width = 3.42 (ROT)")) note("kernel = epan2, degree = 1")
```

From this graph, we can see that the local linear polynomial fit with larger bandwidth (width = 7) corresponds to a smoother line but fails to fit the curvature of the scatterplot data. The smooth obtained using the width equal to one seems to fit most data points, but the corresponding line has several spikes indicating larger variability. The smooth obtained using the ROT bandwidth estimator seems to have a good tradeoff between the fit and variability in this example.
In the above, we also demonstrated how the `generate()` and `addplot()` options may be used to produce overlaid plots obtained from `lpoly` with different options. The `nograph` option saves time when you need to save only results with `generate()`.

However, to avoid generating variables manually, one can use `twoway lpoly` instead; see \[G-2\] `graph twoway lpoly` for more details.

```
. twoway scatter accel time ||
  >   lpoly accel time, degree(1) kernel(epan2) lpattern(solid) ||
  >   lpoly accel time, degree(1) kernel(epan2) bwidth(1) ||
  >   lpoly accel time, degree(1) kernel(epan2) bwidth(7) ||
  >   , legend(label(2 "smooth: width = 3.42 (ROT)" label(3 "smooth: width = 1")
  >     label(4 "smooth: width = 7"))
  >     title("Local polynomial smooth") note("kernel = epan2, degree = 1")
  >     xtitle("time (msec)") ytitle("acceleration (g)"")
```

The ROT estimate is commonly used as an initial guess for the amount of smoothing; this approach may be sufficient when the choice of a bandwidth is less important. In other cases, you can pick your own bandwidth.

When the shape of the regression function has a combination of peaked and flat regions, a variable bandwidth may be preferable over the constant bandwidth to allow for different degrees of smoothness in different regions. The `bwidth()` option allows you to specify the values of the local variable bandwidths as those stored in a variable in your data.

Similar issues with bias and variability arise when choosing a pilot bandwidth (the `pwidth()` option) used to compute standard errors of the local polynomial smoother. The default value is chosen to be $1.5 \times$ ROT. For a review of methods for pilot bandwidth selection, see Fan and Gijbels (1996).

**Confidence bands**

The established asymptotic normality of the local polynomial estimators under certain conditions allows the construction of approximate confidence bands. `lpoly` offers the `ci` option to plot these bands.
Example 3

Let us plot the confidence bands for the local polynomial fit from example 1.

```
. lpoly accel time, degree(3) kernel(epan2) ci
```

You can obtain graphs with overlaid confidence bands by using `twoway lpoly ci`; see [G-2] `graph twoway lpoly ci` for examples.

Constructing the confidence intervals involves computing standard errors obtained by taking a square root of the estimate of the conditional variance of the local polynomial estimator at each grid point \( x_0 \). Estimating the conditional variance requires fitting a polynomial of a higher order locally by using a different bandwidth, the pilot bandwidth. The value of the pilot bandwidth may be supplied by using `pwidth()`. By default, the value of \( 1.5 \times \text{ROT} \) is used. Also, estimates of the residual variance \( \sigma^2(x_0) \) at each grid point, \( x_0 \), are required to obtain the estimates of the conditional variances. These estimates may be supplied by using the `var()` option. By default, they are computed using the normalized weighted residual sum of squares from a local polynomial fit of a higher order. See `Methods and formulas` for details. The standard errors may be saved by using `se()`.

**Stored results**

`lpoly` stores the following in `r()`:

<table>
<thead>

Methods and formulas

Consider model (1), written in matrix notation,

\[ y = m(x) + \epsilon \]

where \( y \) and \( x \) are the \( n \times 1 \) vectors of scatterplot values, \( \epsilon \) is the \( n \times 1 \) vector of errors with zero mean and covariance matrix \( \Sigma = \text{diag}\{\sigma(x_i)\}_1^n \), and \( m() \) and \( \sigma() \) are some unknown functions. Define \( m(x_0) = E[Y|X = x_0] \) and \( \sigma^2(x_0) = \text{Var}[Y|X = x_0] \) to be the conditional mean and conditional variance of random variable \( Y \) (residual variance), respectively, for some realization \( x_0 \) of random variable \( X \).

The method of local polynomial smoothing is based on the approximation of \( m(x) \) locally by a \( p \)th order polynomial in \( (x - x_0) \) for some \( x \) in the neighborhood of \( x_0 \). For the scatterplot data \( \{(x_1, y_1), \ldots, (x_n, y_n)\} \), the \( p \)th-order local polynomial smooth \( \hat{m}(x_0) \) is equal to \( \hat{\beta}_0 \), an estimate of the intercept of the weighted linear regression,

\[ \hat{\beta} = (X^T W X)^{-1} X^T W y \]

where \( \hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \ldots, \hat{\beta}_p)^T \) is the vector of estimated regression coefficients (with \( \{\hat{\beta}_j = (j!)^{-1} \hat{m}^{(j)}(x)|_{x=x_0}, j = 0, \ldots, p\} \) also representing estimated coefficients from a corresponding Taylor expansion); \( X = \{(x_i - x_0)^j\}_{i,j=0}^{n,p} \) is a design matrix; and \( W = \text{diag}\{K_h(x_i - x_0)\}_{1}^{n \times n} \) is a weighting matrix with weights \( K_h(\cdot) \) defined as \( K_h(x) = h^{-1}K(x/h) \), with \( K(\cdot) \) being a kernel function and \( h \) defining a bandwidth. The kernels are defined in Methods and formulas of [R] kdensity.

The default bandwidth is obtained using the ROT method of bandwidth selection. The ROT bandwidth is the plug-in estimator of the asymptotically optimal constant bandwidth. This is the bandwidth that minimizes the conditional weighted mean integrated squared error. The ROT plugin bandwidth selector for the smoothing bandwidth \( h \) is defined as follows; assuming constant residual variance \( \sigma^2(x_0) = \sigma^2 \) and odd degree \( p \):

\[ \hat{h} = C_{0,p}(K) \left[ \frac{\hat{\sigma}^2}{n \int \left\{ \hat{m}^{(p+1)}(x) \right\}^2 w_0(x) f(x) dx} \right]^{1/(2p+3)} \]

where \( C_{0,p}(K) \) is a constant, as defined in Fan and Gijbels (1996), that depends on the kernel function \( K(\cdot) \), and the degree of a polynomial \( p \) and \( w_0 \) is chosen to be an indicator function on the interval \([\text{min}_x + 0.05 \times \text{range}_x, \text{max}_x - 0.05 \times \text{range}_x] \) with \( \text{min}_x \), \( \text{max}_x \), and \( \text{range}_x \) being, respectively, the minimum, maximum, and the range of \( x \). To obtain the estimates of a constant residual variance, \( \hat{\sigma}^2 \), and \( (p + 1) \)th order derivative of \( m(x) \), denoted as \( \hat{m}^{(p+1)}(x) \), a polynomial in \( x \) of order \( (p + 3) \) is fit globally to \( y \). \( \hat{\sigma}^2 \) is estimated as a standardized residual sum of squares from this fit.

The expression for the asymptotically optimal constant bandwidth used in constructing the ROT bandwidth estimator is derived for the odd-order polynomial approximations. For even-order polynomial fits the expression would depend not only on \( m^{(p+1)}(x) \) but also on \( m^{(p+2)}(x) \) and the design density and its derivative, \( f(x) \) and \( f'(x) \). Therefore, the ROT bandwidth selector would require estimation of these additional quantities. Instead, for an even-degree \( p \) of the local polynomial, 1poly uses the value of the ROT estimator (3) computed using degree \( p + 1 \). As such, for even degrees this is not a plugin estimator of the asymptotically optimal constant bandwidth.

The estimates of the conditional variance of local polynomial estimators are obtained using

\[ \text{Var}\{\hat{m}(x_0)|X = x_0\} = \hat{\sigma}^2_m(x_0) = (X^T W X)^{-1} (X^T W^2 X)(X^T W X)^{-1} \hat{\sigma}^2(x_0) \]
where $\hat{\sigma}^2(x_0)$ is estimated by the normalized weighted residual sum of squares from the $(p + 2)$th order polynomial fit using pilot bandwidth $h^*$. When the bias is negligible the normal-approximation method yields a $(1 - \alpha) \times 100\%$ confidence interval for $m(x_0)$,

$$\{ \hat{m}(x_0) - z_{(1-\alpha/2)}\hat{\sigma}_m(x_0), \hat{m}(x_0) + z_{(1-\alpha/2)}\hat{\sigma}_m(x_0) \}$$

where $z_{(1-\alpha/2)}$ is the $(1 - \alpha/2)$th quantile of the standard Gaussian distribution, and $\hat{m}(x_0)$ and $\hat{\sigma}_m(x_0)$ are as defined in (2) and (4), respectively.

Weights are allowed; see [U] 11.1.6 weight.

`lroc` is not appropriate after the _svy_ prefix.

## Menu

Statistics > Binary outcomes > Postestimation > ROC curve after logistic/logit/probit/ivprobit

## Description

`lroc` graphs the ROC curve and calculates the area under the curve.

`lroc` requires that the current estimation results be from logistic, logit, probit, or ivprobit; see [R] logistic, [R] logit, [R] probit, or [R] ivprobit.
Options

Main

all requests that the statistic be computed for all observations in the data, ignoring any if or in
restrictions specified by the estimation command.

nograph suppresses graphical output.

Advanced

beta(matname) specifies a row vector containing model coefficients. The columns of the row vector
must be labeled with the corresponding names of the independent variables in the data. The
dependent variable depvar must be specified immediately after the command name. See Models
other than the last fitted model later in this entry.

Plot

cline_options, marker_options, and marker_label_options affect the rendition of the ROC curve—the
plotted points connected by lines. These options affect the size and color of markers, whether and
how the markers are labeled, and whether and how the points are connected; see [G-3] cline_options,

rlopts(cline_options) affects the rendition of the reference line; see [G-3] cline_options.

Add plots

addplot(plot) provides a way to add other plots to the generated graph; see [G-3] addplot_option.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These
include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see

Remarks and examples

Remarks are presented under the following headings:

Introduction
Samples other than the estimation sample
Models other than the last fitted model

Introduction

Stata also has a suite of commands for performing both parametric and nonparametric receiver
operating characteristic (ROC) analysis. See [R] roc for an overview of these commands.

lroc graphs the ROC curve—a graph of sensitivity versus one minus specificity as the cutoff $c$
is varied—and calculates the area under it. Sensitivity is the fraction of observed positive-outcome
cases that are correctly classified; specificity is the fraction of observed negative-outcome cases that
are correctly classified. When the purpose of the analysis is classification, you must choose a cutoff.
The curve starts at \((0, 0)\), corresponding to \(c = 1\), and continues to \((1, 1)\), corresponding to \(c = 0\). A model with no predictive power would be a \(45^\circ\) line. The greater the predictive power, the more bowed the curve, and hence the area beneath the curve is often used as a measure of the predictive power. A model with no predictive power has area 0.5; a perfect model has area 1.

The ROC curve was first discussed in signal detection theory (Peterson, Birdsall, and Fox 1954) and then was quickly introduced into psychology (Tanner and Swets 1954). It has since been applied in other fields, particularly medicine (for instance, Metz [1978]). For a classic text on ROC techniques, see Green and Swets (1966).

`lroc` also plots sensitivity and specificity; see [R] `lroc`.

### Example 1

Hardin and Hilbe (2012) examine data from the National Canadian Registry of Cardiovascular Disease (FASTRAK), sponsored by Hoffman-La Roche Canada. They model death within 48 hours based on whether a patient suffers an anterior infarct (heart attack) rather than an inferior infarct using a logistic regression and evaluate the model using an ROC curve. We replicate their analysis here.

Both anterior and inferior refer to sites on the heart where damage occurs. The model is also adjusted for `hcabg`, whether the subject has had a cardiac bypass surgery (CABG); `age`, a four-category age-group indicator; and `killip`, a four-level risk indicator.

We load the data and then estimate the parameters of the logistic regression with `logistic`. Factor-variable notation is used for each predictor, because they are categorical; see [U] 11.4.3 Factor variables.

```stata
. use http://www.stata-press.com/data/r13/heart (Heart attacks)
. logistic death i.site i.hcabg i.killip i.age
```

| death | Odds Ratio | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|-------|------------|-----------|-----|-----|----------------------|
| site  |            |           |     |     |                      |
| Anterior | 1.901333 | .3185757  | 3.83 | 0.000 | 1.369103 2.640464   |
| 1.hcabg | 2.105275 | .7430694  | 2.11 | 0.035 | 1.054076 4.204801   |
| killip |            |           |     |     |                      |
| 2     | 2.251732  | .4064423  | 4.50 | 0.000 | 1.580786 3.207453   |
| 3     | 2.172105  | .584427   | 2.88 | 0.004 | 1.281907 3.680487   |
| 4     | 14.29137  | 5.087654  | 7.47 | 0.000 | 7.112964 28.71423   |
| age   |            |           |     |     |                      |
| 60-69 | 1.63726   | .5078582  | 1.59 | 0.112 | .8914261 3.007115   |
| 70-79 | 4.532029  | 1.206534  | 5.68 | 0.000 | 2.689568 7.636647   |
| >=80  | 8.893222  | 2.41752   | 8.04 | 0.000 | 5.219991 15.15125   |
| _cons| .0063961  | .0016541  | -19.54 | 0.000 | .0038529 .010618   |

The odds ratios for a unit change in each covariate are reported by `logistic`. At fixed values of the other covariates, patients who enter Canadian hospitals with an anterior infarct have nearly twice the odds of death within 48 hours than those with an inferior infarct. Those who have had a previous CABG have approximately twice the risk of death of those who have not. Those with higher Killip risks and those who are older are also at greater risk of death.
We use \texttt{lroc} to draw the ROC curve for the model. The area under the curve of approximately 0.8 indicates acceptable discrimination for the model.

\begin{verbatim}
. lroc
Logistic model for death
number of observations = 4483
area under ROC curve = 0.7965
\end{verbatim}

\begin{figure}
\centering
\includegraphics[width=\textwidth]{roc_curve.png}
\caption{Area under ROC curve = 0.7965}
\end{figure}

\textbf{Samples other than the estimation sample}

\texttt{lroc} can be used with samples other than the estimation sample. By default, \texttt{lroc} remembers the estimation sample used with the last \texttt{logistic}, \texttt{logit}, \texttt{probit}, or \texttt{ivprobit} command. To override this, simply use an \texttt{if} or \texttt{in} restriction to select another set of observations, or specify the \texttt{all} option to force the command to use all the observations in the dataset.

See example 3 in \texttt{[R] estat gof} for an example of using \texttt{lroc} with a sample other than the estimation sample.

\textbf{Models other than the last fitted model}

By default, \texttt{lroc} uses the last model fit by \texttt{logistic}, \texttt{logit}, \texttt{probit}, or \texttt{ivprobit}. You may also directly specify the model to \texttt{lroc} by inputting a vector of coefficients with the \texttt{beta()} option and passing the name of the dependent variable \texttt{depvar} to \texttt{lroc}.

\textbf{Example 2}

Suppose that someone publishes the following logistic model of low birthweight:

\[
\Pr(\text{low} = 1) = F(-0.02 \text{age} - 0.01 \text{lwt} + 1.3 \text{black} + 1.1 \text{smoke} + 0.5 \text{ptl} + 1.8 \text{ht} + 0.8 \text{ui} + 0.5)
\]

where $F$ is the cumulative logistic distribution. These coefficients are not odds ratios; they are the equivalent of what \texttt{logit} produces.
We can see whether this model fits our data. First we enter the coefficients as a row vector and label its columns with the names of the independent variables plus _cons for the constant (see [P] matrix define and [P] matrix rownames).

```
. use http://www.stata-press.com/data/r13/lbw3, clear
   (Hosmer & Lemeshow data)
. matrix input b = (-.02, -.01, 1.3, 1.1, .5, 1.8, .8, .5)
. matrix colnames b = age lwt black smoke ptl ht ui _cons
```

Here we use lroc to examine the predictive ability of the model:

```
. lroc low, beta(b) nograph
Logistic model for low
   number of observations =     189
   area under ROC curve      =  0.7275
```

The area under the curve indicates that this model does have some predictive power. We can obtain a graph of sensitivity and specificity as a function of the cutoff probability by typing

```
. lsens low, beta(b)
```

See [R] lsens.

### Stored results

`lroc` stores the following in `r()`:

- Scalars
  - `r(N)` number of observations
  - `r(area)` area under the ROC curve

### Methods and formulas

The ROC curve is a graph of specificity against \( (1 - sensitivity) \). This is guaranteed to be a monotone nondecreasing function because the number of correctly predicted successes increases and the number of correctly predicted failures decreases as the classification cutoff \( c \) decreases.
The area under the ROC curve is the area on the bottom of this graph and is determined by integrating the curve. The vertices of the curve are determined by sorting the data according to the predicted index, and the integral is computed using the trapezoidal rule.

Statistics > Postestimation > Tests > Likelihood-ratio test

Description

`lrtest` performs a likelihood-ratio test of the null hypothesis that the parameter vector of a statistical model satisfies some smooth constraint. To conduct the test, both the unrestricted and the restricted models must be fit using the maximum likelihood method (or some equivalent method), and the results of at least one must be stored using `estimates store`; see \[R\] estimates store.

`modelspec1` and `modelspec2` specify the restricted and unrestricted model in any order. `modelspec1` and `modelspec2` cannot have names in common; for example, `lrtest (A B C) (C D E)` is not allowed because both model specifications include `C`. If `modelspec2` is not specified, the last estimation result is used; this is equivalent to specifying `modelspec2` as a period (\.

`lrtest` supports composite models specified by a parenthesized list of model names. In a composite model, we assume that the log likelihood and dimension (number of free parameters) of the full model are obtained as the sum of the log-likelihood values and dimensions of the constituting models.

`lrtest` provides an important alternative to `test` (see \[R\] test) for models fit via maximum likelihood or equivalent methods.
**Options**

`stats` displays statistical information about the unrestricted and restricted models, including the information indices of Akaike and Schwarz.

`dir` displays descriptive information about the unrestricted and restricted models; see `estimates dir` in [R] `estimates store`.

`df(#)` is seldom specified; it overrides the automatic degrees-of-freedom calculation.

`force` forces the likelihood-ratio test calculations to take place in situations where `lrtest` would normally refuse to do so and issue an error. Such situations arise when one or more assumptions of the test are violated, for example, if the models were fit with `vce(robust)`, `vce(cluster clustvar)`, or `pweights`; when the dependent variables in the two models differ; when the null log likelihoods differ; when the samples differ; or when the estimation commands differ. If you use the `force` option, there is no guarantee as to the validity or interpretability of the resulting test.

**Remarks and examples**

The standard way to use `lrtest` is to do the following:

1. Fit either the restricted model or the unrestricted model by using one of Stata’s estimation commands and then store the results using `estimates store name`.

2. Fit the alternative model (the unrestricted or restricted model) and then type `‘lrtest name .’`. `lrtest` determines for itself which of the two models is the restricted model by comparing the degrees of freedom.

Often you may want to store the alternative model with `estimates store name2`, for instance, if you plan additional tests against models yet to be fit. The likelihood-ratio test is then obtained as `lrtest name name2`.

Remarks are presented under the following headings:

- Nested models
- Composite models

**Nested models**

`lrtest` may be used with any estimation command that reports a log likelihood, including `heckman`, `logit`, `poisson`, `stcox`, and `streg`. You must check that one of the model specifications implies a statistical model that is nested within the model implied by the other specification. Usually, this means that both models are fit with the same estimation command (for example, both are fit by `logit`, with the same dependent variables) and that the set of covariates of one model is a subset of the covariates of the other model. Second, `lrtest` is valid only for models that are fit by maximum likelihood or by some equivalent method, so it does not apply to models that were fit with probability weights or clusters. Specifying the `vce(robust)` option similarly would indicate that you are worried about the valid specification of the model, so you would not use `lrtest`. Third, `lrtest` assumes that under the null hypothesis, the test statistic is (approximately) distributed as chi-squared. This assumption is not true for likelihood-ratio tests of “boundary conditions”, such as tests for the presence of overdispersion or random effects (Gutierrez, Carter, and Drukker 2001).

**Example 1**

We have data on infants born with low birthweights along with the characteristics of the mother (Hosmer, Lemeshow, and Sturdivant 2013; see also [R] `logistic`). We fit the following model:
. use http://www.stata-press.com/data/r13/lbw
    (Hosmer & Lemeshow data)
. logistic low age lwt i.race smoke ptl ht ui
Logistic regression  Number of obs   =        189
                     LR chi2(8)    =     33.22
                     Prob > chi2   =     0.0001
Log likelihood = -100.724  Pseudo R2   =     0.1416

|     | Odds Ratio | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|-----|------------|-----------|------|------|----------------------------|
| age |   .9732636 |   .035476 | -0.74| 0.457|   .9061578 - 1.045339   |
| lwt |   .9849634 |   .006822 | -2.19| 0.029|   .9716834 - 0.9984249 |
| race|         |           |      |      |   |
| black|  3.534767 |   1.860737|  2.40| 0.016|   1.259736 - 9.918406 |
| other|   2.368079 |   1.039949|  1.96| 0.050|   1.001356 - 5.600207 |
| smoke|  2.517698 |   1.00916 |  2.30| 0.021|   1.147676 - 5.523162 |
| ptl |  1.719161 |   0.595258|  1.56| 0.118|   0.872144 - 3.388787 |
| ht  |  6.249602 |   4.322408|  2.65| 0.008|   1.611152 - 24.24199 |
| ui  |   2.1351   |   0.980815|  1.65| 0.099|   0.867752 - 5.2534   |
| _cons|  1.586014 |   1.910496|  0.38| 0.702|   0.149609 - 16.8134 |

We now wish to test the constraint that the coefficients on `age`, `lwt`, `ptl`, and `ht` are all zero or, equivalently here, that the odds ratios are all 1. One solution is to type

. test age lwt ptl ht
   ( 1) [low]age = 0
   ( 2) [low]lwt = 0
   ( 3) [low]ptl = 0
   ( 4) [low]ht = 0
   chi2( 4) = 12.38
   Prob > chi2 = 0.0147

This test is based on the inverse of the information matrix and is therefore based on a quadratic approximation to the likelihood function; see [R] test. A more precise test would be to refit the model, applying the proposed constraints, and then calculate the likelihood-ratio test.

We first save the current model:

. estimates store full

We then fit the constrained model, which here is the model omitting `age`, `lwt`, `ptl`, and `ht`:

. logistic low i.race smoke ui
Logistic regression  Number of obs   =        189
                     LR chi2(4)    =     18.80
                     Prob > chi2   =     0.0009
Log likelihood = -107.93404  Pseudo R2   =     0.0801

|     | Odds Ratio | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|-----|------------|-----------|------|------|----------------------------|
| race|         |           |      |      |   |
| black|  3.052746 |   1.498087|  2.27| 0.023|   1.166747 - 7.987382 |
| other|   2.922593 |   1.189229|  2.64| 0.008|   1.316457 - 6.488285 |
| smoke|  2.945742 |   1.101838|  2.89| 0.004|   1.415167 - 6.131715 |
| ui  |   2.419131 |   1.047359|  2.04| 0.041|   1.035459 - 5.651788 |
| _cons|  1.140220 |   0.512295| -5.38| 0.000|   0.068521 - 2.869447 |
That done, \texttt{lrtest} compares this model with the model we previously stored:

\begin{verbatim}
. lrtest full.
Likelihood-ratio test LR chi2(4) = 14.42
(Assumption: . nested in full) Prob > chi2 = 0.0061
\end{verbatim}

Let’s compare results. \texttt{test} reported that \texttt{age, lwt, ptl, and ht} were jointly significant at the 1.5\% level; \texttt{lrtest} reports that they are significant at the 0.6\% level. Given the quadratic approximation made by \texttt{test}, we could argue that \texttt{lrtest}’s results are more accurate.

\texttt{lrtest} explicates the assumption that, from a comparison of the degrees of freedom, it has assessed that the last fit model (. ) is nested within the model stored as \texttt{full}. In other words, \texttt{full} is the unconstrained model and . is the constrained model.

The names in “(Assumption: . nested in full)” are actually links. Click on a name, and the results for that model are replayed.

Aside: The \texttt{nestreg} command provides a simple syntax for performing likelihood-ratio tests for nested model specifications; see \texttt{[R] nestreg}. In the previous example, we fit a full logistic model, used \texttt{estimates store} to store the \texttt{full} model, fit a constrained logistic model, and used \texttt{lrtest} to report a likelihood-ratio test between two models. To do this with one call to \texttt{nestreg}, use the \texttt{lrtable} option.

\section*{Technical note}
\texttt{lrtest} determines the degrees of freedom of a model as the rank of the (co)variance matrix $e(V)$. There are two issues here. First, the \textit{numerical} determination of the rank of a matrix is a subtle problem that can, for instance, be affected by the scaling of the variables in the model. The rank of a matrix depends on the number of (independent) linear combinations of coefficients that sum exactly to zero. In the world of numerical mathematics, it is hard to tell whether a very small number is really nonzero or is a real zero that happens to be slightly off because of roundoff error from the finite precision with which computers make floating-point calculations. Whether a small number is being classified as one or the other, typically on the basis of a threshold, affects the determined degrees of freedom. Although Stata generally makes sensible choices, it is bound to make mistakes occasionally. The moral of this story is to make sure that the calculated degrees of freedom is as you expect before interpreting the results.

\section*{Technical note}
A second issue involves \texttt{regress} and related commands such as \texttt{anova}. Mainly for historical reasons, \texttt{regress} does not treat the residual variance, $\sigma^2$, the same way that it treats the regression coefficients. Type \texttt{estat vce} after \texttt{regress}, and you will see the regression coefficients, not $\hat{\sigma}^2$. Most estimation commands for models with ancillary parameters (for example, \texttt{streg} and \texttt{heckman}) treat all parameters as equals. There is nothing technically wrong with \texttt{regress} here; we are usually focused on the regression coefficients, and their estimators are uncorrelated with $\hat{\sigma}^2$. But, formally, $\sigma^2$ adds a degree of freedom to the model, which does not matter if you are comparing two regression models by a likelihood-ratio test. This test depends on the difference in the degrees of freedom, and hence being “off by 1” in each does not matter. But, if you are comparing a regression model with a larger model—for example, a heteroskedastic regression model fit by \texttt{arch}—the automatic determination of the degrees of freedom is incorrect, and you must specify the \texttt{df(#)} option.
Example 2

Returning to the low-birthweight data in the example 1, we now wish to test that the coefficient on `race` (black) is equal to that on `other`. The base model is still stored under the name `full`, so we need only fit the constrained model and perform the test. With $z$ as the index of the logit model, the base model is

$$z = \beta_0 + \beta_1 \text{age} + \beta_2 \text{lwt} + \beta_3 \text{race} + \beta_4 \text{other} + \cdots$$

If $\beta_3 = \beta_4$, this can be written as

$$z = \beta_0 + \beta_1 \text{age} + \beta_2 \text{lwt} + (\beta_3 \text{race} + \text{other}) + \cdots$$

We can fit the constrained model as follows:

```
. constraint 1 2.race = 3.race
. logistic low age lwt i.race smoke ptl ht ui, constraints(1)
```

Logistic regression
Number of obs = 189
Wald chi2(7) = 25.17
Log likelihood = -100.9997 Prob > chi2 = 0.0007
( 1) 

```
|      | Odds Ratio | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|------|------------|-----------|------|------|----------------------|
| age  | .9716799   | .0352638  | -0.79| 0.429| .9049649 1.043313   |
| lwt  | .9864971   | .0064627  | -2.08| 0.038| .9739114 .9992453  |
| black| 2.728186   | 1.080207  | 2.53 | 0.011| 1.255586 5.927907  |
| other| 2.728186   | 1.080207  | 2.53 | 0.011| 1.255586 5.927907  |
| smoke| 2.664498   | 1.052379  | 2.48 | 0.013| 1.226833 5.778414  |
| ptl  | 1.709129   | .5924776  | 1.55 | 0.122| .8663666 3.371691  |
| ht   | 6.116391   | 4.215585  | 2.63 | 0.009| 1.58425 23.61385 |
| ui   | 2.09936    | .9699702  | 1.61 | 0.108| .8487997 5.192407  |
| _cons| 1.309371   | 1.527398  | 0.23 | 0.817| .1330839 12.8825   |
```

Comparing this model with our original model, we obtain

```
. lrtest full
Likelihood-ratio test LR chi2(1) = 0.55
(Assumption: . nested in full) Prob > chi2 = 0.4577
```

By comparison, typing `test 2.race=3.race` after fitting our base model results in a significance level of 0.4572. Alternatively, we can first store the restricted model, here using the name `equal`.

Next `lrtest` is invoked specifying the names of the restricted and unrestricted models (we do not care about the order). This time, we also add the option `stats` requesting a table of model statistics, including the model selection indices AIC and BIC.

```
. estimates store equal
. lrtest equal full, stats
Likelihood-ratio test LR chi2(1) = 0.55
(Assumption: equal nested in full) Prob > chi2 = 0.4577
```

```

```

Note: N=Obs used in calculating BIC; see `[R] BIC note`
Composite models

`lrtest` supports composite models; that is, models that can be fit by fitting a series of simpler models or by fitting models on subsets of the data. Theoretically, a composite model is one in which the likelihood function, \( L(\theta) \), of the parameter vector, \( \theta \), can be written as the product

\[
L(\theta) = L_1(\theta_1) \times L_2(\theta_2) \times \cdots \times L_k(\theta_k)
\]

of likelihood terms with \( \theta = (\theta_1, \ldots, \theta_k) \) a partitioning of the full parameter vector. In such a case, the full-model likelihood \( L(\theta) \) is maximized by maximizing the likelihood terms \( L_j(\theta_j) \) in turn. Obviously, \( \log L(\hat{\theta}) = \sum_{j=1}^{k} \log L_j(\hat{\theta}_j) \). The degrees of freedom for the composite model is obtained as the sum of the degrees of freedom of the constituting models.

Example 3

As an example of the application of composite models, we consider a test of the hypothesis that the coefficients of a statistical model do not differ between different portions (“regimes”) of the covariate space. Economists call a test for such a hypothesis a Chow test.

We continue the analysis of the data on children of low birthweight by using logistic regression modeling and study whether the regression coefficients are the same among the three races: white, black, and other. A likelihood-ratio Chow test can be obtained by fitting the logistic regression model for each of the races and then comparing the combined results with those of the model previously stored as `full`. Because the full model included dummies for the three races, this version of the Chow test allows the intercept of the logistic regression model to vary between the regimes (races).

Note: N=Obs used in calculating BIC; see [R] BIC note

We cannot reject the hypothesis that the logistic regression model applies to each of the races at any reasonable significance level. By specifying the stats option, we can verify the degrees of freedom of the test: 12 = 7 + 7 + 7 − 9. We can obtain the same test by fitting an expanded model with interactions between all covariates and race.

. lrtest full

Likelihood-ratio test LR chi2(12) = 9.83
(Assumption: full nested in .) Prob > chi2 = 0.6310

Applying lrtest for the full model against the model with all interactions yields the same test statistic and p-value as for the full model against the composite model for the three regimes. Here the specification of the model with interactions was convenient, and logistic had no problem computing the estimates for the expanded model. In models with more complicated likelihoods, such as Heckman's selection model (see [R] heckman) or complicated survival-time models (see [ST] streg), fitting the models with all interactions may be numerically demanding and may be much more time consuming than fitting a series of models separately for each regime.

Given the model with all interactions, we could also test the hypothesis of no differences among the regions (races) by a Wald version of the Chow test by using the testparm command; see [R] test.
. testparm race#c.(age lwt smoke ptl ht ui)
   ( 1) [low]2.race#c.age = 0
   ( 2) [low]3.race#c.age = 0
   ( 3) [low]2.race#c.lwt = 0
   ( 4) [low]3.race#c.lwt = 0
   ( 5) [low]2.race#c.smoke = 0
   ( 6) [low]3.race#c.smoke = 0
   ( 7) [low]2.race#c.ptl = 0
   ( 8) [low]3.race#c.ptl = 0
   ( 9) [low]2.race#c.ht = 0
  (10) [low]3.race#c.ht = 0
  (11) [low]2.race#c.ui = 0
  (12) [low]3.race#c.ui = 0

    chi2( 12) = 8.24
    Prob > chi2 = 0.7663

We conclude that, here, the Wald version of the Chow test is similar to the likelihood-ratio version of the Chow test.

Stored results

`lrtest` stores the following in `r()`:

Scalars
- `r(p)`         level of significance
- `r(df)`        degrees of freedom
- `r(chi2)`      LR test statistic

Programmers wishing their estimation commands to be compatible with `lrtest` should note that `lrtest` requires that the following results be returned:

- `e(cmd)`      name of estimation command
- `e(ll)`       log likelihood
- `e(V)`        variance–covariance matrix of the estimators
- `e(N)`        number of observations

`lrtest` also verifies that `e(N)`, `e(ll=0)`, and `e(depvar)` are consistent between two noncomposite models.

Methods and formulas

Let $L_0$ and $L_1$ be the log-likelihood values associated with the full and constrained models, respectively. The test statistic of the likelihood-ratio test is $LR = -2(L_1 - L_0)$. If the constrained model is true, $LR$ is approximately $\chi^2$ distributed with $d_0 - d_1$ degrees of freedom, where $d_0$ and $d_1$ are the model degrees of freedom associated with the full and constrained models, respectively (Greene 2012, 526–527).

`lrtest` determines the degrees of freedom of a model as the rank of `e(V)`, computed as the number of nonzero diagonal elements of `invsym(e(V))`.

lsens — Graph sensitivity and specificity versus probability cutoff

Syntax

    lsens [ depvar ] [ if ] [ in ] [ weight ] [ , options ]

options        Description

Main

    all           graph all observations in the data
    genprob( varname )    create variable containing probability cutoffs
    gensens( varname )    create variable containing sensitivity
    genspec( varname )    create variable containing specificity
    replace        overwrite existing variables
    nograph        suppress the graph

Advanced

    beta( matname )    row vector containing model coefficients

Plot

    connect_options    affect rendition of the plotted points connected by lines

Add plots

    addplot( plot )    add other plots to the generated graph

Y axis, X axis, Titles, Legend, Overall

    twoway_options    any options other than by() documented in [G-3] twoway_options

fweights are allowed; see [U] 11.1.6 weight.
lsens is not appropriate after the svy prefix.

Menu

Statistics > Binary outcomes > Postestimation > Sensitivity/specificity plot

Description

lsens graphs sensitivity and specificity versus probability cutoff and optionally creates new variables containing these data.

lsens requires that the current estimation results be from logistic, logit, probit, or ivprobit; see [R] logistic, [R] logit, [R] probit, or [R] ivprobit.
Options

Main

all requests that the statistic be computed for all observations in the data, ignoring any if or in
restrictions specified by the estimation command.

genprob(varname), gensens(varname), and genspec(varname) specify the names of new variables
created to contain, respectively, the probability cutoffs and the corresponding sensitivity and
specificity.

replace requests that existing variables specified for genprob(), gensens(), or genspec() be
overwritten.

nograph suppresses graphical output.

Advanced

beta(matname) specifies a row vector containing model coefficients. The columns of the row vector
must be labeled with the corresponding names of the independent variables in the data. The
dependent variable depvar must be specified immediately after the command name. See Models
other than the last fitted model later in this entry.

Plot

connect_options affect the rendition of the plotted points connected by lines; see connect_options in

Add plots

addplot(plot) provides a way to add other plots to the generated graph. See [G-3] addplot_option.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These
include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see

Remarks and examples

Remarks are presented under the following headings:

Introduction

Models other than the last fitted model

Introduction

lsens plots sensitivity and specificity; it plots both sensitivity and specificity versus probability
cutoff \( c \). The graph is equivalent to what you would get from \texttt{estat classification} (see [R] estat
classification) if you varied the cutoff probability \( c \) from 0 to 1.
Example 1

We illustrate \texttt{lsens} after \texttt{logistic}; see \cite{R logistic}.

\begin{verbatim}
. use http://www.stata-press.com/data/r13/lbw
    (Hosmer & Lemeshow data)
. logistic low age i.race smoke ui
    (output omitted)
. lsens
\end{verbatim}

\texttt{lsens} optionally creates new variables containing the probability cutoff, sensitivity, and specificity.

\begin{verbatim}
. lsens, genprob(p) gensens(sens) genspec(spec) nograph
\end{verbatim}

The variables created will have $M + 2$ distinct nonmissing values: one for each of the $M$ covariate patterns, one for $c = 0$, and another for $c = 1$. Values are recorded for $p = 0$, for each of the observed predicted probabilities, and for $p = 1$. The total number of observations required to do this can be fewer than \_N, the same as \_N, or \_N + 1, or \_N + 2. If more observations are added, they are added at the end of the dataset and the values of the original variables are set to missing in the added observations. How the values added align with existing observations is irrelevant.

\section*{Technical note}

\texttt{logistic}, \texttt{logit}, \texttt{probit}, or \texttt{ivprobit} and \texttt{lsens} keep track of the estimation sample. If you type, for instance, \texttt{logistic ... if x==1}, then when you type \texttt{lsens}, the statistics will be calculated on the $x==1$ subsample of the data automatically.

You should specify \texttt{if} or \texttt{in} with \texttt{lsens} only when you wish to produce graphs and calculate statistics for a set of observations other than the estimation sample.

If the \texttt{logistic} model was fit with \texttt{fweights}, \texttt{lsens} properly accounts for the weights in its calculations. You do not have to specify the weights when you run \texttt{lsens}. Weights should be specified with \texttt{lsens} only when you wish to use a different set of weights.
Models other than the last fitted model

By default, `lsens` uses the last model fit. You may also directly specify the model to `lsens` by inputting a vector of coefficients with the `beta()` option and passing the name of the dependent variable `depvar` to `lsens`.

➤ Example 2

Suppose that someone publishes the following logistic model of low birthweight:

\[
\Pr(\text{low} = 1) = F(-0.02 \text{age} - 0.01 \text{lwt} + 1.3 \text{black} + 1.1 \text{smoke} + 0.5 \text{ptl} + 1.8 \text{ht} + 0.8 \text{ui} + 0.5)
\]

where \( F \) is the cumulative logistic distribution. These coefficients are not odds ratios; they are the equivalent of what `logit` produces.

We can see whether this model fits our data. First we enter the coefficients as a row vector and label its columns with the names of the independent variables plus `_cons` for the constant (see `[P] matrix define` and `[P] matrix rownames`).

```
. use http://www.stata-press.com/data/r13/lbw3, clear
(Hosmer & Lemeshow data)
. matrix input b = (-0.02, -.01, 1.3, 1.1, .5, 1.8, .8, .5)
. matrix colnames b = age lwt black smoke ptl ht ui _cons
```

We can use `lroc` (see `[R] lroc`) to examine the predictive ability of the model:

```
. lroc low, beta(b) nograph
Logistic model for low
number of observations = 189
area under ROC curve = 0.7275
```

The area under the curve indicates that this model does have some predictive power. We can obtain a graph of sensitivity and specificity as a function of the cutoff probability by typing

```
. lsens low, beta(b)
```

![Graph of sensitivity and specificity versus probability cutoff](image)
Stored results

`lsens` stores the following in `r()`:  

Scalars  
`r(N)` number of observations

Methods and formulas

Let $j$ index observations and $c$ be the cutoff probability. Let $p_j$ be the predicted probability of a positive outcome and $y_j$ be the actual outcome, which we will treat as 0 or 1, although Stata treats it as 0 and non-0, excluding missing observations.

A prediction is classified as positive if $p_j \geq c$ and otherwise is classified as negative. The classification is correct if it is positive and $y_j = 1$ or if it is negative and $y_j = 0$.

Sensitivity is the fraction of $y_j = 1$ observations that are correctly classified. Specificity is the percentage of $y_j = 0$ observations that are correctly classified.

Syntax

\[ \text{lv} \ [ \text{varlist} ] \ [ \text{if} ] \ [ \text{in} ] \ [ , \ generating \ \text{tail}(#) ] \]

by is allowed; see [D] by.

Menu

Statistics > Summaries, tables, and tests > Distributional plots and tests > Letter-value display

Description

\text{lv} \ shows \ a \ letter-value \ display \ (Tukey \ 1977, \ 44–49; \ Hoaglin \ 1983) \ for \ each \ variable \ in \ varlist. \ If \ no \ variables \ are \ specified, \ letter-value \ displays \ are \ shown \ for \ each \ numeric \ variable \ in \ the \ data.

Options

generate \ adds \ four \ new \ variables \ to \ the \ data: \ _mid, \ containing \ the \ midsummaries; \ _spread, \ containing \ the \ spreads; \ _psigma, \ containing \ the \ pseudosigmas; \ and \ _z2, \ containing \ the \ squared \ values \ from \ a \ standard \ normal \ distribution \ corresponding \ to \ the \ particular \ letter \ value. \ If \ the \ variables \ _mid, \ _spread, \ _psigma, \ and \ _z2 \ already \ exist, \ their \ contents \ are \ replaced. \ At \ most, \ only \ the \ first \ 11 \ observations \ of \ each \ variable \ are \ used; \ the \ remaining \ observations \ contain \ missing. \ If \ varlist \ specifies \ more \ than \ one \ variable, \ the \ newly \ created \ variables \ contain \ results \ for \ the \ last \ variable \ specified. \ The \ generate \ option \ may \ not \ be \ used \ with \ the \ by \ prefix.

tail(#) \ indicates \ the \ inverse \ of \ the \ tail \ density \ through \ which \ letter \ values \ are \ to \ be \ displayed: \ 2 \ corresponds \ to \ the \ median \ (meaning \ half \ in \ each \ tail), \ 4 \ to \ the \ fourths \ (roughly \ the \ 25th \ and \ 75th \ percentiles), \ 8 \ to \ the \ eighths, \ and \ so \ on. \ # \ may \ be \ specified \ as \ 4, \ 8, \ 16, \ 32, \ 64, \ 128, \ 256, \ 512, \ or \ 1,024 \ and \ defaults \ to \ a \ value \ of \ # \ that \ has \ corresponding \ depth \ just \ greater \ than \ 1. \ The \ default \ is \ taken \ as \ 1,024 \ if \ the \ calculation \ results \ in \ a \ number \ larger \ than \ 1,024. \ Given \ the \ intelligent \ default, \ this \ option \ is \ rarely \ specified.

Remarks and examples

Letter-value displays are a collection of observations drawn systematically from the data, focusing especially on the tails rather than the middle of the distribution. The displays are called letter-value displays because letters have been (almost arbitrarily) assigned to tail densities:

<table>
<thead>
<tr>
<th>Letter</th>
<th>Tail area</th>
<th>Letter</th>
<th>Tail area</th>
</tr>
</thead>
<tbody>
<tr>
<td>M</td>
<td>1/2</td>
<td>B</td>
<td>1/64</td>
</tr>
<tr>
<td>F</td>
<td>1/4</td>
<td>A</td>
<td>1/128</td>
</tr>
<tr>
<td>E</td>
<td>1/8</td>
<td>Z</td>
<td>1/256</td>
</tr>
<tr>
<td>D</td>
<td>1/16</td>
<td>Y</td>
<td>1/512</td>
</tr>
<tr>
<td>C</td>
<td>1/32</td>
<td>X</td>
<td>1/1024</td>
</tr>
</tbody>
</table>
Example 1

We have data on the mileage ratings of 74 automobiles. To obtain a letter-value display, we type

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. lv mpg
```

```
# 74 Mileage (mpg)
M 37.5 20
F 19 18 21.5 25 7 5.216359
E 10 15 21.5 28 13 5.771728
D 5.5 14 22.25 30.5 16.5 5.576303
C 3 14 24.5 35 21 5.831039
B 2 12 23.5 35 23 5.732448
A 1.5 12 25 38 26 6.040635
1 12 26.5 41 29 6.16562
```

The decimal points can be made to line up and thus the output made more readable by specifying a display format for the variable; see [U] 12.5 Formats: Controlling how data are displayed.

```
. format mpg %9.2f
. lv mpg
```

```
# 74 Mileage (mpg)
M 37.5 20.00
F 19 18.00 21.50 25.00 7.00 5.22
E 10 15.00 21.50 28.00 13.00 5.77
D 5.5 14.00 22.25 30.50 16.50 5.58
C 3 14.00 24.50 35.00 21.00 5.83
B 2 12.00 23.50 35.00 23.00 5.73
A 1.5 12.00 25.00 38.00 26.00 6.04
1 12.00 26.50 41.00 29.00 6.17
```

At the top, the number of observations is indicated as 74. The first line shows the statistics associated with M, the letter value that puts half the density in each tail, or the median. The median has depth 37.5 (that is, in the ordered data, M is 37.5 observations in from the extremes) and has value 20. The next line shows the statistics associated with F or the fourths. The fourths have depth 19 (that is, in the ordered data, the lower fourth is observation 19, and the upper fourth is observation 74 − 19 + 1), and the values of the lower and upper fourths are 18 and 25. The number in the middle is the point halfway between the fourths—called a midsummary. If the distribution were perfectly symmetric, the midsummary would equal the median. The spread is the difference between the lower and upper summaries (25 − 18 = 7). For fourths, half the data lie within a 7-mpg band. The pseudosigma is a calculation of the standard deviation using only the lower and upper summaries and assuming that the variable is normally distributed. If the data really were normally distributed, all the pseudosigmas would be roughly equal.

After the letter values, the line labeled with depth 1 reports the minimum and maximum values. Here the halfway point between the extremes is 26.5, which is greater than the median, indicating that 41 is more extreme than 12, at least relative to the median. And with each letter value, the midsummaries are increasing—our data are skewed. The pseudosigmas are also increasing, indicating
that the data are spreading out relative to a normal distribution, although, given the evident skewness, this elongation may be an artifact of the skewness.

At the end is an attempt to identify outliers, although the points so identified are merely outside some predetermined cutoff. Points outside the inner fence are called outside values or mild outliers. Points outside the outer fence are called severe outliers. The inner fence is defined as \((3/2) \text{IQR}\) and the outer fence as \(3 \text{IQR}\) above and below the F summaries, where the interquartile range (IQR) is the spread of the fourths.

Technical note

The form of the letter-value display has varied slightly with different authors. lv displays appear as described by Hoaglin (1983) but as modified by Emerson and Stoto (1983), where they included the midpoint of each of the spreads. This format was later adopted by Hoaglin (1985). If the distribution is symmetric, the midpoints will all be roughly equal. On the other hand, if the midpoints vary systematically, the distribution is skewed.

The pseudosigmas are obtained from the lower and upper summaries for each letter value. For each letter value, they are the standard deviation a normal distribution would have if its spread for the given letter value were to equal the observed spread. If the pseudosigmas are all roughly equal, the data are said to have neutral elongation. If the pseudosigmas increase systematically, the data are said to be more elongated than a normal, that is, have thicker tails. If the pseudosigmas decrease systematically, the data are said to be less elongated than a normal, that is, have thinner tails.

Interpretation of the number of mild and severe outliers is more problematic. The following discussion is drawn from Hamilton (1991):

Obviously, the presence of any such outliers does not rule out that the data have been drawn from a normal distribution; in large datasets, there will most certainly be observations outside \((3/2) \text{IQR}\) and \(3 \text{IQR}\). Severe outliers, however, make up about two per million (0.0002%) of a normal population. In samples, they lie far enough out to have substantial effects on means, standard deviations, and other classical statistics. The 0.0002%, however, should be interpreted carefully; outliers appear more often in small samples than one might expect from population proportions because of sampling variation in estimated quartiles. Monte Carlo simulation by Hoaglin, Iglewicz, and Tukey (1986) obtained these results on the percentages and numbers of outliers in random samples from a normal population:

<table>

</table>

Thus the presence of any severe outliers in samples of less than 300 is sufficient to reject normality. Hoaglin, Iglewicz, and Tukey (1981) suggested the approximation \(0.00698 + 0.4/n\) for the fraction of mild outliers in a sample of size \(n\) or, equivalently, \(0.00698n + 0.4\) for the number of outliers.
Example 2

The `generate` option adds the `_mid`, `_spread`, `_psigma`, and `_z2` variables to our data, making possible many of the diagnostic graphs suggested by Hoaglin (1985).

```
.lv mpg, generate
(output omitted)
.list _mid _spread _psigma _z2 in 1/12
```

</tbody>
</table>

Observations 12 through the end are missing for these new variables. The definition of the observations is always the same. The first observation contains the M summary; the second, the F; the third, the E; and so on. Observation 11 always contains the summary for depth 1. Observations 8–10—corresponding to letter values Z, Y, and X—contain missing because these statistics were not calculated. We have only 74 observations, and their depth would be 1.

Hoaglin (1985) suggests graphing the midsummary against $z^2$. If the distribution is not skewed, the points in the resulting graph will be along a horizontal line:

```
.scatter _mid _z2
```

The graph clearly indicates the skewness of the distribution. We might also graph `_psigma` against `_z2` to examine elongation.
Stored results

`lv` stores the following in `r()`:

Scalars

- `r(N)` number of observations
- `r(u_C)` upper 32nd
- `r(l_B)` lower 64th
- `r(max)` maximum
- `r(u_B)` upper 64th
- `r(min)` minimum
- `r(l_A)` lower 128th
- `r(median)` median
- `r(l_B)` lower 256th
- `r(l_E)` lower 8th
- `r(l_Y)` lower 512th
- `r(u_A)` upper 128th
- `r(u_B)` upper 256th
- `r(l_F)` lower 4th
- `r(l_D)` lower 16th
- `r(u_E)` upper 8th
- `r(l_Z)` lower 1024th
- `r(u_A)` upper 512th
- `r(u_F)` upper 8th
- `r(l_D)` lower 1024th
- `r(l_C)` lower 32nd
- `r(u_X)` upper 1024th
- `r(u_Z)` upper 512th
- `r(u_Y)` upper 1024th

The lower/upper 8ths, 16ths, ..., 1024ths will be defined only if there are sufficient data.

Methods and formulas

Let \( N \) be the number of (nonmissing) observations on \( x \), and let \( x_{(i)} \) refer to the ordered data when \( i \) is an integer. Define \( x_{(i+0.5)} = (x_{(i)} + x_{(i+1)}) / 2 \); the median is defined as \( x_{\lfloor (N+1)/2 \rfloor} \).

Define \( x_{[d]} \) as the pair of numbers \( x_{(d)} \) and \( x_{(N+1-d)} \), where \( d \) is called the depth. Thus \( x_{[1]} \) refers to the minimum and maximum of the data. Define \( m = (N+1)/2 \) as the depth of the median, \( f = ([m] + 1)/2 \) as the depth of the fourths, \( e = ([f] + 1)/2 \) as the depth of the eighths, and so on. Depths are reported on the far left of the letter-value display. The corresponding fourths of the data are \( x_{[f]} \), the eighths are \( x_{[e]} \), and so on. These values are reported inside the display. The middle value is defined as the corresponding midpoint of \( x_{[\cdot]} \). The spreads are defined as the difference in \( x_{[\cdot]} \).

The corresponding point \( z_i \) on a standard normal distribution is obtained as (Hoaglin 1985, 456–457)

\[
z_i = \begin{cases} 
F^{-1}\left\{ \frac{(d_i - 1/3)/(N + 1/3)} \right\} & \text{if } d_i > 1 \\
F^{-1}\left\{ 0.695/(N + 0.390) \right\} & \text{otherwise}
\end{cases}
\]

where \( d_i \) is the depth of the letter value. The corresponding pseudosigma is obtained as the ratio of the spread to \(-2z_i\) (Hoaglin 1985, 431).

Define \((F_l, F_u) = x_{[f]}\). The inner fence has cutoffs \( F_l - \frac{3}{2}(F_u - F_l) \) and \( F_u + \frac{3}{2}(F_u - F_l) \). The outer fence has cutoffs \( F_l - 3(F_u - F_l) \) and \( F_u + 3(F_u - F_l) \).

The inner-fence values reported by `lv` are almost equal to those used by `graph`, box to identify outside points. The only difference is that `graph` uses a slightly different definition of fourths, namely, the 25th and 75th percentiles as defined by `summarize`; see [R] `summarize`.

### Syntax

```
margins [marginlist] [if] [in] [weight] [, response_options options]
```

where `marginlist` is a list of factor variables or interactions that appear in the current estimation results. The variables may be typed with or without the `i.` prefix, and you may use any factor-variable syntax:

- `margins i.sex i.group i.sex#i.group`
- `margins sex group sex#i.group`
- `margins sex##group`

Menu
Statistics > Postestimation > Marginal means and predictive margins
Statistics > Postestimation > Marginal effects

Description
Margins are statistics calculated from predictions of a previously fit model at fixed values of some covariates and averaging or otherwise integrating over the remaining covariates.
The `margins` command estimates margins of responses for specified values of covariates and presents the results as a table.

Capabilities include estimated marginal means, least-squares means, average and conditional marginal and partial effects (which may be reported as derivatives or as elasticities), average and conditional adjusted predictions, and predictive margins.

### Options

Warning: The option descriptions are brief and use jargon. Skip to Remarks and examples if you are reading about margins for the first time.

**Main**

- `predict(pred_opt)` and `expression(pnl_exp)` are mutually exclusive; they specify the response. If neither is specified, the response will be the default prediction that would be produced by `predict` after the underlying estimation command.

- `predict(pred_opt)` specifies the option(s) to be specified with the `predict` command to produce the variable that will be used as the response. After estimation by `logistic`, you could specify `predict(xb)` to obtain linear predictions rather than the `predict` command’s default, the probabilities.

- `expression(pnl_exp)` specifies the response as an expression. See [R] `predictnl` for a full description of `pnl_exp`. After estimation by `logistic`, you might specify `expression(exp(predict(xb)))` to use relative odds rather than probabilities as the response. For examples, see Example 12: Margins of a specified expression.

- `dydx(varlist)`, `eyex(varlist)`, `dyex(varlist)`, and `eydx(varlist)` request that `margins` report derivatives of the response with respect to `varlist` rather than on the response itself. `eyex()`, `dyex()`, and `eydx()` report derivatives as elasticities; see Expressing derivatives as elasticities.

- `continuous` is relevant only when one of `dydx()` or `eydx()` is also specified. It specifies that the levels of factor variables be treated as continuous; see Derivatives versus discrete differences. This option is implied if there is a single-level factor variable specified in `dydx()` or `eydx()`.

- `grand` specifies that the overall margin be reported. `grand` is assumed when `marginlist` is empty.

**At**

- `at(atspec)` specifies values for covariates to be treated as fixed.
  - `at(age=20)` fixes covariate `age` to the value specified. `at()` may be used to fix continuous or factor covariates.
  - `at(age=20 sex=1)` simultaneously fixes covariates `age` and `sex` at the values specified.
  - `at(age=(20 30 40 50))` fixes age first at 20, then at 30, . . . . `margins` produces separate results for each specified value.
  - `at(age=(20(10)50))` does the same as `at(age=(20 30 40 50));` that is, you may specify a numlist.
  - `at((mean) age (median) distance)` fixes the covariates at the summary statistics specified. `at((p25) _all)` fixes all covariates at their 25th percentile values. See Syntax of `at()` for the full list of summary-statistic modifiers.
  - `at((mean) _all (median) x x2=1.2 z=(1 2 3))` is read from left to right, with latter specifiers overriding former ones. Thus all covariates are fixed at their means except for `x` (fixed at its median), `x2` (fixed at 1.2), and `z` (fixed first at 1, then at 2, and finally at 3).
at((means) _all (asobserved) x2) is a convenient way to set all covariates except x2 to the mean.

Multiple at() options can be specified, and each will produce a different set of margins. See Syntax of at() for more information.

atmeans specifies that covariates be fixed at their means and is shorthand for at((mean) _all). atmeans differs from at((mean) _all) in that atmeans will affect subsequent at() options. For instance,

\[
\text{. margins ... at((p25) x) at((p75) x)}
\]

produces two sets of margins with both sets evaluated at the means of all covariates except x.

asbalanced is shorthand for at((asbalanced) _factor) and specifies that factor covariates be evaluated as though there were an equal number of observations in each level; see Obtaining margins as though the data were balanced. asbalanced differs from at((asbalanced) _factor) in that asbalanced will affect subsequent at() options in the same way as atmeans does.

over(varlist) specifies that separate sets of margins be estimated for the groups defined by varlist. The variables in varlist must contain nonnegative integer values. The variables need not be covariates in your model. When over() is combined with the vce(unconditional) option, each group is treated as a subpopulation; see [SVY] subpopulation estimation.

subpop([ varname ] [ if ]) is intended for use with the vce(unconditional) option. It specifies that margins be estimated for the single subpopulation identified by the indicator variable or by the if expression or by both. Zero indicates that the observation be excluded; nonzero, that it be included; and missing value, that it be treated as outside of the population (and so ignored). See [SVY] subpopulation estimation for why subpop() is preferred to if expressions and in ranges when also using vce(unconditional). If subpop() is used without vce(unconditional), it is treated merely as an additional if qualifier.

within(varlist) allows for nested designs. varlist contains the nesting variable(s) over which margins are to be estimated. See Obtaining margins with nested designs. As with over(varlist), when within(varlist) is combined with vce(unconditional), each level of the variables in varlist is treated as a subpopulation.

Contrast

c contrast_options are any of the options documented in [R] margins, contrast.

Pairwise comparisons

pwcompare_options are any of the options documented in [R] margins, pwcompare.

SE

vce(delta) and vce(unconditional) specify how the VCE and, correspondingly, standard errors are calculated.

vce(delta) is the default. The delta method is applied to the formula for the response and the VCE of the estimation command. This method assumes that values of the covariates used to calculate the response are given or, if all covariates are not fixed using at(), that the data are given.
vce(unconditional) specifies that the covariates that are not fixed be treated in a way that accounts for their having been sampled. The VCE is estimated using the linearization method. This method allows for heteroskedasticity or other violations of distributional assumptions and allows for correlation among the observations in the same manner as vce(robust) and vce(cluster ...), which may have been specified with the estimation command. This method also accounts for complex survey designs if the data are svyset. See Obtaining margins with survey data and representative samples. When you use complex survey data, this method requires that the linearized variance estimation method be used for the model. See [SVY] svy postestimation for an example of margins with replication-based methods.

nose suppresses calculation of the VCE and standard errors. See Requirements for model specification for an example of the use of this option.

noweights specifies that any weights specified on the previous estimation command be ignored by margins. By default, margins uses the weights specified on the estimator to average responses and to compute summary statistics. If weights are specified on the margins command, they override previously specified weights, making it unnecessary to specify noweights. The noweights option is not allowed after svy: estimation when the vce(unconditional) option is specified.

noesample specifies that margins not restrict its computations to the estimation sample used by the previous estimation command. See Example 15: Margins evaluated out of sample.

With the default delta-method VCE, noesample margins may be estimated on samples other than the estimation sample; such results are valid under the assumption that the data used are treated as being given.

You can specify noesample and vce(unconditional) together, but if you do, you should be sure that the data in memory correspond to the original e(sample). To show that you understand that, you must also specify the force option. Be aware that making the vce(unconditional) calculation on a sample different from the estimation sample would be equivalent to estimating the coefficients on one set of data and computing the scores used by the linearization on another set; see [P] _robust.

emptycells(strict) and emptycells(reweight) are relevant only when the asbalanced option is also specified. emptycells() specifies how empty cells are handled in interactions involving factor variables that are being treated as balanced; see Obtaining margins as though the data were balanced.

emptycells(strict) is the default; it specifies that margins involving empty cells be treated as not estimable.

emptycells(reweight) specifies that the effects of the observed cells be increased to accommodate any missing cells. This makes the margin estimable but changes its interpretation. emptycells(reweight) is implied when the within() option is specified.

estimtolerance(tol) specifies the numerical tolerance used to determine estimable functions. The default is estimtolerance(1e-5).

A linear combination of the model coefficients $z$ is found to be not estimable if

$$\text{mreldif}(z, z \times H) > tol$$

where $H$ is defined in Methods and formulas.
noestimcheck specifies that margins not check for estimability. By default, the requested margins are checked and those found not estimable are reported as such. Nonestimability is usually caused by empty cells. If noestimcheck is specified, estimates are computed in the usual way and reported even though the resulting estimates are manipulable, which is to say they can differ across equivalent models having different parameterizations. See Estimability of margins.

force instructs margins to proceed in some situations where it would otherwise issue an error message because of apparent violations of assumptions. Do not be casual about specifying force. You need to understand and fully evaluate the statistical issues. For an example of the use of force, see Using margins after the estimates use command.

chainrule and nochainrule specify whether margins uses the chain rule when numerically computing derivatives. You need not specify these options when using margins after any official Stata estimator; margins will choose the appropriate method automatically.

Specify nochainrule after estimation by a user-written command. We recommend using nochainrule, even though chainrule is usually safe and is always faster. nochainrule is safer because it makes no assumptions about how the parameters and covariates join to form the response.

nochainrule is implied when the expression() option is specified.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

mcompare(method) specifies the method for computing p-values and confidence intervals that account for multiple comparisons within a factor-variable term.

Most methods adjust the comparisonwise error rate, $\alpha_c$, to achieve a prespecified experimentwise error rate, $\alpha_e$.

mcompare(noadjust) is the default; it specifies no adjustment.

$$\alpha_c = \alpha_e$$

mcompare(bonferroni) adjusts the comparisonwise error rate based on the upper limit of the Bonferroni inequality

$$\alpha_e \leq m \alpha_c$$

where $m$ is the number of comparisons within the term.

The adjusted comparisonwise error rate is

$$\alpha_c = \alpha_e / m$$

mcompare(sidak) adjusts the comparisonwise error rate based on the upper limit of the probability inequality

$$\alpha_e \leq 1 - (1 - \alpha_c)^m$$

where $m$ is the number of comparisons within the term.

The adjusted comparisonwise error rate is

$$\alpha_c = 1 - (1 - \alpha_e)^{1/m}$$

This adjustment is exact when the $m$ comparisons are independent.

mcompare(scheffe) controls the experimentwise error rate using the $F$ or $\chi^2$ distribution with degrees of freedom equal to the rank of the term.
mcompare(method adjustall) specifies that the multiple-comparison adjustments count all comparisons across all terms rather than performing multiple comparisons term by term. This leads to more conservative adjustments when multiple variables or terms are specified in marginslist. This option is compatible only with the bonferroni and sidak methods.

noatlegend specifies that the legend showing the fixed values of covariates be suppressed.

post causes margins to behave like a Stata estimation (e-class) command. margins posts the vector of estimated margins along with the estimated variance–covariance matrix to e(), so you can treat the estimated margins just as you would results from any other estimation command. For example, you could use test to perform simultaneous tests of hypotheses on the margins, or you could use lincom to create linear combinations. See Example 10: Testing margins—contrasts of margins.

display_options: noci, nopvalues, vsquish, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch.

noci suppresses confidence intervals from being reported in the coefficient table.

nopvalues suppresses p-values and their test statistics from being reported in the coefficient table.

vsquish specifies that the blank space separating factor-variable terms or time-series–operated variables from other variables in the model be suppressed.

nofvlabel displays factor-variable level values rather than attached value labels. This option overrides the fvlabel setting; see [R] set showbaselevels.

fvwrap(#) allows long value labels to wrap the first # lines in the coefficient table. This option overrides the fvwrap setting; see [R] set showbaselevels.

fvwrapon(style) specifies whether value labels that wrap will break at word boundaries or break based on available space.

fvwrapon(word), the default, specifies that value labels break at word boundaries.

fvwrapon(width) specifies that value labels break based on available space.

This option overrides the fvwrapon setting; see [R] set showbaselevels.

cformat(%fmt) specifies how to format margins, standard errors, and confidence limits in the table of estimated margins.

pformat(%fmt) specifies how to format p-values in the table of estimated margins.

sformat(%fmt) specifies how to format test statistics in the table of estimated margins.

nolstretch specifies that the width of the table of estimated margins not be automatically widened to accommodate longer variable names. The default, lstretch, is to automatically widen the table of estimated margins up to the width of the Results window. To change the default, use set lstretch off. nolstretch is not shown in the dialog box.

The following option is available with margins but is not shown in the dialog box:

df(#) specifies that the t distribution with # degrees of freedom be used for computing p-values and confidence intervals. The default typically is to use the standard normal distribution. However, if the estimation command computes the residual degrees of freedom (e(df_r)) and predict(xb) is specified with margins, the default is to use the t distribution with e(df_r) degrees of freedom.
Remarks and examples

Remarks are presented under the following headings:

Introduction

Obtaining margins of responses

Glossary

Introduction

*b* margins is a postestimation command, a command for use after you have fit a model using an estimation command such as *regress* or *logistic*, or using almost any other estimation command.

*b* margins estimates and reports margins of responses and margins of derivatives of responses, also known as marginal effects. A margin is a statistic based on a fitted model in which some of or all the
covariates are fixed. Marginal effects are changes in the response for change in a covariate, which can be reported as a derivative, elasticity, or semielasticity.

For a brief overview of \texttt{margins}, see Williams (2012).

\section*{Obtaining margins of responses}

What we call margins of responses are also known as predictive margins, adjusted predictions, and recycled predictions. When applied to balanced data, margins of responses are also called estimated marginal means and least-squares means.

A margin is a statistic based on a fitted model calculated over a dataset in which some of or all the covariates are fixed at values different from what they really are. For instance, after a linear regression fit on males and females, the marginal mean (margin of mean) for males is the predicted mean of the dependent variable, where every observation is treated as if it represents a male; thus those observations that in fact do represent males are included, as well as those observations that represent females. The marginal mean for female would be similarly obtained by treating all observations as if they represented females.

In making the calculation, sex is treated as male or female everywhere it appears in the model. The model might be

\begin{verbatim}
. regress y age bp i.sex sex#c.age sex#c.bp
\end{verbatim}

and then, in making the marginal calculation of the mean for males and females, \texttt{margins} not only accounts for the direct effect of \texttt{i.sex} but also for the indirect effects of \texttt{sex#c.age} and \texttt{sex#c.bp}.

The response being margined can be any statistic produced by \texttt{[R] predict}, or any expression of those statistics.

Standard errors are obtained by the delta method, at least by default. The delta method assumes that the values at which the covariates are evaluated to obtain the marginal responses are fixed. When your sample represents a population, whether you are using \texttt{svy} or not (see \texttt{[SVY] svy}), you can specify \texttt{margins' vce(unconditional)} option and \texttt{margins} will produce standard errors that account for the sampling variability of the covariates. Some researchers reserve the term predictive margins to describe this.

The best way to understand \texttt{margins} is to see some examples. You can run the following examples yourself if you type

\begin{verbatim}
. use http://www.stata-press.com/data/r13/margex
\end{verbatim}

(Artificial data for margins)
Example 1: A simple case after *regress*

```
. regress y i.sex i.group
(output omitted)
. margins sex
Predictive margins                        Number of obs  =  3000
Model VCE      : OLS
Expression     : Linear prediction, predict()

                      Delta-method             t     P>|t|      [95% Conf. Interval]
                      Margin     Std. Err.   z     P>|z|       [95% Conf. Interval]

       sex
      male     60.56034    .5781782  104.74     0.000    59.42668    61.69401
     female    78.88236    .5772578  136.65     0.000    77.75050    80.01422
```

The numbers reported in the “Margin” column are average values of $y$. Based on a linear regression of $y$ on sex and group, 60.6 would be the average value of $y$ if everyone in the data were treated as if they were male, and 78.9 would be the average value if everyone were treated as if they were female.

Example 2: A simple case after *logistic*

```
margins may be used after almost any estimation command.

. logistic outcome i.sex i.group
(output omitted)
. margins sex
Predictive margins                        Number of obs  =  3000
Model VCE      : OIM
Expression     : Pr(outcome), predict()

                      Delta-method             z     P>|z|       [95% Conf. Interval]
                      Margin     Std. Err.   z     P>|z|       [95% Conf. Interval]

       sex
      male     .1286796   .0111424   11.55     0.000     .106841     .1505182
     female    .1905087   .0089719   21.23     0.000     .1729241     .2080933
```

The numbers reported in the “Margin” column are average predicted probabilities. Based on a logistic regression of outcome on sex and group, 0.13 would be the average probability of outcome if everyone in the data were treated as if they were male, and 0.19 would be the average probability if everyone were treated as if they were female.

```
margins reports average values after *regress* and average probabilities after *logistic*. By default, margins makes tables of whatever it is that predict (see [R] predict) predicts by default. Alternatively, margins can make tables of anything that predict can produce if you use margins’ predict() option; see Example 11: Margins of a specified prediction.
```
Example 3: Average response versus response at average

In example 2, margins reported average probabilities of outcome for \( \text{sex} = 0 \) and \( \text{sex} = 1 \). If we instead wanted the predicted probabilities evaluated at the mean of the covariates, we would specify margins’ \texttt{atmeans} option. We previously typed

```
. logistic outcome i.sex i.group
(output omitted)
. margins sex
(output omitted)
```

and now we type

```
. margins sex, atmeans
```

```
Adjusted predictions Number of obs = 3000
Model VCE : OIM
Expression : Pr(outcome), predict()
at : 0.sex = .4993333 (mean)
     1.sex = .5006667 (mean)
     1.group = .3996667 (mean)
     2.group = .3726667 (mean)
     3.group = .2276667 (mean)

<table>
<thead>
<tr>
<th></th>
<th>Delta-method</th>
<th></th>

</tr>
</tbody>
</table>
```

The prediction at the average of the covariates is different from the average of the predictions. The first is the expected probability of a person with average characteristics, a person who, in another problem, might be 3/4 married and have 1.2 children. The second is the average of the probability among actual persons in the data.

When you specify \texttt{atmeans} or any other at option, \texttt{margins} reports the values used for the covariates in the legend above the table. \texttt{margins} lists the values for all the covariates, including values it may not use, in the results that follow. In this example, \texttt{margins} reported means for \texttt{sex} even though those means were not used. They were not used because we asked for the margins of \texttt{sex}, so \texttt{sex} was fixed first at 0 and then at 1.

If you wish to suppress this legend, specify the \texttt{nolegend} option.

Example 4: Multiple margins from one command

More than one margin can be reported by just one \texttt{margins} command. You can type

```
. margins sex group
```

and doing that is equivalent in terms of the output to typing

```
. margins sex
. margins group
```

When multiple margins are requested on the same command, each is estimated separately. There is, however, a difference when you also specify \texttt{margins’ post} option. Then the variance–covariance matrix for all margins requested is posted, and that is what allows you to test equality of margins, etc. Testing equality of margins is covered in \textit{Example 10: Testing margins—contrasts of margins}. 
In any case, below we request margins for *sex* and for *group*.

```
margins sex group
```

Predictive margins

|             | Std. Err. | z    | P>|z|   | 95% Conf. Interval |
|-------------|-----------|------|-------|-------------------|
| sex         |           |      |       |                   |
| male        | 0.1286796 | 0.0111424 | 11.55 | 0.000 | 0.106841 - 0.1505182 |
| female      | 0.1905087 | 0.0089719 | 21.23 | 0.000 | 0.1729241 - 0.2080933 |
| group       |           |       |       |                   |
| 1           | 0.2826207 | 0.0146234 | 19.33 | 0.000 | 0.2539593 - 0.311282 |
| 2           | 0.1074814 | 0.0094901 | 11.33 | 0.000 | 0.0888812 - 0.1260817 |
| 3           | 0.0291065 | 0.0073417 | 3.96  | 0.000 | 0.0147169 - 0.043496 |

**Example 5: Margins with interaction terms**

The estimation command on which margins bases its calculations may contain interaction terms, such as an interaction of *sex* and *group*:

```
.logistic outcome i.sex i.group sex#group
```

```
(output omitted)
```

```
margins sex group
```

Predictive margins

|             | Std. Err. | z    | P>|z|   | 95% Conf. Interval |
|-------------|-----------|------|-------|-------------------|
| sex         |           |      |       |                   |
| male        | 0.1561738 | 0.0132774 | 11.76 | 0.000 | 0.1301506 - 0.182197 |
| female      | 0.1983749 | 0.0101546 | 19.54 | 0.000 | 0.1784723 - 0.2182776 |
| group       |           |       |       |                   |
| 1           | 0.3211001 | 0.0176403 | 18.20 | 0.000 | 0.2865257 - 0.3566744 |
| 2           | 0.1152127 | 0.0099854 | 11.54 | 0.000 | 0.0956417 - 0.1347838 |
| 3           | 0.0265018 | 0.0073417 | 2.41  | 0.016 | 0.0049811 - 0.0480226 |

We fit the model by typing logistic outcome i.sex i.group sex#group, but the meaning would have been the same had we typed logistic outcome sex##group.

As mentioned in example 4, the results for *sex* and the results for *group* are calculated independently, and we would have obtained the same results had we typed margins sex followed by margins group.

The margin for male (*sex = 0*) is 0.16. The probability 0.16 is the average probability if everyone in the data were treated as if *sex = 0*, including *sex = 0* in the main effect and *sex = 0* in the interaction of *sex* with *group*.

Had we specified margins sex, atmeans, we would have obtained not average probabilities but the probabilities evaluated at the average. Rather than obtaining 0.16, we would have obtained 0.10
for $\text{sex} = 0$. The 0.10 is calculated by taking the fitted model, plugging in $\text{sex} = 0$ everywhere, and plugging in the average value of the group indicator variables everywhere they are used. That is, rather than treating the group indicators as being (1, 0, 0), (0, 1, 0), or (0, 0, 1) depending on observation, the group indicators are treated as being (0.40, 0.37, 0.23), which are the average values of $\text{group} = 1$, $\text{group} = 2$, and $\text{group} = 3$.

**Example 6: Margins with continuous variables**

To the above example, we will add the continuous covariate $\text{age}$ to the model and then rerun `margins sex group`.

```
.logistic outcome i.sex i.group sex#group age
(output omitted)
.margins sex group
```

|          | Delta-method | Margin | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|----------|--------------|--------|-----------|-----|-----|---------------------|
| sex      |              |        |           |     |     |                     |
| male     | .1600644     | .0125653 | 12.74     | 0.000 | .1354368 | .184692 |
| female   | .1966902     | .0100043 | 19.66     | 0.000 | .1770821 | .2162983 |
| group    |              |        |           |     |     |                     |
| 1        | .2251302     | .0123233 | 18.27     | 0.000 | .200977 | .2492834 |
| 2        | .150603      | .0116506 | 12.93     | 0.000 | .1277685 | .1734376 |
| 3        | .0736157     | .0337256 | 2.18      | 0.029 | .0075147 | .1397167 |

Compared with the results presented in example 5, results for sex change little, but results for groups 1 and 3 change markedly. The tables differ because now we are adjusting for the continuous covariate $\text{age}$, as well as for sex and group.

We will continue examining interactions in example 8. Because we have added a continuous variable, let’s take a detour to explain how to obtain margins for continuous variables and to explain their interpretation.

**Example 7: Margins of continuous variables**

Continuing with our example of

```
.logistic outcome i.sex i.group sex#group age
```

let’s examine the continuous covariate $\text{age}$. 
You are not allowed to type `margins age`; doing that will produce an error:

```
. margins age
   `age' not found in list of covariates
r(322);
```

The message “‘age’ not found in list of covariates” is `margins`’ way of saying, “Yes, age might be in the model, but if it is, it is not included as a factor variable; it is in as a continuous variable.” Sometimes, Stata is overly terse. `margins` might also say that because age is continuous there are an infinite number of values at which it could evaluate the margins. At what value(s) should age be fixed? `margins` requires more guidance with continuous covariates. We can provide that guidance by using the `at()` option and typing

```
. margins, at(age=40)
```

To understand why that yields the desired result, let us tell you that if you were to type

```
. margins
```

`margins` would report the overall margin—the margin that holds nothing constant. Because our model is logistic, the average value of the predicted probabilities would be reported. The `at()` option fixes one or more covariates to the value(s) specified and can be used with both factor and continuous variables. Thus, if you typed `margins, at(age=40)`, then `margins` would average over the data the responses for everybody, setting `age=40`. Here is what happens when you type that:

```
. margins, at(age=40)
```

```
Predictive margins
Model VCE : OIM
Expression : Pr(outcome), predict()
at : age = 40

                   Delta-method
                  Margin  Std. Err.     z  P>|z|     [95% Conf. Interval]
     _cons        .1133603   .0070731  16.03   0.000     .0994972   .1272234
```

Reported is the margin for `age = 40`, adjusted for the other covariates in our model. If we wanted to obtain the margins for age 30, 35, 40, 45, and 50, we could type

```
. margins, at(age=(30 35 40 45 50))
```
or, equivalently,

```
. margins, at(age=(30(5)50))
```

**Example 8: Margins of interactions**

Our model is

```
. logistic outcome i.sex i.group sex#group age
```
We can obtain the margins of all possible combinations of the levels of `sex` and the levels of `group` by typing

```
. margins sex#group
```

Predictive margins                              Number of obs = 3000  
Model VCE : OIM                                     01M                
Expression : Pr(outcome), predict(                   

| Sex#Group | Margin | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|-----------|--------|-----------|------|------|---------------------|
| male#1    | 0.238  | 0.024     | 10.0 | 0.0  | 0.191 - 0.284       |
| male#2    | 0.066  | 0.011     | 6.25 | 0.0  | 0.045 - 0.086       |
| male#3    | 0.054  | 0.014     | 3.94 | 0.0  | 0.027 - 0.081       |
| female#1  | 0.216  | 0.011     | 19.1 | 0.0  | 0.193 - 0.239       |
| female#2  | 0.205  | 0.018     | 11.2 | 0.0  | 0.169 - 0.241       |
| female#3  | 0.085  | 0.053     | 1.60 | 0.1  | -0.019 - 0.190      |

The first line in the table reports the marginal probability for `sex` = 0 (male) and `group` = 1. That is, it reports the estimated probability if everyone in the data were treated as if they were `sex` = 0 and `group` = 1.

Also reported are all the other combinations of `sex` and `group`.

By the way, we could have typed `margins sex#group` even if our fitted model did not include `sex#group`. Estimation is one thing, and asking questions about the nature of the estimates is another. `margins` does, however, require that `i.sex` and `i.group` appear somewhere in the model, because fixing a value outside the model would just produce the grand margin, and you can separately ask for that if you want it by typing `margins` without arguments.

**Example 9: Decomposing margins**

We have the model

```
. logistic outcome i.sex i.group sex#group age
```

In example 6, we typed `margins sex` and obtained 0.160 for males and 0.197 for females. We are going to decompose each of those numbers. Let us explain:

1. The margin for males, 0.160, treats everyone as if they were male, and that amounts to simultaneously
   1a. treating males as males and
   1b. treating females as males.
2. The margin for females, 0.197, treats everyone as if they were female, and that amounts to simultaneously
   2a. treating males as females and
   2b. treating females as females.

The margins 1a and 1b are the decomposition of 1, and the margins 2a and 2b are the decomposition of 2.

We could obtain 1a and 2a by typing

```
. margins if sex==0, at(sex=(0 1))
```
because the qualifier if sex==0 would restrict margins to running on only the males. Similarly, we could obtain 1b and 2b by typing

```
. margins if sex==1, at(sex=(0 1))
```

We run these examples below:

```
. margins if sex==0, at(sex=(0 1))
Predictive margins                  Number of obs =  1498
Model VCE : OIM
Expression : Pr(outcome), predict()
1._at : sex = 0
2._at : sex = 1

```

Putting together the results from example 6 and the results above, we have

- Margin treating everybody as themself: 0.170
- Margin treating everybody as male: 0.160
- Margin treating male as male: 0.079
- Margin treating female as male: 0.240
- Margin treating everybody as female: 0.197
- Margin treating male as female: 0.134
- Margin treating female as female: 0.260

**Example 10: Testing margins—contrasts of margins**

Continuing with the previous example, it would be interesting to test the equality of 2b and 1b, to test whether the average probability of a positive outcome for females treated as females is equal to that for females treated as males. That test would be different from testing the overall significance of sex in our model. The test performed on our model would be a test of whether the probability of a positive outcome differs between males and females when they have equal values of the other covariates. The test of equality of margins is a test of whether the average probabilities differ given the different pattern of values of the other covariates that the two sexes have in our data.
We can also perform such tests by treating the results from `margins` as estimation results. There are three steps required to perform tests on margins. First, you must arrange it so that all the margins of interest are reported by just one `margins` command. Second, you must specify `margins`’ post option. Third, you perform the test with the `test` command.

Such tests and comparisons can be readily performed by contrasting margins; see [R] margins, contrast. Also see *Contrasts of margins—effects (discrete marginal effects)* in [R] marginsplot.

In the previous example, we used two commands to obtain our results, namely,

```
. margins if sex==0, at(sex=(0 1))
. margins if sex==1, at(sex=(0 1))
```

We could, however, have obtained the same results by typing just one command:

```
. margins, over(sex) at(sex=(0 1))
```

Performing `margins, over(sex)` first restricts the sample to `sex==0` and then restricts it to `sex==1`, and that is equivalent to the two different if conditions that we specified before.

To test whether females treated as females is equal to females treated as males, we will need to type

```
. margins, over(sex) at(sex=(0 1)) post
. test _b[2._at#1.sex] = _b[1._at#1.sex]
```

We admit that the second command may seem to have come out of nowhere. When we specify `post` on the `margins` command, `margins` behaves as if it were an estimation command, which means that 1) it posts its estimates and full VCE to `e()`, 2) it gains the ability to replay results just as any estimation command can, and 3) it gains access to the standard postestimation commands. Item 3 explains why we could use `test`. We learned that we wanted to test `_b[2._at#1.sex]` and `_b[1._at#1.sex]` by replaying the estimation results, but this time with the standard estimation command `coeflegend` option. So what we typed was

```
. margins, over(sex) at(sex=(0 1)) post
. margins, coeflegend
. test _b[2._at#1.sex] = _b[1._at#1.sex]
```
We will let you try `margins, coeflegend` for yourself. The results of running the other two commands are

```
. margins, over(sex) at(sex=(0 1)) post
Predictive margins Number of obs = 3000
Model VCE : OIM
Expression : Pr(outcome), predict() over : sex
1._at : 0.sex
    sex = 0
    1.sex
    sex = 0
2._at : 0.sex
    sex = 1
    1.sex
    sex = 1

```

```
. test _b[2._at#1.sex] = _b[1._at#1.sex]
( 1) 1bn._at#1.sex + 2._at#1.sex = 0
chi2( 1) = 0.72
Prob > chi2 = 0.3951
```

We can perform the same test in one command using contrasts of margins:

```
. logistic outcome i.sex i.group sex#group age
(output omitted)
. margins, over(sex) at(sex=(0 1)) contrast(atcontrast(r._at) wald)
Contrasts of predictive margins
Model VCE : OIM
Expression : Pr(outcome), predict() over : sex
1._at : 0.sex
    sex = 0
    1.sex
    sex = 0
2._at : 0.sex
    sex = 1
    1.sex
    sex = 1

|            | df | chi2  | P>|chi2|
|------------|----|-------|-------|
|_at@sex    |    |       |       |
|(2 vs 1) male | 1  | 14.59 | 0.0001|
|(2 vs 1) female | 1 | 0.72  | 0.3951|
|Joint       | 2  | 16.13 | 0.0003|
```
We refitted our logistic model because its estimation results were replaced when we posted our margins. The syntax to perform the contrast we want is admittedly not obvious. Contrasting (testing) across at() groups is more difficult than contrasting across the margins themselves or across over() groups, because we have no natural place for the contrast operators (r., in our case). We also explicitly requested Wald tests of the contrasts, which are not provided by default. Nevertheless, the chi-squared statistic and its $p$-value for (2 vs 1) for male matches the results of our test command. We also obtain the test of whether the response of males treated as males is equal to the response of males treated as females.

For a gentler introduction to contrasts of margins, see [R] margins, contrast.

Example 11: Margins of a specified prediction

We will fit the model

```stata
. use http://www.stata-press.com/data/r13/margex
. tobit ycn i.sex i.group sex#group age, ul(90)
```

and we will tell the following story about the variables: We run a peach orchard where we allow people to pick their own peaches. A person receives one empty basket in exchange for $20, along with the right to enter the orchard. There is no official limit on how many peaches a person can pick, but only 90 peaches will fit into a basket. The dependent variable in the above tobit model, ycn, is the number of peaches picked. We use tobit, a special case of censored-normal regression, because ycn is censored at 90.

After fitting this model, if we typed

```stata
. margins sex
```

we would obtain the margins for males and for females of the uncensored number of peaches picked. We would obtain that because predict after tobit produces the uncensored number by default. To obtain the censored prediction, we would have to specify predict’s ystar(.,90) option. If we want the margins based on that response, we type

```stata
. margins sex, predict(ystar(.,90))
```
The results of typing that are

```
. tobit ycn i.sex i.group sex#group age, ul(90)
(output omitted)
. margins sex, predict(ystar(.,90))
```

Predictive margins  
Model VCE : OIM  
Expression : E(ycn*|ycn<90), predict(ystar(.,90))

| sex   | Delta-method | Margin | Std. Err. | z      | P>|z|   | [95% Conf. Interval] |
|-------|--------------|--------|-----------|--------|-------|----------------------|
| male  |              | 62.21804 | .5996928  | 103.75 | 0.000 | 61.04266 63.39342    |
| female|              | 78.34272 | .455526   | 171.98 | 0.000 | 77.4499  79.23553    |

In our previous examples, sex = 1 has designated females, so evidently the females visiting our orchard are better at filling baskets than the men.

**Example 12: Margins of a specified expression**

Continuing with our peach orchard example and the previously fit model

```
. use http://www.stata-press.com/data/r13/margex
. tobit ycn i.sex i.group sex#group age, ul(90)
```

let’s examine how well our baskets are working for us. What is the proportion of the number of peaches actually picked to the number that would have been picked were the baskets larger? As mentioned in example 11, predict, ystar(.,90) produces the expected number picked given the limit of basket size. predict, xb would predict the expected number without a limit. We want the ratio of those two predictions. That ratio will measure as a proportion how well the baskets work. Thus we could type

```
. margins sex, expression(predict(ystar(.,90))/predict(xb))
```

That would give us the proportion for everyone treated as male and everyone treated as female, but what we want to know is how well baskets work for true males and true females, so we will type

```
. margins, over(sex) expression(predict(ystar(.,90))/predict(xb))
. margins, over(sex) expression(predict(ystar(0,90))/predict(xb))
```

| sex   | Delta-method | Margin | Std. Err. | z      | P>|z|   | [95% Conf. Interval] |
|-------|--------------|--------|-----------|--------|-------|----------------------|
| male  |              | .9811785 | .0013037  | 752.60 | 0.000 | .9786233  .9837337   |
| female|              | .9419962 | .0026175  | 359.88 | 0.000 | .936866   .9471265   |

By the way, we could count the number of peaches saved by the limited basket size during the period of data collection by typing
The number of peaches saved turns out to be 9,183.

**Example 13: Margins with multiple outcomes (responses)**

Estimation commands such as `mlogit` and `mprobit` (see [R] `mlogit` and [R] `mprobit`) calculate multiple responses, and those multiple responses are reflected in the options available with `predict` after estimation. Obtaining margins for such estimators is thus the same as obtaining margins of a specified prediction, which was demonstrated in example 11. The solution is to include the `predict_option` that selects the desired response in margins' `predict(predict_option)` option.

If we fit the multinomial logistic model

```
. mlogit group i.sex age
```

then to obtain the margins for the probability that `group = 1`, we would type

```
. margins sex, predict(outcome(1))
```

and to obtain the margins for the probability that `group = 3`, we would type

```
. margins sex, predict(outcome(3))
```

We learned about the `outcome(1)` and `outcome(3)` options by looking in [R] `mlogit postestimation`. For an example using `margins` with a multiple-outcome estimator, see example 4 in [R] `mlogit postestimation`.

**Example 14: Margins with multiple equations**

Estimation commands such as `mvreg`, `manova`, `sureg`, and `reg3` (see [MV] `mvreg`, [MV] `manova`, [R] `sureg`, and [R] `reg3`) fit multiple equations. Obtaining margins for such estimators is the same as obtaining margins with multiple outcomes (see example 13), which in turn is the same as obtaining margins of a specified prediction (see example 11). You place the relevant option from the estimator’s `predict` command into margins’ `predict(predict_option)` option.

If we fit the seemingly unrelated regression model

```
. sureg (y = i.sex age) (distance = i.sex i.group)
```

we can obtain the marginal means of `y` for males and females by typing

```
. margins sex, predict(equation(y))
```

and we can obtain the marginal means of `distance` by typing

```
. margins sex, predict(equation(distance))
```

We could obtain the difference between the margins of `y` and `distance` by typing

```
. margins sex, expression(predict(equation(y)) - predict(equation(distance)))
```

More examples can be found in [MV] `manova` and [MV] `manova postestimation`. 
Example 15: Margins evaluated out of sample

You can fit your model on one dataset and use margins on another if you specify margins' noesample option. Remember that margins reports estimated average responses, and, unless you lock all the covariates at fixed values by using the at() option, the remaining variables are allowed to vary as they are observed to vary in the data. That is indeed the point of using margins. The fitted model provides the basis for adjusting for the remaining variables, and the data provide their values. The predictions produced by margins are of interest assuming the data used by margins are in some sense interesting or representative. In some cases, you might need to fit your model on one set of data and perform margins on another.

In example 11, we fit the model

```
. tobit ycn i.sex i.group sex#group age, ul(90)
```

and we told a story about our peach orchard in which we charged people $20 to collect a basket of peaches, where baskets could hold at most 90 peaches. Let us now tell you that we believe the data on which we estimated those margins were unrepresentative, or at least, we have a more representative sample stored in another .dta file. That dataset includes the demographics of our customers but does not include counts of peaches picked. It is a lot of work counting those peaches.

Thus we will fit our model just as we did previously using the detailed data, but we will bring the other, more representative dataset into memory before issuing the margins sex, predict(ystar(.,90)) command, and we will add noesample to it.

```
. use http://www.stata-press.com/data/r13/margex
(Artificial data for margins)
. tobit ycn i.sex i.group sex#group age, ul(90)
(output omitted)
. use http://www.stata-press.com/data/r13/peach
. margins sex, predict(ystar(.,90)) noesample
```

Predictive margins
Number of obs = 2727
Model VCE : OIM
Expression : E(ycn*|ycn<90), predict(ystar(.,90))

<table>
<thead>
<tr>
<th></th>
<th>Delta-method</th>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Margin</td>
<td>Std. Err.</td>

<td>116.54</td>
<td>0.000</td>
<td>73.75975</td>
<td>76.28317</td>
</tr>
</tbody>
</table>

In example 12, we produced an estimate of the number of peaches saved by the limited-size baskets. We can update that estimate using the new demographic data by typing

```
. count
2727
. margins, exp(2727*(predict(xb)-predict(ystar(.,90)))) noesample
(output omitted)
```

By running the above, we find that the updated number of peaches saved is 6,408.
Obtaining margins of derivatives of responses (a.k.a. marginal effects)

Derivatives of responses are themselves responses, so everything said above in Obtaining margins of responses is equally true of derivatives of responses, and every example above could be repeated here substituting the derivative of the response for the response.

Derivatives are of interest because they are an informative way of summarizing fitted results. The change in a response for a change in the covariate is easy to understand and to explain. In simple models, one hardly needs margins to assist in obtaining such margins. Consider the simple linear regression

\[ y = \beta_0 + \beta_1 \times \text{sex} + \beta_2 \times \text{age} + \epsilon \]

The derivatives of the responses are

\[ \frac{dy}{d(\text{sex})} = \beta_1 \]
\[ \frac{dy}{d(\text{age})} = \beta_2 \]

The derivatives are the fitted coefficients. How does \( y \) change between males and females? It changes by \( \beta_1 \). How does \( y \) change with age? It changes by \( \beta_2 \) per year.

If you make the model a little more complicated, however, the need for margins arises. Consider the model

\[ y = \beta_0 + \beta_1 \times \text{sex} + \beta_2 \times \text{age} + \beta_3 \times \text{age}^2 + \epsilon \]

Now the derivative with respect to age is

\[ \frac{dy}{d(\text{age})} = \beta_2 + 2 \times \beta_3 \times \text{age} \]

The change in \( y \) for a change in age itself changes with age, and so to better understand the fitted results, you might want to make a table of the change in \( y \) for a change in age for age = 30, age = 40, and age = 50. margins can do that.

Consider an even more complicated model, such as

\[ y = \beta_0 + \beta_1 \times \text{sex} + \beta_2 \times \text{age} + \beta_3 \times \text{age}^2 + \beta_4 \times \text{bp} + \beta_5 \times \text{sex} \times \text{bp} + \beta_6 \times \text{tmt} + \beta_7 \times \text{tmt} \times \text{age} + \beta_8 \times \text{tmt} \times \text{age}^2 + \epsilon \]  

(1)

The derivatives are

\[ \frac{dy}{d(\text{sex})} = \beta_1 + \beta_5 \times \text{bp} \]
\[ \frac{dy}{d(\text{age})} = \beta_2 + 2 \times \beta_3 \times \text{age} + \beta_7 \times \text{tmt} + 2 \times \beta_8 \times \text{tmt} \times \text{age} \]
\[ \frac{dy}{d(\text{bp})} = \beta_4 + \beta_5 \times \text{sex} \]
\[ \frac{dy}{d(\text{tmt})} = \beta_6 + \beta_7 \times \text{age} + \beta_8 \times \text{age}^2 \]

At this point, margins becomes indispensable.
Do not specify marginlist when you mean over()

`margins` has the same syntax when used with derivatives of responses as when used with responses. To obtain derivatives, one specifies the `dydx()` option. If we wanted to examine the response variable \( dy/d(tmt) \), we would specify `margins' dydx(tmt)` option. The rest of the `margins` command has the same syntax as ordinarily, although one tends to specify different syntactical elements. For instance, one usually does not specify a `marginlist`. If we typed

```
    . margins sex, dydx(tmt)
```

we would obtain \( dy/d(tmt) \) calculated first as if everyone were male and then as if everyone were female. At the least, we would probably want to specify

```
    . margins sex, dydx(tmt) grand
```

so as also to obtain \( dy/d(tmt) \), the overall margin, the margin with everyone having their own value of sex. Usually, however, all we want is the overall margin, and because `grand` is the default when the `marginlist` is not specified, we would just type

```
    . margins, dydx(tmt)
```

Alternatively, if we were interested in the decomposition by sex, then rather than type `margins` `sex, dydx(tmt)`, we probably want to type

```
    . margins, over(sex) dydx(tmt)
```

This command gives us the average effect of `tmt` for males and again for females rather than the average effect with everyone treated as male and then again with everyone treated as female.

Use at() freely, especially with continuous variables

Another option one tends to use more often with derivatives of responses than one does with responses is `at()`. Such use is often to better understand or to communicate how the response varies, or, in technical jargon, to explore the nature of the response surface.

For instance, the effect \( dy/d(tmt) \) in (1) is equal to \( \beta_6 + \beta_7 \times \text{age} + \beta_8 \times \text{age}^2 \), and so simply to understand how treatment varies with age, we may want to fix age at various values. We might type

```
    . margins, dydx(tmt) over(sex) at(age=(30 40 50))
```

Expressing derivatives as elasticities

You specify the `dydx(varname)` option on the `margins` command to use \( dy/d(varname) \) as the response variable. If you want that derivative expressed as an elasticity, you can specify `eyex(varname)`, `eydx(varname)`, or `dyex(varname)`. You substitute \( e \) for \( d \) where you want an elasticity. The formulas are

\[
\begin{align*}
\text{dydx()} &= dy/dx \\
\text{eyex()} &= dy/dx \times (x/y) \\
\text{eydx()} &= dy/dx \times (1/y) \\
\text{dyex()} &= dy/dx \times (x)
\end{align*}
\]
and the interpretations are

- \(\frac{dy}{dx}\): change in \(y\) for a change in \(x\)
- \(\frac{ey}{ex}\): proportional change in \(y\) for a proportional change in \(x\)
- \(\frac{ey}{dx}\): proportional change in \(y\) for a change in \(x\)
- \(\frac{dy}{ex}\): change in \(y\) for a proportional change in \(x\)

As `margins` always does with response functions, calculations are made at the observational level and are then averaged. Let’s assume that in observation 5, \(\frac{dy}{dx} = 0.5\), \(y = 15\), and \(x = 30\); then

\[
\begin{align*}
\frac{dy}{dx} &= 0.5 \\
\frac{ey}{ex} &= 1.0 \\
\frac{ey}{dx} &= 0.03 \\
\frac{dy}{ex} &= 15.0
\end{align*}
\]

Many social scientists would informally explain the meaning of \(\frac{ey}{ex} = 1\) as "\(y\) increases 100\% when \(x\) increases 100\%" or as "\(y\) doubles when \(x\) doubles", although neither statement is literally true. \(\frac{ey}{ex}\), \(\frac{ey}{dx}\), and \(\frac{dy}{ex}\) are rates evaluated at a point, just as \(\frac{dy}{dx}\) is a rate, and all such interpretations are valid only for small (infinitesimal) changes in \(x\). It is true that \(\frac{ey}{ex} = 1\) means \(y\) increases with \(x\) at a rate such that, if the rate were constant, \(y\) would double if \(x\) doubled. This issue of casual interpretation is no different from casually interpreting \(\frac{dy}{dx}\) as if it represents the response to a unit change. It is not necessarily true that \(\frac{dy}{dx} = 0.5\) means that "\(y\) increases by 0.5 if \(x\) increases by 1". It is true that "\(y\) increases with \(x\) at a rate such that, if the rate were constant, \(y\) would increase by 0.5 if \(x\) increased by 1".

\(\frac{dy}{dx}\), \(\frac{ey}{ex}\), \(\frac{ey}{dx}\), and \(\frac{dy}{ex}\) may be used with continuous \(x\) variables. \(\frac{dy}{dx}\) and \(\frac{ey}{dx}\) may also be used with factor variables.

**Derivatives versus discrete differences**

In (1),

\[
y = \beta_0 + \beta_1 \times \text{sex} + \beta_2 \times \text{age} + \beta_3 \times \text{age}^2 + \beta_4 \times \text{bp} + \beta_5 \times \text{sex} \times \text{bp} + \beta_6 \times \text{tmt} + \beta_7 \times \text{tmt} \times \text{age} + \beta_8 \times \text{tmt} \times \text{age}^2 + \epsilon
\]

Let us call your attention to the derivatives of \(y\) with respect to age and sex:

\[
\frac{dy}{d(\text{age})} = \beta_2 + 2 \times \beta_3 \times \text{age} + \beta_7 \times \text{tmt} + 2 \times \beta_8 \times \text{tmt} \times \text{age} \tag{2}
\]

\[
\frac{dy}{d(\text{sex})} = \beta_1 + \beta_5 \times \text{bp} \tag{3}
\]

\(\text{age}\) is presumably a continuous variable and (2) is precisely how `margins` calculates its derivatives when you type `margins, dydx(age)`. \(\text{sex}\), however, is presumably a factor variable, and `margins` does not necessarily make the calculation using (3) were you to type `margins, dydx(sex)`. We will explain, but let us first clarify what we mean by a continuous and a factor variable. Say that you fit (1) by typing

```
. regress y i.sex age c.age#c.age i.bp bp#sex
> i.tmt tmt#c.age tmt#c.age#c.age
```
It is important that `sex` entered the model as a factor variable. It would not do to type `regress y sex ...` because then `sex` would be a continuous variable, or at least it would be a continuous variable from Stata’s point of view. The model estimates would be the same, but `margins`’ understanding of those estimates would be a little different. With the model estimated using `i.sex`, `margins` understands that either `sex` is 0 or `sex` is 1. With the model estimated using `sex`, `margins` thinks `sex` is continuous and, for instance, `sex = 1.5` is a possibility.

`margins` calculates `dydx()` differently for continuous and for factor variables. For continuous variables, `margins` calculates `dy/dx`. For factor variables, `margins` calculates the discrete first-difference from the base category. To obtain that for `sex`, write down the model and then subtract from it the model evaluated at the base category for `sex`, which is `sex = 0`. If you do that, you will get the same formula as we obtained for the derivative, namely,

\[
\text{discrete difference}\{(\text{sex} = 1) - (\text{sex} = 0)\} = \beta_1 + \beta_5 \times.bp
\]

We obtain the same formula because our model is linear regression. Outside of linear regression, and outside of linear response functions generally, the discrete difference is not equal to the derivative. The discrete difference is not equal to the derivative for logistic regression, probit, etc. The discrete difference calculation is generally viewed as better for factor variables than the derivative calculation because the discrete difference is what would actually be observed.

If you want the derivative calculation for your factor variables, specify the `continuous` option on the `margins` command.

**Example 16: Average marginal effect (partial effects)**

Concerning the title of this example, the way we use the term marginal effect, the effects of factor variables are calculated using discrete first-differences. If you wanted the continuous calculation, you would specify `margins`’ `continuous` option in what follows.

```
. use http://www.stata-press.com/data/r13/margex
(Artificial data for margins)
. logistic outcome treatment##group age c.age#c.age treatment#c.age
(output omitted)
. margins, dydx(treatment)
```

| Treatment | Delta-method | Std. Err. | z | P>|z| | [95% Conf. Interval] |
|-----------|--------------|-----------|---|-------|----------------------|
| treatment | 0.0385625    | 0.0162848 | 2.37 | 0.018 | 0.0066449 - 0.0704801 |

Note: `dy/dx` for factor levels is the discrete change from the base level.

The average marginal effect of treatment on the probability of a positive outcome is 0.039.
Example 17: Average marginal effect of all covariates

We will continue with the model

```
. logistic outcome treatment##group age c.age#c.age treatment#c.age
```

if we wanted the average marginal effects for all covariates, we would type `margins, dydx(*)` or `margins, dydx(_all)`; they mean the same thing. This is probably the most common way `margins, dydx()` is used.

```
. margins, dydx(*)
Average marginal effects                  Number of obs  =  3000
Model VCE : OIM

Note: dy/dx for factor levels is the discrete change from the base level.

Obtaining margins with survey data and representative samples

The standard errors and confidence intervals produced by margins are based by default on the delta method applied to the VCE of the current estimates. Delta-method standard errors treat the covariates at which the response is evaluated as given or fixed. Such standard errors are appropriate if you specify at() to fix the covariates, and they are appropriate when you are making inferences about groups exactly like your sample whether you specify at() or not.

On the other hand, if you have a representative sample of the population or if you have complex survey data and if you want to make inferences about the underlying population, you need to account for the variation in the covariates that would arise in repeated sampling. You do that using vce(unconditional), which invokes a different standard-error calculation based on Korn and Graubard (1999). Syntactically, there are three cases. They all involve specifying the vce(unconditional) option on the margins command:

1. You have a representative random sample, and you have not svyset your data.

   When you fit the model, you need to specify the vce(robust) or vce(cluster clustvar) option. When you issue the margins command, you need to specify the vce(unconditional) option.
2. You have a weighted sample, and you have not `svyset` your data.
   You need to specify `[pw=weight]` when you fit the model and, of course, specify the `vce(unconditional)` option on the `margins` command. You do not need to specify the weights on the `margins` command because `margins` will obtain them from the estimation results.

3. You have `svyset` your data, whether it be a simple random sample or something more complex including weights, strata, sampling units, or poststratification, and you are using the linearized variance estimator.
   You need to use the `svy` prefix when you fit the model. You need to specify `vce(unconditional)` when you issue the `margins` command. You do not need to respecify the weights.
   Even though the data are `svyset`, and even though the estimation was `svy` estimation, `margins` does not default to `vce(unconditional)`. It does not default to `vce(unconditional)` because there are valid reasons to want the data-specific, `vce(delta)` standard-error estimates. Whether you specify `vce(unconditional)` or not, `margins` uses the weights, so you do not need to respecify them even if you are using `vce(unconditional)`.
   `vce(unconditional)` is allowed only after estimation with `vce(robust)`, `vce(cluster ...)` or the `svy` prefix with the linearized variance estimator. If the VCE of the current estimates was specified as clustered, so will be the VCE estimates of `margins`. If the estimates were from a survey estimation, the survey settings in the dataset will be used by `margins`.
   When you use `vce(unconditional)`, never specify `if exp` or `in range` on the `margins` command; instead, specify the `subpop(if exp)` option. You do that for the usual reasons; see `[SVY] subpopulation estimation`. If you specify `over(varlist)` to examine subgroups, the subgroups will automatically be treated as subpopulations.
   If you are using a replication-based variance estimator, you may want to use this method to estimate the variance of your margins; see `[SVY] svy postestimation`.

Example 19: Inferences for populations, margins of response

In example 6, we fit the model

```plaintext
  . logistic outcome i.sex i.group sex#group age
```

and we obtained margins by sex and margins by group,

```plaintext
  . margins sex group
```

If our data were randomly drawn from the population of interest and we wanted to account for this, we would have typed

```plaintext
  . logistic outcome i.sex i.group sex#group age, vce(robust)
  . margins sex group, vce(unconditional)
```

We do that below:
. logistic outcome i.sex i.group sex#group age, vce(robust)
(output omitted)
. margins sex group, vce(unconditional)

Predictive margins

Expression : Pr(outcome), predict()
Number of obs = 3000

|                | Unconditional | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|----------------|---------------|-----------|-----|------|----------------------|
| sex            |               |           |     |      |                      |
| male           | .1600644      | .0131685  | 12.16 | 0.000  | .1342546 -.1858743  |
| female         | .1966902      | .0104563  | 18.81 | 0.000  | .1761963 -.2171841  |
| group          |               |           |     |      |                      |
| 1              | .2251302      | .0127069  | 17.72 | 0.000  | .200225 -.2500354   |
| 2              | .150603       | .0118399  | 12.72 | 0.000  | .1273972 -.1738088  |
| 3              | .0736157      | .0343188  | 2.15  | 0.032  | .0063522 -.1408793  |

The estimated margins are the same as they were in example 6, but the standard errors and confidence intervals differ, although not by much. Given that we have 3,000 observations in our randomly drawn sample, we should expect this.

**Example 20: Inferences for populations, marginal effects**

In example 17, we fit a logistic model and then obtained the average marginal effects for all covariates by typing

```
. logistic outcome treatment##group age c.age#c.age treatment#c.age
. margins, dydx(*)
```

To repeat that and also obtain standard errors for our population, we would type

```
. logistic outcome treatment##group age c.age#c.age treatment#c.age, vce(robust)
. margins, dydx(*) vce(unconditional)
```

The results are

```
. logistic outcome treatment##group age c.age#c.age treatment#c.age, vce(robust)
(output omitted)
. margins, dydx(*) vce(unconditional)
```

Average marginal effects

Expression : Pr(outcome), predict()

|                    | Unconditional | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|--------------------|---------------|-----------|-----|------|----------------------|
| 1.treatment        | .0385625      | .0163872  | 2.35 | 0.019  | .0064442 -.0706808  |
| group              |               |           |     |      |                      |
| 2                  | -.0776906     | .0179573  | -4.33 | 0.000  | -.1128863 -.0424949 |
| 3                  | -.1505652     | .0411842  | -3.66 | 0.000  | -.2312848 -.0698456 |
| age                | .0095868      | .0007814  | 12.27 | 0.000  | .0080553 -.0111183  |

Note: dy/dx for factor levels is the discrete change from the base level.
Example 21: Inferences for populations with svyset data

See example 3 in [SVY] svy postestimation.

**Standardizing margins**

A standardized margin is the margin calculated on data different from the data used to fit the model. Typically, the word standardized is reserved for situations in which the alternate population is a reference population, which may be real or artificial, and which is treated as fixed.

Say that you work for a hospital and have fit a model of mortality on the demographic characteristics of the hospital’s patients. At this stage, were you to type

`. margins`

you would obtain the mortality rate for your hospital. You have another dataset, hstandard.dta, that contains demographic characteristics of patients across all hospitals along with the population of each hospital recorded in the pop variable. You could obtain the expected mortality rate at your hospital if your patients matched the characteristics of the standard population by typing

`. use http://www.stata-press.com/data/r13/hstandard, clear
. margins [fw=pop], noesample`

You specified `noesample` because the margin is being calculated on data other than the data used to estimate the model. You specified `[fw=pop]` because the reference dataset you are using included population counts, as many reference datasets do.

**Obtaining margins as though the data were balanced**

Here we discuss what are commonly called estimated marginal means or least-squares means. These are margins assuming that all levels of factor variables are equally likely or, equivalently, that the design is balanced. The seminal reference on these margins is Searle, Speed, and Milliken (1980).

In designed experiments, observations are often allocated in a balanced way so that the variances can be easily compared and decomposed. At the Acme Portable Widget Company, they are experimenting with a new machine. The machine has three temperature settings and two pressure settings; a combination of settings will be optimal on any particular day, determined by the weather. At start-up, one runs a quick test and chooses the optimal setting for the day. Across different days, each setting will be used about equally, says the manufacturer.

In experiments with the machine, 10 widgets were collected for stress testing at each of the settings over a six-week period. We wish to know the average stress-test value that can be expected from these machines over a long period.

**Balancing using asbalanced**

The data were intended to be balanced, but unfortunately, the stress test sometimes destroys samples before the stress can be measured. Thus even though the experiment was designed to be balanced, the data are not balanced. You specify the `asbalanced` option to estimate the margins as if the data were balanced. We will type

`. use http://www.stata-press.com/data/r13/acmemanuf
. regress y pressure##temp
. margins, asbalanced
So that you can compare the asbalanced results with the observed results, we will also include margins without the asbalanced option in what follows:

```
. use http://www.stata-press.com/data/r13/acmemanuf
. regress y pressure##temp
(output omitted)
. margins
Predictive margins Number of obs = 49
Model VCE : OLS
Expression : Linear prediction, predict()
```

<table>
<thead>
<tr>
<th></th>
<th>Delta-method</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Margin</td>
</tr>
<tr>
<td>_cons</td>
<td>109.9214</td>
</tr>
</tbody>
</table>

```
. margins, asbalanced
Adjusted predictions Number of obs = 49
Model VCE : OLS
Expression : Linear prediction, predict()
at : pressure (asbalanced)
temp (asbalanced)
```

<table>
<thead>
<tr>
<th></th>
<th>Delta-method</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Margin</td>
</tr>
<tr>
<td>_cons</td>
<td>115.3758</td>
</tr>
</tbody>
</table>

**Technical note**

Concerning how asbalanced calculations are performed, if a factor variable has \( l \) levels, then each level’s coefficient contributes to the response weighted by \( 1/l \). If two factors, \( a \) and \( b \), interact, then each coefficient associated with their interaction is weighted by \( 1/(l_a \times l_b) \).

If a balanced factor interacts with a continuous variable, then each coefficient in the interaction is applied to the value of the continuous variable, and the results are weighted equally. So, if the factor being interacted has \( l_a \) levels, the effect of each coefficient on the value of the continuous covariate is weighted by \( 1/l_a \).

**Balancing by standardization**

To better understand the balanced results, we can perform the balancing ourselves by using the standardizing method shown in *Standardizing margins*. To do that, we will input a balanced dataset and then type `margins, noesample`. 

```
We obtain the same results as previously.

**Balancing nonlinear responses**

If our testing had produced a binary outcome, say, acceptable/unacceptable, rather than a continuous variable, we would type

```
. use http://www.stata-press.com/data/r13/acmemanuf, clear
. logistic acceptable pressure##temp
. margins, asbalanced
```

The result of doing that would be 0.680. If we omitted the `asbalanced` option, the result would have been 0.667. The two results are so similar because `acmemanuf.dta` is nearly balanced.

Even though the `asbalanced` option can be used on both linear and nonlinear responses, such as probabilities, there is an issue of which you should be aware. The most widely used formulas for balancing responses apply the balancing to the linear prediction, average that as if it were balanced, and then apply the nonlinear transform. That is the calculation that produced 0.680.

An alternative would be to apply the standardization method. That amounts to making the linear predictions observation by observation, applying the nonlinear transform to each, and then averaging the nonlinear result as if it were balanced. You could do that by typing

```
. use http://www.stata-press.com/data/r13/acmemanuf, clear
. logistic acceptable pressure##temp
. clear
. input pressure temp
   (see above for entered data)
. margins, noesample
```
The result from the standardization procedure would be 0.672. These two ways of averaging nonlinear responses are discussed in detail in Lane and Nelder (1982) within the context of general linear models.

Concerning the method used by the `asbalanced` option, if your data start balanced and you have a nonlinear response, you will get different results with and without the `asbalanced` option!

### Treating a subset of covariates as balanced

So far, we have treated all the covariates as if they were balanced. `margins` will allow you to treat a subset of the covariates as balanced, too. For instance, you might be performing an experiment in which you are randomly allocating patients to a treatment arm and so want to balance on arm, but you do not want to balance the other characteristics because you want mean effects for the experiment’s population.

In this example, we will imagine that the outcome of the experiment is continuous. We type

```
. use http://www.stata-press.com/data/r13/margex, clear
. regress y arm##sex sex##agegroup
. margins, at((asbalanced) arm)
```

If we wanted results balanced on `agegroup` as well, we could type

```
. margins, at((asbalanced) arm agegroup)
```

If we wanted results balanced on all three covariates, we could type

```
. margins, at((asbalanced) arm agegroup sex)
```

or we could type

```
. margins, at((asbalanced) _factor)
```

or we could type

```
. margins, asbalanced
```

### Using `fvset design`

As a convenience feature, equivalent to

```
. regress y arm##sex sex##agegroup
. margins, at((asbalanced) arm sex)
```

is

```
. fvset design asbalanced arm sex
. regress y arm##sex sex##agegroup
. margins
```

The advantage of the latter is that you have to set the variables as balanced only once. This is useful when balancing is a design characteristic of certain variables and you wish to avoid accidentally treating them as unbalanced.

If you save your data after `fvset`, the settings will be remembered in future sessions. If you want to clear the setting(s), type

```
. fvset clear varlist
```

See [R] `fvset`. 
Balancing in the presence of empty cells

The issue of empty cells is not exclusively an issue of balancing, but there are special considerations when balancing. Empty cells are discussed generally in Estimability of margins.

An empty cell is an interaction of levels of two or more factor variables for which you have no data. Usually, margins involving empty cells cannot be estimated. When balancing, there is an alternate definition of the margin that allows the margin to be estimated. margins makes the alternate calculation when you specify the emptycells(reweight) option. By default, margins uses the emptycells(strict) option.

If you have empty cells in your data and you request margins involving the empty cells, those margins will be marked as not estimable even if you specify the asbalanced option.

```
. use http://www.stata-press.com/data/r13/estimability, clear
   (margins estimability)
. regress y sex##group
   (output omitted)
. margins sex, asbalanced
```

<table>
<thead>
<tr>
<th>Adjusted predictions</th>
<th>Number of obs = 69</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model VCE : OLS</td>
<td></td>
</tr>
<tr>
<td>Expression : Linear prediction, predict()</td>
<td></td>
</tr>
<tr>
<td>at sex (asbalanced)</td>
<td></td>
</tr>
<tr>
<td>group (asbalanced)</td>

<td>sex</td>
<td></td>
</tr>
<tr>
<td>male</td>
<td>21.91389</td>
</tr>
<tr>
<td>female</td>
<td>. (not estimable)</td>
</tr>
</tbody>
</table>

This example is discussed in Estimability of margins, although without the asbalanced option. What is said there is equally relevant to the asbalanced case. For reasons explained there, the margin for sex = 1 (female) cannot be estimated.

The margin for sex = 1 can be estimated in the asbalanced case if you are willing to make an assumption. Remember that margins makes the balanced calculation by summing the responses associated with the levels and then dividing by the number of levels. If you specify emptycells(reweight), margins sums what is available and divides by the number available. Thus you are assuming that, whatever the responses in the empty cells, those responses are such that they would not change the overall mean of what is observed.
The results of specifying `emptycells(reweight)` are

```
. margins sex, asbalanced emptycells(reweight)
```

Obtaining margins with nested designs

Introduction

Factors whose meaning depends on other factors are called nested factors, and the factors on which their meaning depends are called the nesting factors. For instance, assume that we have a sample of patients and each patient is assigned to one doctor. Then patient is nested within doctor. Let the identifiers of the first 5 observations of our data be

<table>
<thead>
<tr>
<th>Doctor</th>
<th>Patient</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>Fred</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>Mary</td>
</tr>
<tr>
<td>1</td>
<td>3</td>
<td>Bob</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>Karen</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>Hank</td>
</tr>
</tbody>
</table>

The first patient on one doctor’s list has nothing whatsoever to do with the first patient on another doctor’s list. The meaning of `patient = 1` is defined only when the value of `doctor` is supplied.

Nested factors enter into models as interactions of nesting and nested; the nested factor does not appear by itself. We might estimate a model such as

```
. regress y i.doctor doctor#patient ...
```

You do not include `i.patient` because the coding for patient has no meaning except within doctor. Patient 1 is Fred for doctor 1 and Karen for doctor 2, etc.

`margins` provides an option to help account for the structure of nested models. The `within(varlist)` option specifies that `margins` estimate and report a set of margins for the value combinations of `varlist`. We might type

```
. margins, within(doctor)
```

Margin calculations are performed first for `doctor = 1`, then for `doctor = 2`, and so on.

Sometimes you need to specify `within()`, and other times you do not. Let’s consider the particular model

```
. regress y i.doctor doctor#patient i.sex sex#doctor#patient
```
The guidelines are the following:

1. You may compute overall margins by typing `margins`.
2. You may compute overall margins within levels of a nesting factor by typing `margins, within(doctor)`.
3. You may compute margins of a nested factor within levels of its nesting factor by typing `margins patient, within(doctor)`.
4. You may compute margins of factors in your model, as long as the factor does not nest other factors and is not nested within other factors, by typing `margins sex`.
5. You may not compute margins of a nesting factor, such as `margins doctor`, because they are not estimable.

For examples using `within()`, see [R] anova.

Margins with nested designs as though the data were balanced

To obtain margins with nested designs as though the data were balanced, the guidelines are the same as above except that 1) you add the `asbalanced` option and 2) whenever you do not specify `within()`, you specify `emptycells(reweight)`. The updated guidelines are

1. You may compute overall margins by typing `margins, asbalanced emptycells(reweight)`.
2. You may compute overall margins within levels of a nesting factor by typing `margins, asbalanced within(doctor)`.
3. You may compute margins of a nested factor within levels of its nesting factor by typing `margins patient, asbalanced within(doctor)`.
4. You may compute margins of factors in your model, as long as the factor does not nest other factors and is not nested within other factors, by typing `margins sex, asbalanced emptycells(reweight)`.
5. You may not compute margins of a nesting factor, such as `margins doctor`, because they are not estimable.

Just as explained in Using fvset design, rather than specifying the `asbalanced` option, you may set the balancing characteristic on the factor variables once and for all by using the command `fvset design asbalanced varlist`.

⚠️ Technical note

Specifying either `emptycells(reweight)` or `within(varlist)` causes `margins` to rebalance over all empty cells in your model. If you have interactions in your model that are not involved in the nesting, `margins` will lose its ability to detect estimability.

⚠️ Technical note

Careful readers will note that the description of `within(varlist)` matches closely the description of `over(varlist)`. The concept of nesting is similar to the concept of subpopulations. `within()` differs from `over()` in that it gracefully handles the missing cells when margins are computed as balanced.
Coding of nested designs

In the *Introduction* to this section, we showed a coding of the nested variable *patient*, where the coding started over with each *doctor*:

<table>
<thead>
<tr>
<th>Doctor</th>
<th>Patient</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>Fred</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>Mary</td>
</tr>
<tr>
<td>1</td>
<td>3</td>
<td>Bob</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>Karen</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>Hank</td>
</tr>
</tbody>
</table>

That coding style is not required. The data could just as well have been coded

<table>
<thead>
<tr>
<th>Doctor</th>
<th>Patient</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>Fred</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>Mary</td>
</tr>
<tr>
<td>1</td>
<td>3</td>
<td>Bob</td>
</tr>
<tr>
<td>2</td>
<td>4</td>
<td>Karen</td>
</tr>
<tr>
<td>2</td>
<td>5</td>
<td>Hank</td>
</tr>
</tbody>
</table>

or even

<table>
<thead>
<tr>
<th>Doctor</th>
<th>Patient</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1037239</td>
<td>Fred</td>
</tr>
<tr>
<td>1</td>
<td>2223942</td>
<td>Mary</td>
</tr>
<tr>
<td>1</td>
<td>0611393</td>
<td>Bob</td>
</tr>
<tr>
<td>2</td>
<td>4433329</td>
<td>Karen</td>
</tr>
<tr>
<td>2</td>
<td>6110271</td>
<td>Hank</td>
</tr>
</tbody>
</table>

Actually, either of the above two alternatives are better than the first one because *margins* will be better able to give you feedback about estimability should you make a mistake following the guidelines. On the other hand, both of these two alternatives require more memory at the estimation step. If you run short of memory, you will need to recode your patient ID to the first coding style, which you could do by typing

```
. sort doctor patient
. by doctor: gen newpatient = _n
```

Alternatively, you can *set emptycells drop* and continue to use your patient ID variable just as it is coded. If you do this, we recommend that you remember to type *set emptycells keep* when you are finished; *margins* is better able to determine estimability that way. If you regularly work with large nested models, you can *set emptycells keep, permanently* so that the setting persists across sessions. See [*R*] *set emptycells*. 
Special topics

Requirements for model specification

The results that `margins` reports are based on the most recently fit model or, in Stata jargon, the most recently issued estimation command. Here we discuss 1) mechanical requirements for how you specify that estimation command, 2) work-arounds to use when those restrictions prove impossible, and 3) requirements for `margins`’ `predict(pred_opt)` option to work.

Concerning 1, when you specify the estimation command, covariates that are logically factor variables must be Stata factor variables, and that includes indicator variables, binary variables, and dummies. It will not do to type

```
. regress y ... female ...
```

even if `female` is a 0/1 variable. You must type

```
. regress y ... i.female ...
```

If you violate this rule, you will not get incorrect results, but you will discover that you will be unable to obtain margins on `female`:

```
. margins female
factor female not found in e(b)
r(111);
```

It is also important that if the same continuous variable appears in your model more than once, differently transformed, those transforms be performed via Stata’s factor-variable notation. It will not do to type

```
. generate age2 = age^2
. regress y ... age age2 ...
```

You must type

```
. regress y ... age c.age#c.age ...
```

You must do that because `margins` needs to know everywhere that variable appears in the model if it is to be able to set covariates to fixed values.

Concerning 2, sometimes the transformations you desire may not be achievable using the factor-variable notation; in those situations, there is a work-around. Let’s assume you wish to estimate

```
. generate age1_5 = age^1.5
. regress y ... age age1_5 ...
```

There is no factor-variable notation for including `age` and `age1.5` in a model, so obviously you are going to obtain the estimates by typing just what we have shown. In what follows, it would be okay if there are interactions of `age` and `age1.5` with other variables specified by the factor-variable notation, so the model could just as well be

```
. regress y ... age age1_5 sex#c.age sex#c.age1_5 ...
```

Let’s assume you have fit one of these two models. On any subsequent `margins` command where you leave `age` free to vary, there will be no issue. You can type

```
. margins female
```
and results will be correct. Issues arise when you attempt to fix age at predetermined values. The following would produce incorrect results:

```
  . margins female, at(age=20)
```

The results would be incorrect because they leave age1 free to vary, and, logically, fixing age implies that age1 should also be fixed. Because we were unable to state the relationship between age and age1 using the factor-variable notation, margins does not know to fix age1 at 20. To get the correct results, you must fix the value of age1 yourself:

```
  . margins female, at(age=20 age1_5=89.442719)
```

That command produces correct results. In the command, 89.442719 is 201.5.

In summary, when there is a functional relationship between covariates of your model and that functional relationship is not communicated to margins via the factor-variable notation, then it becomes your responsibility to ensure that all variables that are functionally related are set to the appropriate fixed values when any one of them is set to a fixed value.

Concerning 3, we wish to amend our claim that you can calculate margins for anything that predict will produce. We need to add a qualifier. Let us show you an example where the statement is not true. After regress, predict will predict something it calls \( pr(a, b) \), which is the probability \( a \leq y \leq b \). Yet if we attempted to use \( pr() \) with margins after estimation by regress, we would obtain

```
  . margins sex, predict(pr(10,20))
  prediction is a function of possibly stochastic quantities other than e(b)
  r(498);
```

What we should have stated was that you can calculate margins for anything that predict will produce for which all the estimated quantities used in its calculation appear in \( e(V) \), the estimated VCE. \( pr() \) is a function of \( \beta \), the estimated coefficients, and of \( s^2 \), the estimated variance of the residual. regress does not post the variance of the residual variance (sic) in \( e(V) \), or even estimate it, and therefore, \( predict(pr(10,20)) \) cannot be specified with margins after estimation by regress.

It is unlikely that you will ever encounter these kinds of problems because there are so few predictions where the components are not posted to \( e(V) \). If you do encounter the problem, the solution may be to specify nose to suppress the standard-error calculation. If the problem is not with computing the margin, but with computing its standard error, margins will report the result:

```
  . margins sex, predict(pr(10,20)) nose
  (output appears with SEs, tests, and CIs left blank)
```

**Technical note**

Programmers: If you run into this after running an estimation command that you have written, be aware that as of Stata 11, you are supposed to set in \( e(marginsok) \) the list of options allowed with predict that are okay to use with margins. When that list is not set, margins looks for violations of its assumptions and, if it finds any, refuses to proceed.
Estimability of margins

Sometimes margins will report that a margin cannot be estimated:

```
. use http://www.stata-press.com/data/r13/estimability, clear
   (margins estimability)
. regress y sex##group
   (output omitted)
. margins sex
Predictive margins
Number of obs = 69
Model VCE : OLS
Expression : Linear prediction, predict()

Delta-method
     Margin  Std. Err.     t  P>|t|   [95% Conf. Interval]
sex
   male    21  .8500245  24.71    0.000   19.30027   22.69973
   female (.  (not estimable)
```

In the above output, the margin for sex = 0 (male) is estimated, but the margin for sex = 1 (female) is not estimable. This occurs because of empty cells. An empty cell is an interaction of levels of two or more factor variables for which you have no data. In the example, the lack of estimability arises because we have two empty cells:

```
. table sex group

     sex  group
         1   2   3   4   5
male  2   9  27   8   2
female 9   9   3
```

To calculate the marginal mean response for sex = 1, we have no responses to average over for group = 4 and group = 5. We obviously could calculate that mean for the observations that really are sex = 1, but remember, the marginal calculation for sex = 1 treats everyone as if female, and we will thus have 8 and 2 observations for which we have no basis for estimating the response.

There is no solution for this problem unless you are willing to treat the data as if it were balanced and adjust your definition of a margin; see *Balancing in the presence of empty cells*.

Manipulability of tests

Manipulability is a problem that arises with some tests, and in particular, arises with Wald tests. Tests of margins are based on Wald tests, hence our interest. This is a generic issue and not specific to the margins command.

Let’s understand the problem. Consider performing a test of whether some statistic $\phi$ is 0. Whatever the outcome of that test, it would be desirable if the outcome were the same were we to test whether the $\sqrt{\phi}$ were 0, or whether $\phi^2$ were 0, or whether any other monotonic transform of $\phi$ were 0 (for $\phi^2$, we were considering only the positive half of the number line). If a test does not have that property, it is manipulable.

Wald tests are manipulable, and that means the tests produced by margins are manipulable. You can see this for yourself by typing
To compare the results from the two `margins` commands, we added the `df(.)` option to the first one, forcing it to report a $z$ statistic even though a $t$ statistic would have been appropriate in this case. We would prefer if the test against zero produced by `margins`, `df(.)` was equal to the test produced by `margins`, `expression(predict(xb)^2)`. But alas, they produce different results. The first produces $z = 12.93$, and the second produces $z = 12.57$.

Regardless of the example, it is important that you base your tests in the metric where the likelihood surface is most quadratic. For further discussion on manipulability, see `Manipulability` in [R] `predictnl`.

This manipulability is not limited to Wald tests after estimation; you can also see the manipulability of results produced by linear regression just by applying nonlinear transforms to a covariate (Phillips and Park 1988; Gould 1996).

### Using margins after the estimates use command

Assume you fit and used `estimates save` (see [R] `estimates save`) to save the estimation results:

```
. regress y sex##group age c.age#c.age if site==1
. ...
. estimates save mymodel
   (file mymodel.ster saved)
```

Later, perhaps in a different Stata session, you reload the estimation results by typing

```
. estimates use mymodel
```

You plan to use `margins` with the reloaded results. You must remember that `margins` bases its results not only on the current estimation results but also on the current data in memory. Before you can use `margins`, you must reload the dataset on which you fit the model or, if you wish to produce standardized margins, some other dataset.

```
. use mydata, clear
   (data for fitting models)
```

If the dataset you loaded contained the data for standardization, you can stop reading; you know that to produce standardized margins, you need to specify the `noesample` option.

We reloaded the original data and want to produce margins for the estimation sample. In addition to the data, `margins` requires that `e(sample)` be set, as `margins` will remind us:

```
. margins sex
   e(sample) does not identify the estimation sample
   r(322);
```
The best solution is to use `estimates esample` to rebuild `e(sample)`:

```
. estimates esample: y sex group age if site==1
```

If we knew we had no missing values in `y` and the covariates, we could type

```
. estimates esample: if site==1
```

Either way, `margins` would now work:

```
. margins sex
(usual output appears)
```

There is an alternative. We do not recommend it, but we admit that we have used it. Rather than rebuilding `e(sample)`, you can use `margins' noesample` option to tell `margins` to skip using `e(sample)`. You could then specify the appropriate `if` statement (if necessary) to identify the estimation sample:

```
. estimates use mymodel
. use mydata, clear
(data for fitting models)
. margins sex if !missing(y, sex, group age) & site==1, noesample
(usual output appears)
```

In the above, we are not really running on a sample different from the estimation sample; we are merely using `noesample` to fool `margins`, and then we are specifying on the `margins` command the conditions equivalent to re-create `e(sample)`.

If we wish to obtain `vce(unconditional)` results, however, `noesample` will be insufficient. We must also specify the `force` option,

```
. margins sex if !missing(y, sex, group age) & site==1,
> vce(unconditional) noesample force
(usual output appears)
```

Regardless of the approach you choose—resetting `e(sample)` or specifying `noesample` and possibly `force`—make sure you are right. In the `vce(delta)` case, you want to be right to ensure that you obtain the results you want. In the `vce(unconditional)` case, you need to be right because otherwise results will be statistically invalid.

### Syntax of at()

In `at(atspec)`, `atspec` may contain one or more of the following specifications:

- `varlist`
- `(stat) varlist`
- `varname = #`
- `varname = (numlist)`
- `varname = generate(exp)`

where

1. `varnames` must be covariates in the previously fit model (estimation command).
2. Variable names (whether in `varname` or `varlist`) may be continuous variables, factor variables, or specific level variables, such as `age`, `group`, or `3.group`.

3. *varlist* may also be one of three standard lists:
   a. `_all` (all covariates),
   b. `_factor` (all factor-variable covariates), or
   c. `_continuous` (all continuous covariates).

4. Specifications are processed from left to right with latter specifications overriding previous ones.

5. *stat* can be any of the following:

<table>
<thead>
<tr>
<th>stat</th>
<th>Description</th>
<th>Variables allowed</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>asobserved</code></td>
<td>at observed values in the sample (default)</td>
<td>all</td>
</tr>
<tr>
<td><code>mean</code></td>
<td>means (default for <em>varlist</em>)</td>
<td>all</td>
</tr>
<tr>
<td><code>median</code></td>
<td>medians</td>
<td>continuous</td>
</tr>
<tr>
<td><code>p1</code></td>
<td>1st percentile</td>
<td>continuous</td>
</tr>
<tr>
<td><code>p2</code></td>
<td>2nd percentile</td>
<td>continuous</td>
</tr>
<tr>
<td>...</td>
<td>3rd–49th percentiles</td>
<td>continuous</td>
</tr>
<tr>
<td><code>p50</code></td>
<td>50th percentile (same as <em>median</em>)</td>
<td>continuous</td>
</tr>
<tr>
<td>...</td>
<td>51st–97th percentiles</td>
<td>continuous</td>
</tr>
<tr>
<td><code>p98</code></td>
<td>98th percentile</td>
<td>continuous</td>
</tr>
<tr>
<td><code>p99</code></td>
<td>99th percentile</td>
<td>continuous</td>
</tr>
<tr>
<td><code>min</code></td>
<td>minimums</td>
<td>continuous</td>
</tr>
<tr>
<td><code>max</code></td>
<td>maximums</td>
<td>continuous</td>
</tr>
<tr>
<td><code>zero</code></td>
<td>fixed at zero</td>
<td>continuous</td>
</tr>
<tr>
<td><code>base</code></td>
<td>base level</td>
<td>factors</td>
</tr>
<tr>
<td><code>asbalanced</code></td>
<td>all levels equally probable and sum to 1</td>
<td>factors</td>
</tr>
</tbody>
</table>

Any *stat* except *zero*, *base*, and *asbalanced* may be prefixed with an *o* to get the overall statistic—the sample over all *over()* groups. For example, *omean*, *omedian*, and *op25*. Overall statistics differ from their correspondingly named statistics only when the *over()* or *within()* option is specified. When no *stat* is specified, *mean* is assumed.

**Estimation commands that may be used with margins**

`margins` may be used after most estimation commands.

`margins` cannot be used after estimation commands that do not produce full variance matrices, such as *exlogistic* and *expoisson* (see [R] exlogistic and [R] expoisson).

`margins` is all about covariates and cannot be used after estimation commands that do not post the covariates, which eliminates *gmm* (see [R] gmm).

`margins` cannot be used after estimation commands that have an odd data organization, and that excludes *asclogit*, *asmprobit*, *asprobit*, and *nlogit* (see [R] asclogit, [R] asmprobit, [R] asprobit, and [R] nlogit).
Video examples

Introduction to margins, part 1: Categorical variables
Introduction to margins, part 2: Continuous variables
Introduction to margins, part 3: Interactions

Glossary

adjusted mean. A margin when the response is the linear predictor from linear regression, ANOVA, etc. For some authors, adjusting also implies adjusting for unbalanced data. See Obtaining margins of responses and see Obtaining margins as though the data were balanced.

average marginal effect. See marginal effect and average marginal effect.

average partial effect. See partial effect and average partial effect.

conditional margin. A margin when the response is evaluated at fixed values of all the covariates. If any covariates are left to vary, the margin is called a predictive margin.

effect. The effect of \( x \) is the derivative of the response with respect to covariate \( x \), or it is the difference in responses caused by a discrete change in \( x \). Also see marginal effect.

The effect of \( x \) measures the change in the response for a change in \( x \). Derivatives or differences might be reported as elasticities. If \( x \) is continuous, the effect is measured continuously. If \( x \) is a factor, the effect is measured with respect to each level of the factor and may be calculated as a discrete difference or as a continuous change, as measured by the derivative. margins calculates the discrete difference by default and calculates the derivative if the continuous option is specified.

elasticity and semielasticity. The elasticity of \( y \) with respect to \( x \) is \( d(\ln y)/d(\ln x) = (x/y) \times (dy/dx) \), which is approximately equal to the proportional change in \( y \) for a proportional change in \( x \).

The semielasticity of \( y \) with respect to \( x \) is either 1) \( dy/d(\ln x) = x \times (dy/dx) \) or 2) \( d(\ln y)/dx = (1/y) \times (dy/dx) \), which is approximately 1) the change in \( y \) for a proportional change in \( x \) or 2) the proportional change in \( y \) for a change in \( x \).

empty cell. An interaction of levels of two or more factor variables for which you have no data. For instance, you have sex interacted with group in your model, and in your data there are no females in group 1. Empty cells affect which margins can be estimated; see Estimability of margins.

estimability. Estimability concerns whether a margin can be uniquely estimated (identified); see Estimability of margins.

estimated marginal mean. This is one of the few terms that has the same meaning across authors. An estimated marginal mean is a margin assuming the levels of each factor covariate are equally likely (balanced), including interaction terms. This is obtained using margins’ asbalanced option. In addition, there is an alternate definition of estimated marginal mean in which margins involving empty cells are redefined so that they become estimable. This is invoked by margins’ emptycells(reweight) option. See Balancing in the presence of empty cells.

least-squares mean. Synonym for estimated marginal mean.

margin. A statistic calculated from predictions or other statistics of a previously fit model at fixed values of some covariates and averaging or otherwise integrating over the remaining covariates. The prediction or other statistic on which the margin is based is called the response.

If all the covariates are fixed, then the margin is called a conditional margin. If any covariates are left to vary, the margin is called a predictive margin.
In this documentation, we divide margins on the basis of whether the statistic is a response or a derivative of a response; see \textit{Obtaining margins of responses} and \textit{Obtaining margins of derivatives of responses}.

\textbf{marginal effect} and \textbf{average marginal effect}. The marginal effect of $x$ is the \textit{margin} of the \textit{effect} of $x$. The term is popular with social scientists, and because of that, you might think the word \textit{marginal} in marginal effect means derivative because of terms like marginal cost and marginal revenue. Marginal used in that way, however, refers to the derivative of revenue and the derivative of cost; it refers to the numerator, whereas marginal effect refers to the denominator. Moreover, \textit{effect} is already a derivative or difference.

Some researchers interpret marginal in marginal effect to mean instantaneous, and thus a marginal effect is the instantaneous derivative rather than the discrete first-difference, corresponding to \texttt{margins’ continuous option}. Researchers who use marginal in this way refer to the discrete difference calculation of an effect as a partial effect.

Other researchers define marginal effect to be the margin when all covariates are held fixed and the average marginal effect when some covariates are not fixed.

\textbf{out-of-sample prediction}. Predictions made in one dataset using the results from a model fit on another. Sample here refers to the sample on which the model was fit, and out-of-sample refers to the dataset on which the predictions are made.

\textbf{partial effect} and \textbf{average partial effect}. Some authors restrict the term \textit{marginal effect} to mean derivatives and use the term partial effect to denote discrete differences; see \textit{marginal effect and average marginal effect}.

\textbf{population marginal mean}. The theoretical (true) value that is estimated by \textit{estimated marginal mean}.

We avoid this term because it can be confused with the concept of a population in survey statistics, with which the population marginal mean has no connection.

\textbf{posting results, posting margins}. A Stata concept having to do with storing the results from the \texttt{margins} command in \texttt{e()} so that those results can be used as if they were estimation results, thus allowing the subsequent use of postestimation commands, such as \texttt{test}, \texttt{testnl}, \texttt{lincom}, and \texttt{nlcom} (see \texttt{[R] test}, \texttt{[R] testnl}, \texttt{[R] lincom}, and \texttt{[R] nlcom}). This is achieved by specifying \texttt{margins’ post option}. See \texttt{Example 10: Testing margins—contrasts of margins}.

\textbf{predictive margin}. A \textit{margin} in which all the covariates are not fixed. When all covariates are fixed, it is called a \textit{conditional margin}.

\textbf{recycled prediction}. A synonym for \textit{predictive margin}.

\textbf{response}. A prediction or other statistic derived from combining the parameter estimates of a fitted model with data or specified values on covariates. Derivatives of responses are themselves responses. Responses are what we take \textit{margins} of.

\textbf{standardized margin}. The margin calculated on data different from the data used to fit the model. The term standardized is usually reserved for situations in which the alternate population is a reference population, which may be real or artificial, and which is treated as fixed.

\textbf{subpopulation}. A subset of your sample that represents a subset of the population, such as the males in a sample of people. In survey contexts when it is desired to account for sampling of the covariates, standard errors for marginal statistics and effects need to account for both the population and the subpopulation. This is accomplished by specifying the \texttt{vce(unconditional)} option and one of the \texttt{subpop()} or \texttt{over()} options. In fact, the above is allowed even when your data are not \texttt{svyset} because \texttt{vce(unconditional)} implies that the sample represents a population.
Stored results

`margins` stores the following in \textit{r}():

### Scalars

- \texttt{r(N)}: number of observations
- \texttt{r(N_sub)}: subpopulation observations
- \texttt{r(N_clust)}: number of clusters
- \texttt{r(N_psu)}: number of sampled PSUs, survey data only
- \texttt{r(N_strata)}: number of strata, survey data only
- \texttt{r(df_r)}: variance degrees of freedom, survey data only
- \texttt{r(N_poststrata)}: number of post strata, survey data only
- \texttt{r(kMargins)}: number of terms in \textit{marginlist}
- \texttt{r(k_by)}: number of subpopulations
- \texttt{r(k_at)}: number of \texttt{at()} options
- \texttt{r(level)}: confidence level of confidence intervals

### Macros

- \texttt{r(cmd)}: \texttt{margins}
- \texttt{r(cmdline)}: command as typed
- \texttt{r(est_cmd)}: \texttt{e(cmd)} from original estimation results
- \texttt{r(est_cmdline)}: \texttt{e(cmdline)} from original estimation results
- \texttt{r(title)}: title in output
- \texttt{r(subpop)}: \texttt{subspec} from \texttt{subpop()}
- \texttt{r(model_vce)}: \texttt{vcetype} from estimation command
- \texttt{r(model_vcetype)}: Std. Err. title from estimation command
- \texttt{r(vce)}: \texttt{vcetype} specified in \texttt{vce()}
- \texttt{r(vcetype)}: title used to label Std. Err.
- \texttt{r(clustvar)}: name of cluster variable
- \texttt{r(margins)}: \textit{marginlist}
- \texttt{r(predict_label)}: label from \texttt{predict()}
- \texttt{r(expression)}: response expression
- \texttt{r(xvars)}: \texttt{varlist} from \texttt{dydx()}, \texttt{dyex()}, \texttt{eydx()}, or \texttt{eyex()}
- \texttt{r(derivatives)}: \texttt{“,”, “dy/dx”, “dy/ex”, “ey/dx”, “ey/ex”}
- \texttt{r(over)}: \texttt{varlist} from \texttt{over()}
- \texttt{r(within)}: \texttt{varlist} from \texttt{within()}
- \texttt{r(by)}: union of \texttt{r(over)} and \texttt{r(within)} lists
- \texttt{r(by#)}: interaction notation identifying the \texttt{#}th subpopulation
- \texttt{r(atstats#)}: the \texttt{#}th \texttt{at()} specification
- \texttt{r(emptycells)}: \texttt{empspec} from \texttt{emptycells()}
- \texttt{r(mcompare)}: \texttt{method} from \texttt{mcompare()}
- \texttt{r(mcadjustall)}: \texttt{adjustall} or \texttt{empty}

### Matrices

- \texttt{r(b)}: estimates
- \texttt{r(V)}: variance–covariance matrix of the estimates
- \texttt{r(Jacobian)}: Jacobian matrix
- \texttt{r(_N)}: sample size corresponding to each margin estimate
- \texttt{r(at)}: matrix of values from the \texttt{at()} options
- \texttt{r(chainrule)}: chainrule information from the fitted model
- \texttt{r(error)}: margin estimability codes;
  - 0 means estimable,
  - 8 means not estimable
- \texttt{r(table)}: matrix containing the margins with their standard errors, test statistics, \textit{p}-values, and confidence intervals
Margins with the post option also stores the following in e():

Scalars
- `e(N)`: number of observations
- `e(N_sub)`: subpopulation observations
- `e(N_clust)`: number of clusters
- `e(N_psu)`: number of sampled PSUs, survey data only
- `e(N_strata)`: number of strata, survey data only
- `e(df_r)`: variance degrees of freedom, survey data only
- `e(N_poststrata)`: number of post strata, survey data only
- `e(k_margins)`: number of terms in `marginlist`
- `e(k_by)`: number of subpopulations
- `e(k_at)`: number of `at()` options

Macros
- `e(cmd)`: `margins`
- `e(cmdline)`: command as typed
- `e(est_cmd)`: `e(cmd)` from original estimation results
- `e(est_cmdline)`: `e(cmdline)` from original estimation results
- `e(title)`: title in estimation output
- `e(subpop)`: `subspec` from `subpop()`
- `e(model_vce)`: `vcetype` from estimation command
- `e(model_vcetype)`: Std. Err. title from estimation command
- `e(vce)`: `vcetype` specified in `vce()`
- `e(vcetype)`: title used to label Std. Err.
- `e(clustvar)`: name of cluster variable
- `e(margins)`: `marginlist`
- `e(predict_label)`: label from `predict()`
- `e(expression)`: prediction expression
- `e(xvars)`: `varlist` from `dydx()`, `dyex()`, `eydx()`, or `eyex()`
- `e(derivatives)`: “dy/dx”, “dy/ex”, “ey/dx”, “ey/ex”
- `e(over)`: `varlist` from `over()`
- `e(within)`: `varlist` from `within()`
- `e(by)`: union of `r(over)` and `r(within)` lists
- `e(by#)`: interaction notation identifying the #th subpopulation
- `e(atstats#)`: the #th `at()` specification
- `e(emptycells)`: `empspec` from `emptycells()`
- `e(mcmethod)`: `method` from `mcompare()`
- `e(mcadjustall)`: adjustall or empty

Matrices
- `e(b)`: estimates
- `e(V)`: variance–covariance matrix of the estimates
- `e(Jacobian)`: Jacobian matrix
- `e(N)`: sample size corresponding to each margin estimate
- `e(at)`: matrix of values from the `at()` options
- `e(chainrule)`: chainrule information from the fitted model

Functions
- `e(sample)`: marks estimation sample

Methods and formulas

Margins are statistics calculated from predictions of a previously fit model at fixed values of some covariates and averaging or otherwise integrating over the remaining covariates. There are many names for the different statistics that `margins` can compute: estimates marginal means (see Searle, Speed, and Milliken [1980]), predictive margins (see Graubard and Korn [2004]), marginal effects (see Greene [2012]), and average marginal/partial effects (see Wooldridge [2010] and Bartus [2005]).
Methods and formulas are presented under the following headings:

**Notation**
- Marginal effects
- Fixing covariates and balancing factors
- Estimable functions
- Standard errors conditional on the covariates
- Unconditional standard errors

**Notation**

Let \( \theta \) be the vector of parameters in the current model fit, let \( z \) be a vector of covariate values, and let \( f(z, \theta) \) be a scalar-valued function returning the value of the predictions of interest. The following table illustrates the parameters and default prediction for several of Stata’s estimation commands.

<table>
<thead>
<tr>
<th>Command</th>
<th>( \theta )</th>
<th>( z )</th>
<th>( f(z, \theta) )</th>
</tr>
</thead>

<td>( \beta, \ln \alpha )</td>
<td>( x )</td>
<td>( e^{x\beta} )</td>
</tr>
</tbody>
</table>

\( \Phi() \) and \( \Phi_2() \) are cumulative distribution functions: \( \Phi() \) for the standard normal distribution and \( \Phi_2() \) for the standard bivariate normal distribution.

**margins** computes estimates of

\[
p(\theta) = \frac{1}{M_{S_p}} \sum_{j=1}^{M} \delta_j(S_p) f(z_j, \theta)
\]

where \( \delta_j(S_p) \) identifies elements within the subpopulation \( S_p \) (for the prediction of interest),

\[
\delta_j(S_p) = \begin{cases} 1, & j \in S_p \\ 0, & j \notin S_p \end{cases}
\]

\( M_{S_p} \) is the subpopulation size,

\[
M_{S_p} = \sum_{j=1}^{M} \delta_j(S_p)
\]

and \( M \) is the population size.

Let \( \hat{\theta} \) be the vector of parameter estimates. Then **margins** estimates \( p(\theta) \) via

\[
\hat{p} = \frac{1}{w} \sum_{j=1}^{N} \delta_j(S_p) w_j f(z_j, \hat{\theta})
\]
where
\[
    w_j = \sum_{j=1}^{N} \delta_j(S_p)w_j
\]
\(\delta_j(S_p)\) indicates whether observation \(j\) is in subpopulation \(S_p\), \(w_j\) is the weight for the \(j\)th observation, and \(N\) is the sample size.

**Marginal effects**

`margins` also computes marginal/partial effects. For the marginal effect of continuous covariate \(x\), `margins` computes
\[
    \hat{p} = \frac{1}{w} \sum_{j=1}^{N} \delta_j(S_p)w_j h(z_j, \hat{\theta})
\]
where
\[
    h(z, \theta) = \frac{\partial f(z, \theta)}{\partial x}
\]
The marginal effect for level \(k\) of factor variable \(A\) is the simple contrast (a.k.a. difference) comparing its margin with the margin at the base level.
\[
    h(z, \theta) = f(z, \theta|A=k) - f(z, \theta|A=\text{base})
\]

**Fixing covariates and balancing factors**

`margins` controls the values in each \(z\) vector through the `marginlist`, the `at()` option, the `atmeans` option, and the `asbalanced` and `emptycells()` options. Suppose \(z\) is composed of the elements from the equation specification
\[
    A##B x
\]
where \(A\) is a factor variable with \(a\) levels, \(B\) is a factor variable with \(b\) levels, and \(x\) is a continuous covariate. To simplify the notation for this discussion, assume the levels of \(A\) and \(B\) start with 1 and are contiguous. Then
\[
    z = (A_1, \ldots, A_a, B_1, \ldots, B_b, A_1B_1, A_1B_2, \ldots, A_aB_b, x, 1)
\]
where \(A_i\), \(B_j\), and \(A_iB_j\) represent the indicator values for the factor variables \(A\) and \(B\) and the interaction \(A#B\).

When factor \(A\) is in the `marginlist`, `margins` replaces \(A\) with \(i\) and then computes the mean of the subsequent prediction, for \(i = 1, \ldots, a\). When the interaction term \(A#B\) is in the `marginlist`, `margins` replaces \(A\) with \(i\) and \(B\) with \(j\), and then computes the mean of the subsequent prediction, for all combinations of \(i = 1, \ldots, a\) and \(j = 1, \ldots, b\).
The `at()` option sets model covariates to fixed values. For example, `at(x=15)` causes `margins` to temporarily set `x` to 15 for each observation in the dataset before computing any predictions. Similarly, `at((median) x)` causes `margins` to temporarily set `x` to the median of `x` using the current dataset.

When factor variable `A` is specified as `asbalanced`, `margins` sets each `A_i` to `1/a`. Thus each `z` vector will look like

\[ z = (1/a, \ldots, 1/a, B, B/a, B/a, \ldots, x, 1) \]

If `B` is also specified as `asbalanced`, then each `B_j` is set to `1/b`, and each `z` vector will look like

\[ z = (1/a, \ldots, 1/a, 1/b, \ldots, 1/b, 1/ab, 1/ab, \ldots, 1/ab, x, 1) \]

If `emptycells(reweight)` is also specified, then `margins` uses a different balancing weight for each element of `z`, depending on how many empty cells the element is associated with. Let \( \delta_{ij} \) indicate that the `ij`th cell of `A#B` was observed in the estimation sample.

\[ \delta_{ij} = \begin{cases} 0, & \text{if } A = i \text{ and } B = j \text{ was an empty cell} \\ 1, & \text{otherwise} \end{cases} \]

For the grand margin, the affected elements of `z` and their corresponding balancing weights are

\[ A_i = \frac{\sum_j \delta_{ij}}{\sum_k \sum_j \delta_{kj}} \]

\[ B_j = \frac{\sum_i \delta_{ij}}{\sum_i \sum_k \delta_{ik}} \]

\[ A_i B_j = \frac{\delta_{ij}}{\sum_k \sum_l \delta_{kl}} \]

For the `j`th margin of `B`, the affected elements of `z` and their corresponding balancing weights are

\[ A_i = \frac{\delta_{ij}}{\sum_k \delta_{kj}} \]

\[ B_l = \begin{cases} 1, & \text{if } l = j \text{ and not all } \delta_{ij} \text{ are zero} \\ 0, & \text{otherwise} \end{cases} \]

\[ A_i B_l = \frac{\delta_{il}}{\sum_k \delta_{kl}} B_l \]
Estimable functions

The fundamental idea behind estimable functions is clearly defined in the statistical literature for linear models; see Searle (1971). Assume that we are working with the following linear model:

\[ y = Xb + e \]

where \( y \) is an \( N \times 1 \) vector of responses, \( X \) is an \( N \times p \) matrix of covariate values, \( b \) is a \( p \times 1 \) vector of coefficients, and \( e \) is a vector of random errors. Assuming a constant variance for the random errors, the normal equations for the least-squares estimator, \( \hat{b} \), are

\[ X'X\hat{b} = X'y \]

When \( X \) is not of full column rank, we will need a generalized inverse (g-inverse) of \( X'X \) to solve for \( \hat{b} \). Let \( G \) be a g-inverse of \( X'X \).

Searle (1971) defines a linear function of the parameters as \textit{estimable} if it is identically equal to some linear function of the expected values of the \( y \) vector. Let \( H = GX'X \). Then this definition simplifies to the following rule:

\( zb \) is estimable if \( z = zH \)

\textit{margins} generalizes this to nonlinear functions by assuming the prediction function \( f(z, \theta) \) is a function of one or more of the linear predictions from the equations in the model that \( \theta \) represents.

\[ f(z, \theta) = h(z_1\beta_1, z_2\beta_2, \ldots, z_k\beta_k) \]

\( z_i\beta_i \) is considered estimable if \( z_i = z_iH_i \), where \( H_i = G_iX'_iX_i \), \( G_i \) is a g-inverse for \( X'_iX_i \), and \( X_i \) is the matrix of covariates from the \( i \)th equation of the fitted model. \textit{margins} considers \( p(\theta) \) to be estimable if every \( z_i\beta_i \) is estimable.

Standard errors conditional on the covariates

By default, \textit{margins} uses the delta method to estimate the variance of \( \hat{p} \).

\[ \hat{\text{var}}(\hat{p} | z) = v'Vv \]

where \( V \) is a variance estimate for \( \hat{\theta} \) and

\[ v = \left. \frac{\partial \hat{p}}{\partial \theta} \right|_{\theta = \hat{\theta}} \]

This variance estimate is conditional on the \( z \) vectors used to compute the marginalized predictions.
Unconditional standard errors

_margins_ with the _vce(unconditional)_ option uses linearization to estimate the unconditional variance of \( \hat{\theta} \). Linearization uses the variance estimator for the total of a score variable for \( \hat{p} \) as an approximate estimator for \( \text{Var}(\hat{p}) \); see [SVY] variance estimation. _margins_ requires that the model was fit using some form of linearized variance estimator and that _predict, scores_ computes the appropriate score values for the linearized variance estimator.

The score for \( \hat{p} \) from the \( j \)th observation is given by

\[
s_j = \frac{\partial \hat{p}}{\partial w_j} = -\frac{\delta_j(S_p)}{w.} \hat{p} + \frac{\delta_j(S_p)}{w.} f(z_j, \hat{\theta}) + \frac{1}{w.} \sum_{i=1}^{N} \delta_i(S_p)w_i \frac{\partial f(z_i, \hat{\theta})}{\partial w_j}
\]

The remaining partial derivative can be decomposed using the chain rule.

\[
\frac{\partial f(z_i, \hat{\theta})}{\partial w_j} = \left( \frac{\partial f(z_i, \theta)}{\partial \theta} \Bigg|_{\theta=\hat{\theta}} \right) \left( \frac{\partial \hat{\theta}}{\partial w_j} \right)'
\]

This is the inner product of two vectors, the second of which is not a function of the \( i \) index. Thus the score is

\[
s_j = -\frac{\delta_j(S_p)}{w.} \hat{p} + \frac{\delta_j(S_p)}{w.} f(z_j, \hat{\theta}) + \left( \frac{\partial \hat{p}}{\partial \theta} \Bigg|_{\theta=\hat{\theta}} \right) \left( \frac{\partial \hat{\theta}}{\partial w_j} \right)'
\]

If \( \hat{\theta} \) was derived from a system of equations (such as in linear regression or maximum likelihood estimation), then \( \hat{\theta} \) is the solution to

\[
G(\theta) = \sum_{j=1}^{N} \delta_j(S_m)w_j g(\theta, y_j, x_j) = 0
\]

where \( S_m \) identifies the subpopulation used to fit the model, \( g() \) is the model’s gradient function, and \( y_j \) and \( x_j \) are the values of the dependent and independent variables for the \( j \)th observation. We can use linearization to derive a first-order approximation for \( \frac{\partial \hat{\theta}}{\partial w_j} \).

\[
G(\hat{\theta}) \approx G(\theta_0) + \frac{\partial G(\theta)}{\partial \theta} \bigg|_{\theta=\theta_0} (\hat{\theta} - \theta_0)
\]

Let \( H \) be the Hessian matrix

\[
H = \frac{\partial G(\theta)}{\partial \theta} \bigg|_{\theta=\theta_0}
\]

Then

\[
\hat{\theta} \approx \theta_0 + (-H)^{-1} G(\theta_0)
\]
and

$$\frac{\partial \hat{\theta}}{\partial w_j} \approx (-H)^{-1} \frac{\partial G(\theta)}{\partial w_j} \bigg|_{\theta = \hat{\theta}} = (-H)^{-1} \delta_j(S_m)g(\hat{\theta}, y_j, x_j)$$

The computed value of the score for $\hat{p}$ for the $j$th observation is

$$s_j = v'u_j$$

where

$$v = \begin{bmatrix} -\frac{\hat{p}}{w} \\ 1 \\ \frac{\partial \hat{p}}{\partial \theta}(-H)^{-1} \end{bmatrix}$$

and

$$u_j = \begin{bmatrix} \delta_j(S_p) \\ \delta_j(S_p)f(z_j, \hat{\theta}) \\ \delta_j(S_m)g(\hat{\theta}, y_j, x_j) \end{bmatrix}$$

Thus the variance estimate for $\hat{p}$ is

$$\hat{\text{Var}}(\hat{p}) = v'\hat{\text{Var}}(U)v$$

where

$$\hat{U} = \sum_{j=1}^{N} w_j u_j$$

margins uses the model-based variance estimates for $(-H)^{-1}$ and the scores from predict for $g(\hat{\theta}, y_j, x_j)$.

Remarks and examples

Continuing with the example from Example 8: Margins of interactions in [R] margins, we use the dataset and reestimate the logistic model of outcome:

. use http://www.stata-press.com/data/r13/margex
  (Artificial data for margins)
. logistic outcome sex##group age
  (output omitted)
We then estimate the margins for males and females and post the margins as estimation results with a full VCE.

```
margins sex, post
Predictive margins
Model VCE : OIM
Expression : Pr(outcome), predict()
```

| sex   | Margin | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|-------|--------|-----------|------|------|----------------------|
| male  | .1600644 | .0125653 | 12.74 | 0.000 | .1354368 .184692 |
| female| .1966902 | .0100043 | 19.66 | 0.000 | .1770821 .2162983 |

We can now use `nlcom` (see [R] `nlcom`) to estimate a risk ratio of females to males using the average probabilities for females and males posted by `margins`:

```
nlcom (risk_ratio: _b[1.sex] / _b[0.sex])
risk_ratio: _b[1.sex] / _b[0.sex]
```

| Coef.  | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|--------|-----------|------|------|----------------------|
| risk_ratio | 1.228819 | .1149538 | 10.69 | 0.000 | 1.003514 1.454124 |

We could similarly estimate the average risk difference between females and males:

```
nlcom (risk_diff: _b[1.sex] - _b[0.sex])
risk_diff: _b[1.sex] - _b[0.sex]
```

| Coef.  | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|--------|-----------|------|------|----------------------|
| risk_diff | .0366258 | .0160632 | 2.28 | 0.023 | .0051425 .068109 |

### Syntax

```plaintext
margins [marginlist] [if] [in] [weight] [ , contrast margins_options ]
margins [marginlist] [if] [in] [weight] [ , contrast(suboptions) margins_options ]
```

where `marginlist` is a list of factor variables or interactions that appear in the current estimation results. The variables may be typed with or without contrast operators, and you may use any factor-variable syntax:

- . margins sex##group, contrast
- . margins sex##g.group, contrast
- . margins sex@group, contrast

See the operators (op.) table in [R] contrast for the list of contrast operators. Contrast operators may also be specified on the variables in margins’ over() and within() options to perform contrasts across the levels of those variables.

See [R] margins for the available margins_options.

#### suboptions

Statistics > Postestimation > Contrasts of margins

Description

`margins` with the `contrast` option or with contrast operators performs contrasts of margins. This extends the capabilities of `contrast` to any of the nonlinear responses, predictive margins, or other margins that can be estimated by `margins`.

Suboptions

- **Overall** specifies that a joint hypothesis test over all terms be performed.
- **Lincom** specifies that user-defined contrasts be treated as linear combinations. The default is to require that all user-defined contrasts sum to zero. (Summing to zero is part of the definition of a contrast.)
- **Atcontrast**(`op[_at]`) specifies that the `op` contrast operator be applied to the groups defined by the `at()` option(s). The default behavior, by comparison, is to perform tests and contrasts within the groups defined by the `at()` option(s).
  
  See example 6 in *Remarks and examples*.
- **Atjoint** specifies that joint tests be performed across all groups defined by the `at()` option. The default behavior, by comparison, is to perform contrasts and tests within each group.
  
  See example 5 in *Remarks and examples*.
- **Overjoint** specifies how unoperated variables in the `over()` option are treated.
  
  Each variable in the `over()` option may be specified either with or without a contrast operator. For contrast-operated variables, the specified contrast comparisons are always performed.
  
  **Overjoint** specifies that joint tests be performed across all levels of the unoperated variables. The default behavior, by comparison, is to perform contrasts and tests within each combination of levels of the unoperated variables.
  
  See example 3 in *Remarks and examples*.
- **Withinjoint** specifies how unoperated variables in the `within()` option are treated.
  
  Each variable in the `within()` option may be specified either with or without a contrast operator. For contrast-operated variables, the specified contrast comparisons are always performed.
  
  **Withinjoint** specifies that joint tests be performed across all levels of the unoperated variables. The default behavior, by comparison, is to perform contrasts and tests within each combination of levels of the unoperated variables.
  
  See example 4 in *Remarks and examples*.
- **Marginswithin** specifies how unoperated variables in `marginlist` are treated.
  
  Each variable in `marginlist` may be specified either with or without a contrast operator. For contrast-operated variables, the specified contrast comparisons are always performed.
  
  **Marginswithin** specifies that contrasts and tests be performed within each combination of levels of the unoperated variables. The default behavior, by comparison, is to perform joint tests across all levels of the unoperated variables.
  
  See example 4 in *Remarks and examples*. 
cieffects specifies that a table containing a confidence interval for each individual contrast be reported.
pveffects specifies that a table containing a \( p \)-value for each individual contrast be reported.
effects specifies that a single table containing a confidence interval and \( p \)-value for each individual contrast be reported.

nowald suppresses the table of Wald tests.
noatlevels indicates that only the overall Wald test be reported for each term containing within or nested (\( @ \) or \( | \) ) operators.

nosvyadjust is for use with \( svy \) estimation commands. It specifies that the Wald test be carried out without the default adjustment for the design degrees of freedom. That is to say the test is carried out as \( W/k \sim F(k,d) \) rather than as \( (d-k+1)W/(kd) \sim F(k,d-k+1) \), where \( k \) is the dimension of the test and \( d \) is the total number of sampled PSUs minus the total number of strata.

## Remarks and examples

Remarks are presented under the following headings:

- Contrasts of margins
- Contrasts and the over() option
  - The overjoint suboption
  - The marginswithin suboption
- Contrasts and the at() option
- Estimating treatment effects with margins
- Conclusion

### Contrasts of margins

#### Example 1

Estimating contrasts of margins is as easy as adding a contrast operator to the variable name. Let’s review Example 2: A simple case after logistic of [R] margins. Variable sex is coded 0 for males and 1 for females.

```
. use http://www.stata-press.com/data/r13/margex
. logistic outcome i.sex i.group
(output omitted)
. margins sex
Predictive margins Number of obs = 3000
Model VCE : OIM
Expression : Pr(outcome), predict(

<table>
<thead>
<tr>
<th></th>
<th>Delta-method</th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Margin</td>
<td>Std. Err.</td>
<td>z</td>
<td>P&gt;</td>
<td>z</td>
</tr>
<tr>
<td>sex</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>male</td>
<td>.1286796</td>
<td>.0111424</td>
<td>11.55</td>
<td>0.000</td>
<td>.106841</td>
</tr>
<tr>
<td>female</td>
<td>.1905087</td>
<td>.0089719</td>
<td>21.23</td>
<td>0.000</td>
<td>.1729241</td>
</tr>
</tbody>
</table>
```

The first margin, 0.13, is the average probability of a positive outcome, treating everyone as if they were male. The second margin, 0.19, is the average probability of a positive outcome, treating everyone as if they were female. We can compare females with males by rerunning margins and adding a contrast operator:
. margins r.sex
Contrasts of predictive margins
Model VCE : OIM
Expression : Pr(outcome), predict()

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>sex</td>
<td>1</td>
<td>16.61</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Delta-method
Contrast Std. Err. [95% Conf. Interval]

<p>| | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>sex (female vs male)</td>
<td>0.0618291</td>
<td>0.0151719</td>
<td>0.0320927, 0.0915656</td>
</tr>
</tbody>
</table>

The r. prefix for sex is the reference-category contrast operator—see [R] contrast. (The default reference category is zero, the lowest value of sex.) Contrast operators in a marginlist work just as they do in the termlist of a contrast command.

The contrast estimate of 0.06 says that unconditional on group, females on average are about 6% more likely than males to have a positive outcome. The chi-squared statistic of 16.61 shows that the contrast is significantly different from zero.

You may be surprised that we did not need to include the contrast option to estimate our contrast. If we had included the option, our output would not have changed:

. margins sex group, contrast
Contrasts of predictive margins
Model VCE : OIM
Expression : Pr(outcome), predict()

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>sex</td>
<td>1</td>
<td>16.61</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Delta-method
Contrast Std. Err. [95% Conf. Interval]

<p>| | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>sex (female vs male)</td>
<td>0.0618291</td>
<td>0.0151719</td>
<td>0.0320927, 0.0915656</td>
</tr>
</tbody>
</table>

The contrast option is useful mostly for its suboptions, which control the output and how contrasts are estimated in more complicated situations. But contrast may be specified on its own (without contrast operators or suboptions) if we do not need estimates or confidence intervals:

. margins sex group
Contrasts of predictive margins
Model VCE : OIM
Expression : Pr(outcome), predict()

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>sex</td>
<td>1</td>
<td>16.61</td>
<td>0.0000</td>
</tr>
<tr>
<td>group</td>
<td>2</td>
<td>225.76</td>
<td>0.0000</td>
</tr>
</tbody>
</table>
Each chi-squared statistic is a joint test of constituent contrasts. The test for group has two degrees of freedom because group has three levels.

Contrasts and the over() option

Example 2

It is common to estimate margins at combinations of factor levels, and margins, contrast includes several suboptions for contrasting such margins. Let’s fit a model with two categorical predictors and their interaction:

```
.logistic outcome agegroup##group
```

| outcome | Odds Ratio | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|---------|-----------|-----------|-------|-----|----------------------|
| agegroup  |           |           |       |     |                      |
| 30-39    | 3.54191   | 2.226951  | 2.01  | 0.044 | 1.032882 - 12.14576 |
| 40+      | 16.23351  | 9.61188   | 4.71  | 0.000 | 5.086452 - 51.80955 |
| group    |           |           |       |     |                      |

Each of agegroup and group has three levels. To compare each age group with the reference category on the probability scale, we can again use margins with the r. contrast operator.
. margins r.agegroup
Contrasts of predictive margins
Model VCE : OIM
Expression : Pr(outcome), predict()

<table>
<thead>
<tr>
<th></th>

Our model includes an interaction, though, so it would be nice to estimate the contrasts separately for each value of group. We need the `over()` option:

. margins r.agegroup, over(group)
Contrasts of predictive margins
Model VCE : OIM
Expression : Pr(outcome), predict()
over : group

<table>
<thead>
<tr>
<th></th>

</table>

The effect of `agegroup` appears to be greatest for the first level of `group`.

Including a variable in the `over()` option is not equivalent to including the variable in the main `marginlist`. The variables in the `marginlist` are manipulated in the analysis, so that we can measure, for example, the effect of being in age group 3 and not age group 1. (The manipulation could be mimicked by running `replace` and then `predict`, but the manipulations actually performed by `margins` do not
change the data in memory.) The variables in the \texttt{over()} option are not so manipulated—the values of the \texttt{over()} variables are left as they were observed, and the \texttt{marginlist} variables are manipulated separately for each observed \texttt{over()} group. For more information, see \textit{Do not specify marginlist when you mean over()} in \texttt{[R] margins}.

\section*{The overjoint suboption}

\subsection*{Example 3}

Each variable in an \texttt{over()} option may be specified with or without contrast operators. Our option \texttt{over(group)} did not include a contrast operator, so \texttt{margins} estimated the contrasts separately for each level of \texttt{group}. If we had instead specified \texttt{over(r.group)}, we would have received differences of the contrasts:

\begin{verbatim}
. margins r.agegroup, over(r.group)
Contrasts of predictive margins
Model VCE : OIM
Expression : Pr(outcome), predict()
over : group

|       | df |   chi2 |   P>|chi2 |
|-------|----|--------|-------|
| group#agegroup |     |        |       |
| (2 vs 1) (30-39 vs 20-29) | 1  | 3.55   | 0.0596|
| (2 vs 1) (40+ vs 20-29) | 1  | 33.17  | 0.0000|
| (3 vs 1) (30-39 vs 20-29) | 1  | 2.86   | 0.0906|
| (3 vs 1) (40+ vs 20-29) | 1  | 79.36  | 0.0000|
| Joint | 4  | 83.88  | 0.0000|

<table>
<thead>
<tr>
<th></th>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>group#agegroup</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(2 vs 1) (30-39 vs 20-29)</td>
<td>-0.0653</td>
<td>.0346921</td>
<td>-.133346 -.0026445</td>
</tr>
<tr>
<td>(2 vs 1) (40+ vs 20-29)</td>
<td>-.19069</td>
<td>.0331121</td>
<td>-.25559 -.1257931</td>
</tr>
<tr>
<td>(3 vs 1) (30-39 vs 20-29)</td>
<td>-.05762</td>
<td>.0340551</td>
<td>-.1243719 .0091216</td>
</tr>
<tr>
<td>(3 vs 1) (40+ vs 20-29)</td>
<td>-.29775</td>
<td>.0334237</td>
<td>-.3632572 -.2322385</td>
</tr>
</tbody>
</table>
\end{verbatim}

The contrasts are double differences: the estimate of $-0.19$, for example, says that the difference in the probability of success between age group 3 and age group 1 is smaller in group 2 than in group 1. We can jointly test pairs of the double differences with the \texttt{overjoint} suboption:

\begin{verbatim}
. margins r.agegroup, over(group) contrast(overjoint)
Contrasts of predictive margins
Model VCE : OIM
Expression : Pr(outcome), predict()
over : group

|       | df |   chi2 |   P>|chi2 |
|-------|----|--------|-------|
| group#agegroup |     |        |       |
| (joint) (30-39 vs 20-29) | 2  | 3.62   | 0.1641|
| (joint) (40+ vs 20-29) | 2  | 79.45  | 0.0000|
| Joint | 4  | 83.88  | 0.0000|
\end{verbatim}
The contrast(overjoint) option overrides the default behavior of over() and requests joint tests over the levels of the unoperated variable group. The chi-squared statistic of 3.62 tests that the first and third contrasts from the previous table are jointly zero. The chi-squared statistic of 79.45 jointly tests the other pair of contrasts.

The marginswithin suboption

Example 4

Another suboption that may usefully be combined with over() is marginswithin. marginswithin requests that contrasts be performed within the levels of unoperated variables in the main marginlist, instead of performing them jointly across the levels. marginswithin affects only unoperated variables because contrast operators take precedence over suboptions.

Let’s first look at the default behavior, which occurs when marginswithin is not specified:

```
. margins agegroup, over(r.group) contrast(effects)
```

Contrasts of predictive margins
Model VCE   : OIM
Expression  : Pr(outcome), predict()
over        : group

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>group#agegroup</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(2 vs 1) (joint)</td>
<td>2</td>
<td>33.94</td>
<td>0.0000</td>
</tr>
<tr>
<td>(3 vs 1) (joint)</td>
<td>2</td>
<td>83.38</td>
<td>0.0000</td>
</tr>
<tr>
<td>Joint</td>
<td>4</td>
<td>83.88</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

|                  | Contrast | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|------------------|----------|-----------|-------|------|---------------------|
| group#agegroup   |          |           |       |      |                     |
| (2 vs 1) (30-39 vs base) | -0.0653508 | 0.0346921 | -1.88 | 0.060 | -.133346 -.0026445 |
| (2 vs 1) (40+ vs base) | -0.1906915 | 0.0331121 | -5.76 | 0.000 | -.25559 -.1257931 |
| (3 vs 1) (30-39 vs base) | -0.0576251 | 0.0340551 | -1.69 | 0.091 | -.1243719 -.0091216 |
| (3 vs 1) (40+ vs base) | -0.2977479 | 0.0334237 | -8.91 | 0.000 | -.3632572 -.2322385 |

Here agegroup in the main marginlist is an unoperated variable, so margins by default performs joint tests across the levels of agegroup: the chi-squared statistic of 33.94, for example, jointly tests whether the first two contrast estimates in the lower table differ significantly from zero.
When we specify `margins within`, the contrasts will instead be performed within the levels of `agegroup`:

```stata
    . margins agegroup, over(r.group) contrast(marginswithin effects)
```

Contrasts of predictive margins

Expression: Pr(outcome), predict()

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>group@agegroup</strong></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(2 vs 1) 20-29</td>
<td>1</td>
<td>0.06</td>
<td>0.7991</td>
</tr>
<tr>
<td>(2 vs 1) 30-39</td>
<td>1</td>
<td>7.55</td>
<td>0.0060</td>
</tr>
<tr>
<td>(2 vs 1) 40+</td>
<td>1</td>
<td>68.39</td>
<td>0.0000</td>
</tr>
<tr>
<td>(3 vs 1) 20-29</td>
<td>1</td>
<td>1.80</td>
<td>0.1798</td>
</tr>
<tr>
<td>(3 vs 1) 30-39</td>
<td>1</td>
<td>10.47</td>
<td>0.0012</td>
</tr>
<tr>
<td>(3 vs 1) 40+</td>
<td>1</td>
<td>159.89</td>
<td>0.0000</td>
</tr>
<tr>
<td>Joint</td>
<td>6</td>
<td>186.87</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Joint tests in the top table have been replaced by one-degree-of-freedom tests, one for each combination of the two reference comparisons and three levels of `agegroup`. The reference-category contrasts for `group` have been performed within levels of `agegroup`.

The `at()` option

Example 5

The `at()` option of `margins` is used to set predictors to particular values. When `at()` is used, contrasts are by default performed within each `at()` level:
. margins r.agegroup, at(group=(1/3))

Contrasts of adjusted predictions
Model VCE : OIM
Expression : Pr(outcome), predict()
1._at : group = 1
2._at : group = 2
3._at : group = 3

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegroup@_at</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(30-39 vs 20-29) 1</td>
<td>1</td>
<td>6.94</td>
<td>0.0084</td>
</tr>
<tr>
<td>(30-39 vs 20-29) 2</td>
<td>1</td>
<td>1.18</td>
<td>0.2783</td>

<td>0.0783</td>
</tr>
<tr>
<td>(40+ vs 20-29) 1</td>
<td>1</td>
<td>173.42</td>
<td>0.0000</td>
</tr>
<tr>
<td>(40+ vs 20-29) 2</td>
<td>1</td>
<td>57.77</td>
<td>0.0000</td>
</tr>
<tr>
<td>(40+ vs 20-29) 3</td>
<td>1</td>
<td>5.12</td>
<td>0.0236</td>
</tr>
<tr>
<td>Joint</td>
<td>6</td>
<td>266.84</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegroup@_at</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Joint</td>
<td>4</td>
<td>83.88</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Joint

Our option at(group=(1/3)) manipulates the values of group and is therefore not equivalent to over(group). We see that the reference-category contrasts for agegroup have been performed within each at() level. For a similar example that uses the ._at operator instead of the at() option, see *Contrasts of at() groups—discrete effects* in [R] marginsplot.

The default within behavior of at() may be changed to joint behavior with the atjoint suboption:

. margins r.agegroup, at(group=(1/3)) contrast(atjoint)

Contrasts of adjusted predictions
Model VCE : OIM
Expression : Pr(outcome), predict()
1._at : group = 1
2._at : group = 2
3._at : group = 3

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>_at#agegroup</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(joint) (30-39 vs 20-29)</td>
<td>2</td>
<td>3.62</td>
<td>0.1641</td>
</tr>
<tr>
<td>(joint) (40+ vs 20-29)</td>
<td>2</td>
<td>79.45</td>
<td>0.0000</td>
</tr>
<tr>
<td>Joint</td>
<td>4</td>
<td>83.88</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Now the tests are performed jointly over the levels of group, the at() variable. The atjoint suboption is the analogue for at() of the overjoint suboption from example 3.
Example 6

What if we would like to apply a contrast operator, like \( r \), to the \( \text{at()} \) levels? It is not possible to specify the operator inside the \( \text{at()} \) option. Instead, we need a new suboption, \( \text{atcontrast()} \):

\[
. \text{margins \( r.\text{agegroup}, \text{at}(\text{group}=(1/3)) \text{ contrast(\text{atcontrast}(r))} \)}
\]

Contrasts of adjusted predictions
Model VCE : OIM
Expression : \( \text{Pr(outcome)}, \text{predict()} \)

<table>
<thead>
<tr>
<th>_at</th>
<th>group</th>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>1._at</td>
<td>group</td>
<td>1</td>
<td>3.55</td>
<td>0.0596</td>
</tr>
<tr>
<td>2._at</td>
<td>group</td>
<td>1</td>
<td>33.17</td>
<td>0.0000</td>
</tr>
<tr>
<td>3._at</td>
<td>group</td>
<td>1</td>
<td>79.36</td>
<td>0.0000</td>
</tr>
<tr>
<td>Joint</td>
<td></td>
<td>4</td>
<td>83.88</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

When we specify \( \text{contrast(\text{atcontrast}(r))} \), \text{margins} will apply the \( r \) reference-category operator to the levels of \text{group}, the variable specified inside \( \text{at()} \). The default reference category is 1, the lowest level of \text{group}.

Estimating treatment effects with \text{margins}

\text{margins} with the \text{contrast} option can also be used to estimate treatment effects in certain cases. A treatment effect represents the change in an outcome variable that is attributable to a particular event, controlling for all other factors that could affect the outcome. For example, we might want to know how a person’s wage changes as a result of being in a union. Here the outcome variable is the person’s wage, and the “event” is membership in a union. The treatment effect measures the difference in a person’s wage as a result of being or not being in a union once we control for the person’s educational background, level of experience, industry, and other factors.

In fact, Stata has an entire manual dedicated to estimators designed specifically for estimating treatment effects; see the \textit{Stata Treatment-Effects Reference Manual}. Here we show how \text{margins} can be used to estimate treatment effects using the regression-adjustment estimator when the conditional independence assumption is met; see [TE] \texttt{teffects intro}. Regression adjustment simply means that we are going to use a regression model to predict the outcome variable, controlling for treatment status and other characteristics. The conditional independence assumption implies that we have enough variables in our dataset so that once we control for them in our regression model, the outcomes we would obtain with and without treatment are independent of how treatment status is determined.
Example 7: Regression adjustment with a binary treatment variable

`nlsw88.dta` contains women's wages (`wage`) in dollars per hour, a binary variable indicating their union status (`union`), years of experience (`ttl_exp`), and a variable, `grade`, indicating the number of years of schooling completed. We want to know how being in a union (the treatment) affects women's wages. Traditionally, a wage equation of the form

$$\ln(wage_i) = \beta_0 + \beta_1\text{union}_i + \beta_2\text{grade}_i + \beta_3\text{ttl_exp} + \beta_4\text{ttl_exp}^2 + \epsilon_i$$

would be fit. However, there are two shortcomings that we will improve upon. First, to avoid the problem of predicting the level of a log-transformed dependent variable, we will use `poisson` with the `vce(robust)` option to fit an exponential regression model; see Wooldridge (2010, sec. 18.2) for background on this approach. Second, the previous equation implies that factors other than union status have the same impact on wages for both union and nonunion workers. Regression-adjustment estimators allow all the variables to have different impacts depending on the level of the treatment variable, and we can accomplish that here using factor-variable notation. In Stata, we fit our model by typing

```
use http://www.stata-press.com/data/r13/nlsw88
(poisson regression
Number of obs = 1876
Wald chi2(7) = 1047.11
Prob > chi2 = 0.0000
Log pseudolikelihood = -4770.7693
```

| wage | Coef. | Std. Err. | z | P>|z| | [95% Conf. Interval] |
|------|-------|-----------|---|-----|---------------------|
| union | .8638376 | .168233 | 5.13 | 0.000 | .534107 - 1.193568 |
| grade | .0895252 | .0056874 | 15.74 | 0.000 | .0783782 - 1.006722 |
| ttl_exp | .0805737 | .0114534 | 7.03 | 0.000 | .0581255 - 1.03022 |
| c.ttl_exp#c.ttl_exp | -.0015502 | .0004612 | -3.36 | 0.001 | -.0024541 - .0006463 |
| union#c.grade | -.0310298 | .0088259 | -3.52 | 0.000 | -.0483282 - .0137314 |
| union#c.ttl_exp | -.0404226 | .0230113 | -1.76 | 0.079 | -.085524 - .0046788 |
| union#c.ttl_exp#c.ttl_exp | .0011808 | .0008428 | 1.40 | 0.161 | -.0004711 - .0028327 |
| _cons | .017488 | .0893602 | 0.20 | 0.845 | -.1576547 - 1.926308 |
To see how union status affects wages, we can use margins:

```
. margins r.union, vce(unconditional)
```

Contrasts of predictive margins
Expression : Predicted number of events, predict()

|     | df | chi2  | P>|chi2|
|-----|----|-------|-------|
| union | 1  | 26.22 | 0.0000 |

<table>

<td>.1960944</td>
</tr>
</tbody>
</table>

The estimated contrast 1.004 indicates that on average, belonging to a union causes a woman’s wage to be slightly more than a dollar higher than if she were not in the union. This estimated contrast is called the average treatment effect (ATE). Conceptually, we predicted the wage of each woman in the estimation sample assuming she was in a union and obtained the sample mean. We then predicted each woman’s wage assuming she was not in a union and obtained that sample mean. The difference between these two sample means represents the ATE.

We obtain essentially the same results by using teffects ra:

```
. teffects ra (wage c.grade c.ttl_exp##c.ttl_exp, poisson) (union)
```

```
Iteration 0: EE criterion = 2.611e-13
Iteration 1: EE criterion = 1.098e-26
```

```
Number of obs = 1876
```

```
Estimator : regression adjustment
Outcome model : Poisson
```

|-----|-------|-----------|-----|-----|----------------------|
| POmean | union nonunion | 7.346493 | .1096182 | 67.02 | 0.000 | 7.131645 | 7.561341 |

The point estimates of the ATE are identical to those we obtained using margins, though the standard errors differ slightly from those reported by margins. The standard errors from the two estimators are, however, asymptotically equivalent, meaning they would coincide with a sufficiently large dataset. The last statistic in this output table indicates the untreated potential-outcome mean (untreated POM), which is the mean predicted wage assuming each woman did not belong to a union.

If we specify the pomeans option with teffects ra, we can obtain both the treated and the untreated POMs, which represent the predicted mean wages assuming all women were or were not in the union:
Notice that the difference between these two POMs equals 1.004119, which is the ATE we obtained earlier.

In some applications, the average treatment effect of the treated (ATET) is more germane than the ATE. For example, if the untreated subjects in the sample could not possibly receive treatment (perhaps because a medical condition precludes their taking an experimental drug), then considering the counterfactual outcome had those subjects taken the drug may not be relevant. In these cases, the ATET is a better statistic because it measures the effect of the treatment only for those subjects who actually did receive treatment. Like the ATE, the ATET involves computing predicted outcomes for each treatment level, obtaining the sample means, and computing the difference between those two means. Unlike the ATE, however, we only use observations corresponding to treated subjects.

Example 8: Regression adjustment with a binary treatment variable (continued)

Here we calculate the ATET of union membership, first using margins. Because teffects ra overwrote our estimation results, we first quietly refit our poisson model. We then call margins to obtain the ATET:

```
. quietly poisson wage i.union##(c.grade c.ttl_exp##c.ttl_exp), vce(robust)
. margins r.union, subpop(union) vce(unconditional)
```

The key here was specifying the subpop(union) option to restrict margin’s computations to those women who are union members. The results indicate that being in the union causes the union members’ wages to be about 90 cents higher than they would otherwise be.
To replicate these results using `teffects ra`, we include the `atet` option to obtain ATETs:

```
. teffects ra (wage c.grade c.ttl_exp##c.ttl_exp, poisson) (union), atet
```

Iteration 0: EE criterion = 2.611e-13
Iteration 1: EE criterion = 9.324e-27

Treatment-effects estimation

<table>
<thead>
<tr>
<th>Number of obs = 1876</th>
</tr>
</thead>
</table>

**Estimator**: regression adjustment

**Outcome model**: Poisson

**Treatment model**: none

|          | Robust Coef. | Robust Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|----------|--------------|------------------|------|-----|----------------------|
| **ATET** |              |                  |      |     |                      |
| union    |              |                  |      |     |                      |
| (union vs nonunion) |    | .901419 | .2075309 | 4.34 | 0.000 | .4946658 | 1.308172 |
| **POmean** |              |                  |      |     |                      |
| union    |              |                  |      |     |                      |
| nonunion | 7.776417 | .162121 | 47.97 | 0.000 | 7.458665 | 8.094168 |

We obtain the same point estimate of the effect of union status as with `margins`. As before, the standard errors differ slightly between the two estimators, but they are asymptotically equivalent. The output also indicates that among the women who are in a union, their average wage would be $7.78 if they were not in a union.

**Technical note**

One advantage of the ATET over the ATE is that the ATET can be consistently estimated with slightly weaker assumptions than are required to consistently estimate the ATE. See Comparing the ATE and ATET in Remarks and examples of [TE] teffects intro advanced.

Both `margins` and `teffects` can estimate treatment effects using regression adjustment, so which should you use? In addition to regression adjustment, the `teffects` command implements other estimators of treatment effects; some of these estimators possess desirable robustness properties that we cannot replicate using `margins`. Moreover, all the `teffects` estimators use a common syntax and automatically present the estimated treatment effects, whereas we must first fit our own regression model and then call `margins` to obtain the treatment effects.

On the other hand, particularly with the `at()` option, `margins` gives us more flexibility in specifying our scenarios. The `teffects` commands allow us to measure the effect of a single binary or multinomial treatment, but we can have `margins` compute the effects of arbitrary interventions, as we illustrate in the next example.

### Example 9: Interventions involving multiple variables

Suppose we want to see how women’s wages would be affected if we could increase each woman’s education level by one year. That is, we want to measure the treatment effect of an additional year of schooling. We assume that if a woman attains another year of schooling, she cannot simultaneously work. Thus an additional year of education implies her total work experience must decrease by a year. The flexible `at()` option of `margins` allows us to manipulate both variables at once:
. quietly poisson wage i.union##(c.grade c.ttl_exp##c.ttl_exp), vce(robust)
. margins, at((asobserved) _all)
  > at(grade=generate(grade+1) ttl_exp=generate(ttl_exp-1))
  > contrast(atcontrast(r._at))

Contrasts of predictive margins
Model VCE : Robust
Expression : Predicted number of events, predict()

<table>
<thead>
<tr>
<th>df</th>
<th>chi2</th>
<th>P&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>_at</td>
<td>1</td>
<td>58.53</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Delta-method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Contrast</td>
</tr>
<tr>
<td>_at (2 vs 1)</td>
</tr>
</tbody>
</table>

The first at() option instructs margins to obtain predicted wages for all women in the sample using their existing values for grade and ttl_exp and to record the mean of those predictions. The second at() option instructs margins to obtain the mean predicted wage under the counterfactual scenario where each woman’s education level is increased by one year and total work experience is simultaneously decreased by one year. The contrast() option instructs margins to compute the difference between the two means. The output indicates that increasing education by one year, which will necessarily decrease work experience by the same amount, will cause the average wage to increase by about 34 cents per hour, a statistically significant amount.

Conclusion

margins, contrast is a powerful command, and its abundance of suboptions may seem daunting. The suboptions are in the service of only three goals, however. There are three things that margins, contrast can do with a factor variable or a set of at() definitions:

1. Perform contrasts across the levels of the factor or set (as in example 1).
2. Perform a joint test across the levels of the factor or set (as in example 5).
3. Perform other tests and contrasts within each level of the factor or set (as in example 4).

The default behavior for variables specified inside at(), over(), and within() is to perform contrasts within groups; the default behavior for variables in the marginlist is to perform joint tests across groups.
Stored results

`margins, contrast` stores the following additional results in `r()`:

Scalars
- `r(k_terms)` number of terms participating in contrasts

Macros
- `r(cmd)` contrast
- `r(cmd2)` margins
- `r(overall)` overall or empty

Matrices
- `r(L)` matrix of contrasts applied to the margins
- `r(chi2)` vector of $\chi^2$ statistics
- `r(p)` vector of $p$-values corresponding to `r(chi2)`
- `r(df)` vector of degrees of freedom corresponding to `r(p)`

`margins, contrast` with the `post` option also stores the following additional results in `e()`:

Scalars
- `e(k_terms)` number of terms participating in contrasts

Macros
- `e(cmd)` contrast
- `e(cmd2)` margins
- `e(overall)` overall or empty

Matrices
- `e(L)` matrix of contrasts applied to the margins
- `e(chi2)` vector of $\chi^2$ statistics
- `e(p)` vector of $p$-values corresponding to `e(chi2)`
- `e(df)` vector of degrees of freedom corresponding to `e(p)`

Statistics > Postestimation > Pairwise comparisons of margins

Description

margins with the pwcompare option performs pairwise comparisons of margins. margins, pwcompare extends the capabilities of pwcompare to any of the nonlinear responses, predictive margins, or other margins that can be estimated by margins.
Suboptions

cieffects specifies that a table of the pairwise comparisons with their standard errors and confidence intervals be reported. This is the default.

pveffects specifies that a table of the pairwise comparisons with their standard errors, test statistics, and \( p \)-values be reported.

effects specifies that a table of the pairwise comparisons with their standard errors, test statistics, \( p \)-values, and confidence intervals be reported.

cimargins specifies that a table of the margins with their standard errors and confidence intervals be reported.

groups specifies that a table of the margins with their standard errors and group codes be reported. Margins with the same letter in the group code are not significantly different at the specified significance level.

sort specifies that the reported tables be sorted on the margins or contrasts in each term.

Remarks and examples

You should be familiar with the concepts and syntax of both `margins` and `pwcompare` before using the `pwcompare` option of `margins`. These remarks build on those in [R] `margins` and [R] `pwcompare`.

`margins` can perform pairwise comparisons of any of the margins that it estimates.

We begin by fitting a logistic regression model using the NHANES II dataset, ignoring the complex survey nature of the data. Our dependent variable is `highbp`, an indicator for whether a person has high blood pressure. We fit an interacted model including two factor variables representing the region of the country as well as the continuous covariate `bmi`.

```
. use http://www.stata-press.com/data/r13/nhanes2
. logistic highbp region##c.bmi
(output omitted)
```

By default, `margins` will compute the predictive margins of the probability of a positive outcome for each of the terms in `marginlist` after logistic regression. We will margin on `region` so that `margins` will estimate the average predicted probabilities of having high blood pressure conditional on being in each of the four regions and unconditional on BMI. We can specify the `pwcompare` option to obtain all possible pairwise comparisons of these predictive margins:
. margins region, pwcompare
Pairwise comparisons of predictive margins
Model VCE : OIM
Expression : Pr(highbp), predict()

<table>
<thead>
<tr>
<th>Contrast</th>
<th>Delta-method Std. Err.</th>
<th>Unadjusted [95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>MW vs NE</td>
<td>-.0377194 .0133571</td>
<td>-.0638987 -.01154</td>
</tr>
<tr>
<td>S vs NE</td>
<td>-.0156843 .0133986</td>
<td>-.041945 .0108764</td>
</tr>
<tr>
<td>W vs NE</td>
<td>-.006873 .0136595</td>
<td>-.0336451 .019899</td>
</tr>
<tr>
<td>S vs MW</td>
<td>.0220351 .0124564</td>
<td>.0023789 .0464492</td>
</tr>
<tr>
<td>W vs MW</td>
<td>.0308463 .0127366</td>
<td>.0058831 .0558096</td>
</tr>
<tr>
<td>W vs S</td>
<td>.0088112 .0127801</td>
<td>-.0162373 .0338598</td>
</tr>
</tbody>
</table>

This table gives each of the pairwise differences with confidence intervals. We can see that the confidence interval in the row labeled MW vs NE does not include 0. At the 5% level, the predictive margins for the first and second regions, the Northeast and the Midwest, are significantly different. The same is true of the second and fourth regions, the Midwest and the West. With many pairwise comparisons, output in this format can be difficult to sort through. We can organize it by adding the `group` suboption:

. margins region, pwcompare(group)
Pairwise comparisons of predictive margins
Model VCE : OIM
Expression : Pr(highbp), predict()

<table>
<thead>
<tr>
<th>Margin</th>
<th>Delta-method Std. Err.</th>
<th>Unadjusted Groups</th>
</tr>
</thead>
<tbody>
<tr>
<td>NE</td>
<td>.4388358 .010069</td>
<td>B</td>
</tr>
<tr>
<td>MW</td>
<td>.4011164 .0087764</td>
<td>A</td>
</tr>
<tr>
<td>S</td>
<td>.4231516 .0088395</td>
<td>AB</td>
</tr>
<tr>
<td>W</td>
<td>.4319628 .0092301</td>
<td>B</td>
</tr>
</tbody>
</table>

Note: Margins sharing a letter in the group label are not significantly different at the 5% level.

The group output includes the predictive margins for each region and letters denoting margins that are not significantly different from one another. In this case, the Northeast (NE), South (S), and West (W) regions have the letter B in the “Unadjusted Groups” column. The letter B indicates that the average predicted probability for the Northeast region is not significantly different from the average predicted probabilities for the South and West regions at the 5% significance level. The Midwest (MW) region does not share a letter with the Northeast region nor the West region, which indicates that the average predicted probability for the Midwest region is significantly different for each of the other two regions at our 5% level.

We can also include the `mcompare(bonferroni)` option to perform tests using Bonferroni’s method to account for making multiple comparisons.
. margins region, pwcompare(group) mcompare(bonferroni)
Pairwise comparisons of predictive margins
Model VCE      : OIM
Expression     : Pr(highbp), predict()

<table>
<thead>
<tr>
<th></th>
<th>Number of Comparisons</th>
</tr>
</thead>
<tbody>
<tr>
<td>region</td>
<td>6</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th></th>
<th>Delta-method Bonferroni</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Margin</td>
</tr>
<tr>
<td>region</td>
<td></td>
</tr>
<tr>
<td>NE</td>
<td>.4388358</td>
</tr>
<tr>
<td>MW</td>
<td>.4011164</td>
</tr>
<tr>
<td>S</td>
<td>.4231516</td>
</tr>
<tr>
<td>W</td>
<td>.4319628</td>
</tr>
</tbody>
</table>

Note: Margins sharing a letter in the group label are not significantly different at the 5% level.

We now see the letter A on the row corresponding to the West region. At the 5% level and with Bonferroni’s adjustment, the predictive margins for the probability in the Midwest and West regions are not significantly different.

Stored results

margins, pwcompare stores the following additional results in r():

Scalars

r(k_terms) number of terms participating in pairwise comparisons

Macros

r(cmd)                  pwcompare
r(cmd2)                 margins
r(group#)               group code for the #th margin in r(b)
r(mcmethod_vs)          title for method from mcompare()
r(mctitle_vs)           title for method from mcompare()
r(mcadjustall_vs)       adjustall or empty

Matrices

r(b)                    margin estimates
r(V)                    variance–covariance matrix of the margin estimates
r(b_vs)                 margin difference estimates
r(V_vs)                 variance–covariance margin difference of the margin estimates
r(error_vs)             margin difference estimability codes:
                        0 means estimable,
                        8 means not estimable
r(table_vs)             matrix containing the margin differences with their standard errors, test statistics, p-values, and confidence intervals
r(L)                    matrix that produces the margin differences
margins, pwcompare with the `post` option also stores the following additional results in `e()`:

Scalars
- `e(k_terms)` number of terms participating in pairwise comparisons

Macros
- `e(cmd)` `pwcompare`
- `e(cmd2)` `margins`

Matrices
- `e(b)` margin estimates
- `e(V)` variance–covariance matrix of the margin estimates
- `e(b_vs)` margin difference estimates
- `e(V_vs)` variance–covariance margin difference of the margin estimates
- `e(error_vs)` margin difference estimability codes; 0 means estimable, 8 means not estimable
- `e(L)` matrix that produces the margin differences

Syntax

marginsplot [, options]

options

Main

\texttt{xdimension(dimlist[,dimopts])} 
use \texttt{dimlist} to define $x$ axis

\texttt{plotdimension(dimlist[,dimopts])} 
create plots for groups in \texttt{dimlist}

\texttt{bydimension(dimlist[,dimopts])} 
create subgraphs for groups in \texttt{dimlist}

\texttt{graphdimension(dimlist[,dimopts])} 
create graphs for groups in \texttt{dimlist}

\texttt{horizontal} 
swap $x$ and $y$ axes

\texttt{noci} 
do not plot confidence intervals

\texttt{name(name|stub[,replace])} 
name of graph, or stub if multiple graphs

Labels

\texttt{allxlabels} 
place ticks and labels on the $x$ axis for each value

\texttt{nolabels} 
label groups with their values, not their labels

\texttt{allsimplelabels} 
forgo variable name and equal signs in all labels

\texttt{nosimplelabels} 
include variable name and equal signs in all labels

\texttt{separator(string)} 
separator for labels when multiple variables are specified in a dimension

\texttt{noseparator} 
do not use a separator

Plot

\texttt{plotopts(plot_options)} 
affect rendition of all margin plots

\texttt{plot#opts(plot_options)} 
affect rendition of $\#$th margin plot

\texttt{recast(plottype)} 
plot margins using \texttt{plottype}

CI plot

\texttt{ciopts(rcap_options)} 
affect rendition of all confidence interval plots

\texttt{ci#opts(rcap_options)} 
affect rendition of $\#$th confidence interval plot

\texttt{recastci(plottype)} 
plot confidence intervals using \texttt{plottype}

\texttt{mcompare(method)} 
adjust for multiple comparisons

\texttt{level(#)} 
set confidence level

Pairwise

\texttt{unique} 
plot only unique pairwise comparisons

\texttt{csort} 
sort comparison categories first

Add plots

\texttt{addplot(plot)} 
add other plots to the graph
**Y axis, X axis, Titles, Legend, Overall, By**

`twoway_options` any options documented in [G-3] `twoway_options`  
`byopts(byopts)` how subgraphs are combined, labeled, etc.

where `dimlist` may be any of the dimensions across which margins were computed in the immediately preceding `margins` command; see [R] `margins`. That is to say, `dimlist` may be any variable used in the `margins` command, including variables specified in the `at()`, `over()`, and `within()` options. More advanced specifications of `dimlist` are covered in [Addendum: Advanced uses of dimlist].

Statistics > Postestimation > Margins plots and profile plots
Description

marginsplot graphs the results of the immediately preceding margins command; see \[R\] margins. Common names for some of the graphs that marginsplot can produce are profile plots and interaction plots.

Options

xdimension(), plotdimension(), bydimension(), and graphdimension() specify the variables from the preceding margins command whose group levels will be used for the graph’s \(x\) axis, plots, by() subgraphs, and graphs.

marginsplot chooses default dimensions based on the margins command. In most cases, the first variable appearing in an at() option and evaluated over more than one value is used for the \(x\) axis. If no at() variable meets this condition, the first variable in the marginlist is usually used for the \(x\) axis and the remaining variables determine the plotted lines or markers. Pairwise comparisons and graphs of marginal effects (derivatives) have different defaults. In all cases, you may override the defaults and explicitly control which variables are used on each dimension of the graph by using these dimension options.

Each of these options supports suboptions that control the labeling of the dimension—axis labels for xdimension(), plot labels for plotdimension(), subgraph titles for bydimension(), and graph titles for graphdimension() titles.

For examples using the dimension options, see Controlling the graph’s dimensions.

\textbf{xdimension(dimlist [ , dimopts ])} specifies the variables for the \(x\) axis in dimlist and controls the content of those labels with dimopts.

\textbf{plotdimension(dimlist [ , dimopts ])} specifies in dimlist the variables whose group levels determine the plots and optionally specifies in dimopts the content of the plots’ labels.

\textbf{bydimension(dimlist [ , dimopts ])} specifies in dimlist the variables whose group levels determine the by() subgraphs and optionally specifies in dimopts the content of the subgraphs’ titles. For an example using by(), see Three-way interactions.

\textbf{graphdimension(dimlist [ , dimopts ])} specifies in dimlist the variables whose group levels determine the graphs and optionally specifies in dimopts the content of the graphs’ titles.

\textbf{horizontal} reverses the default \(x\) and \(y\) axes. By default, the \(y\) axis represents the estimates of the margins and the \(x\) axis represents one or more factors or continuous covariates. Specifying horizontal swaps the axes so that the \(x\) axis represents the estimates of the margins. This option can be useful if the labels on the factor or continuous covariates are long.

The horizontal option is discussed in Horizontal is sometimes better.

\textbf{noci} removes plots of the pointwise confidence intervals. The default is to plot the confidence intervals.

\textbf{name(name | stub [ , replace ])} specifies the name of the graph or graphs. If the graphdimension() option is specified, or if the default action is to produce multiple graphs, then the argument of name() is taken to be stub and graphs named stub1, stub2, ... are created.

The replace suboption causes existing graphs with the specified name or names to be replaced. If name() is not specified, default names are used and the graphs may be replaced by subsequent marginsplot or other graphing commands.
With the exception of `allxlabels`, all of these options may be specified either directly as options or as `dim opts` within options `x dimension()`, `plot dimension()`, `by dimension()`, and `graph dimension()`. When specified in one of the dimension options, only the labels for that dimension are affected. When specified outside the dimension options, all labels on all dimensions are affected. Specifications within the dimension options take precedence.

`allxlabels` specifies that tick marks and labels be placed on the $x$ axis for each value of the $x$-dimension variables. By default, if there are more than 25 ticks, default graph axis labeling rules are applied. Labeling may also be specified using the standard `graph twoway x-axis label` rules and options—`xlabel()`; see [G-3] `axis label options`.

`nolabels` specifies that value labels not be used to construct graph labels and titles for the group levels in the dimension. By default, if a variable in a dimension has value labels, those labels are used to construct labels and titles for axis ticks, plots, subgraphs, and graphs.

Graphs of contrasts and pairwise comparisons are an exception to this rule and are always labeled with values rather than value labels.

`allsimplelabels` and `nosimplelabels` control whether graphs’ labels and titles include just the values of the variables or include variable names and equal signs. The default is to use just the value label for variables that have value labels and to use variable names and equal signs for variables that do not have value labels. An example of the former is “Female” and the latter is “country=2”.

Sometimes value labels are universally descriptive, and sometimes they have meaning only when considered in relation to their variable. For example, “Male” and “Female” are typically universal, regardless of the variable from which they are taken. “High” and “Low” may not have meaning unless you know they are in relation to a specific measure, say, blood-pressure level. The `allsimplelabels` and `nosimplelabels` options let you override the default labeling.

`allsimplelabels` specifies that all titles and labels use just the value or value label of the variable.

`nosimplelabels` specifies that all titles and labels include `varname=` before the value or value label of the variable.

`separator(string)` and `noseparator` control the separator between label sections when more than one variable is used to specify a dimension. The default separator is a comma followed by a space, but no separator may be requested with `noseparator` or the default may be changed to any string with `separator()`.

For example, if `plot dimension(a b)` is specified, the plot labels in our graph legend might be “a=1, b=1”, “a=1, b=2”, .... Specifying `separator(:)` would create labels “a=1:b=1”, “a=1:b=2”, ....

`plot opts(plot_options)` affects the rendition of all margin plots. The `plot_options` can affect the size and color of markers, whether and how the markers are labeled, and whether and how the points are connected; see [G-3] `marker options`, [G-3] `marker label options`, and [G-3] `cline options`.

These settings may be overridden for specific plots by using the `plot#opts()` option.

`plot#opts(plot_options)` affects the rendition of the #th margin plot. The `plot_options` can affect the size and color of markers, whether and how the markers are labeled, and whether and how the points are connected; see [G-3] `marker options`, [G-3] `marker label options`, and [G-3] `cline options`.
`recast(plottype)` specifies that margins be plotted using `plottype`. `plottype` may be `scatter`, `line`, `connected`, `bar`, `area`, `spike`, `dropline`, or `dot`; see [G-2] `graph twoway`. When `recast()` is specified, the plot-rendition options appropriate to the specified `plottype` may be used in lieu of `plot_options`. For details on those options, follow the appropriate link from [G-2] `graph twoway`.

For an example using `recast()`, see *Continuous covariates*.

You may specify `recast()` within a `plotopts()` or `plot#opts()` option. It is better, however, to specify it as documented here, outside those options. When specified outside those options, you have greater access to the plot-specific rendition options of your specified `plottype`.

`ciplot` affects the rendition of all confidence interval plots; see [G-3] `rcap_options`.

These settings may be overridden for specific confidence interval plots with the `ci#opts()` option.

`ci#opts(rcap_options)` affects the rendition of the #th confidence interval; see [G-3] `rcap_options`.

`recastci(plottype)` specifies that confidence intervals be plotted using `plottype`. `plottype` may be `rarea`, `rbar`, `rspike`, `rcap`, `rcapsym`, `rline`, `rconnected`, or `rscatter`; see [G-2] `graph twoway`. When `recastci()` is specified, the plot-rendition options appropriate to the specified `plottype` may be used in lieu of `rcap_options`. For details on those options, follow the appropriate link from [G-2] `graph twoway`.

For an example using `recastci()`, see *Continuous covariates*.

You may specify `recastci()` within a `ciplot()` or `ci#plot()` option. It is better, however, to specify it as documented here, outside those options. When specified outside those options, you have greater access to the plot-specific rendition options of your specified `plottype`.

`mcompare(method)` specifies the method for confidence intervals that account for multiple comparisons within a factor-variable term. The default is determined by the `margins` results stored in `r()`. If `marginsplot` is working from `margins` results stored in `e()`, the default is `mcompare(noadjust)`.

`level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is determined by the `margins` results stored in `r()`. If `marginsplot` is working from `margins` results stored in `e()`, the default is `level(95)` or as set by `set level`; see [U] 20.7 Specifying the width of confidence intervals.

These options have an effect only when the `pwcompare` option was specified on the preceding `margins` command.

`unique` specifies that only unique pairwise comparisons be plotted. The default is to plot all pairwise comparisons, including those that are mirror images of each other—“male” versus “female” and “female” versus “male”. `margins` reports only the unique pairwise comparisons. `unique` also changes the default `xdimension()` for graphs of pairwise comparisons from the reference categories (`_pw0`) to the comparisons of each pairwise category (`_pw`).

Unique comparisons are often preferred with horizontal graphs that put all pairwise comparisons on the x axis, whereas including the full matrix of comparisons is preferred for charts showing the reference groups on an axis and the comparison groups as plots; see *Pairwise comparisons* and *Horizontal is sometimes better*.

`csort` specifies that comparison categories are sorted first, and then reference categories are sorted within comparison category. The default is to sort reference categories first, and then sort comparison categories within reference categories. This option has an observable effect only when `_pw` is also
specified in one of the dimension options. It then determines the order of the labeling in the dimension where _pw is specified.

addplot(\textit{plot}) provides a way to add other plots to the generated graph; see [G-3] \texttt{addplot} option.

For an example using addplot(), see \textit{Adding scatterplots of the data}.

If multiple graphs are drawn by a single \texttt{marginsplot} command or if \textit{plot} specifies plots with multiple \textit{y} variables, for example, \texttt{scatter y1 y2 x}, then the graph’s legend will not clearly identify all the plots and will require customization using the \texttt{legend()} option; see [G-3] \texttt{legend_options}.

\texttt{twoway_options} are any of the options documented in [G-3] \texttt{twoway_options}. These include options for titling the graph (see [G-3] \texttt{title_options}); for saving the graph to disk (see [G-3] \texttt{saving_option}); for controlling the labeling and look of the axes (see [G-3] \texttt{axis_options}); for controlling the look, contents, position, and organization of the legend (see [G-3] \texttt{legend_options}); for adding lines (see [G-3] \texttt{added_line_options}) and text (see [G-3] \texttt{added_text_options}); and for controlling other aspects of the graph’s appearance (see [G-3] \texttt{twoway_options}).

The label() suboption of the legend() option has no effect on \texttt{marginsplot}. Use the order() suboption instead.

\texttt{byopts(byopts)} affects the appearance of the combined graph when bydimension() is specified or when the default graph has subgraphs, including the overall graph title, the position of the legend, and the organization of subgraphs. See [G-3] \texttt{by_option}.

**Remarks and examples**

Remarks are presented under the following headings:

- Introduction
- Dataset
- Profile plots
- Interaction plots
- Contrasts of margins—effects (discrete marginal effects)
- Three-way interactions
- Continuous covariates
- Plots at every value of a continuous covariate
- Contrasts of at() groups—discrete effects
- Controlling the graph’s dimensions
- Pairwise comparisons
- Horizontal is sometimes better
- Marginal effects
- Plotting a subset of the results from margins
- Advanced usage
  - Plots with multiple terms
  - Plots with multiple at() options
  - Adding scatterplots of the data
- Video examples
Introduction

marginsplot is a post-margins command. It graphs the results of the margins command, whether those results are marginal means, predictive margins, marginal effects, contrasts, pairwise comparisons, or other statistics; see [R] margins.

By default, the margins are plotted on the $y$ axis, and all continuous and factor covariates specified in the margins command will usually be placed on the $x$ axis or used to identify plots. Exceptions are discussed in the following sections and in Addendum: Advanced uses of dimlist below.

marginsplot produces classic plots, such as profile plots and interaction plots. Beyond that, anything that margins can compute, marginsplot can graph.

We will be using some relatively complicated margins commands with little explanation of the syntax. We will also avoid lengthy interpretations of the results of margins. See [R] margins for the complete syntax of margins and discussions of its results.

All graphs in this entry were drawn using the s2gcolor scheme; see [G-4] scheme s2.

Mitchell (2012) shows in many examples how to use marginsplot to understand a fitted model.

Dataset

For continuity, we will use one dataset for most examples—the Second National Health and Nutrition Examination Survey (NHANES II) (McDowell et al. 1981). NHANES II is part of a study to assess the health and nutritional status of adults and children in the United States. It is designed to be a nationally representative sample of the U.S. population. This particular sample is from 1976 to 1980.

The survey nature of the dataset—weights, strata, and sampling units—will be ignored in our analyses. We are discussing graphing, not survey statistics. If you would like to see the results with the appropriate adjustments for the survey design, just add svy: before each estimation command, and if you wish, add vce(unconditional) as an option to each margins command. See [R] margins, particularly the discussion and examples under Obtaining margins with survey data and representative samples, for reasons why you probably would want to add vce(unconditional) when analyzing survey data. For the most part, adjusting for survey design produces moderately larger confidence intervals and relatively small changes in point estimates.

Profile plots

What does my estimation say about how my response varies as one (or more) of my covariates changes? That is the question that is answered by profile plots. Profile plots are also referred to as plots of estimated (or expected, or least-squares) means, though that is unnecessarily restrictive when considering models of binary, count, and ordered outcomes. In the latter cases, we might prefer to say they plot conditional expectations of responses, where a response might be a probability.

What we do with the other covariates depends on the questions we wish to answer. Sometimes we wish to hold other covariates at fixed values, and sometimes we wish to average the response over their values. margins can do either, so you can graph either.

We can fit a fully factorial two-way ANOVA of systolic blood pressure on age group and sex using the NHANES II data.

If you are more comfortable with regression than ANOVA, then type

. regress bpsystol agegrp##sex

The `anova` and `regress` commands fit identical models. The output from `anova` displays all the terms in the model and thus tends to be more conducive to exploration with `margins` and `marginsplot`.

We estimate the predictive margins of systolic blood pressure for each age group using `margins`.

The six predictive margins are just the averages of the predictions over the estimation sample, holding `agegrp` to each of its six levels. If this were a designed experiment rather than survey data, we might wish to assume the cells are balanced—that they have the same number of observations—and thus estimate what are often called expected means or least-squares means. To do that, we would simply add the `asbalanced` option to the `margins` command. The NHANES II data are decidedly unbalanced over `sex#agegrp` cells. So much so that it is unreasonable to assume the cells are balanced.
We graph the results:

```
. marginsplot
Variables that uniquely identify margins: agegrp
```

Profile plots are often drawn without confidence intervals (CIs). The CIs may be removed by adding the `noci` option. We prefer to see the CIs.

Disciplines vary widely in their use of the term profile plot. Some disciplines consider any connected plot of a response over values of other variables to be a profile plot. By that definition, most graphs in this entry are profile plots.

**Interaction plots**

Interaction plots are often used to explore the form of an interaction. The interaction term in our ANOVA results is highly significant. Are the interaction effects also large enough to matter? What form do they take? We can answer these questions by fixing `agegrp` and `sex` to each possible combination of the two covariates and estimating the margins for those cells.

```
. margins agegrp#sex
```
Then we can graph the results:

```
. marginsplot
  Variables that uniquely identify margins: agegrp sex
```

It is clear that the effect of age differs by sex—there is an interaction. If there were no interaction, then the two lines would be parallel.

While males start out with higher systolic blood pressure, females catch up to the males as age increases and may even surpass males in the upper age groups. We say “may” because we cannot tell if the differences are statistically significant. The CIs overlap for the top three age groups. It is tempting to conclude from this overlap that the differences are not statistically significant. Do not fall into this trap. Likewise, do not fall into the trap that the first three age groups are different because their CIs do not overlap. The CIs are for the point estimates, not the differences. There is a covariance between the differences that we must consider if we are to make statements about those differences.

**Contrasts of margins—effects (discrete marginal effects)**

To assess the differences, all we need do is ask `margins` to contrast the sets of effects that we just estimated; see [R] `margins, contrast`. With only two groups in sex, it does not matter much which contrast operator we choose. We will use the reference contrast. It will compare the difference between males and females, with males (the first category) as the reference category.

Because we are looking for effects that are different from 0, we will add a reference line at 0 to our graph.

. marginsplot, yline(0)

Variables that uniquely identify margins: agegrp

We can now say that females’ systolic blood pressure is substantially and significantly lower than males’ in the first three age groups but is significantly higher in the last two age groups. Despite the overlapping CIs for the last two age groups in the interaction graph, the effect of sex is significant in these age groups.
The terminology for what we just estimated and graphed varies widely across disciplines. Those versed in design of experiments refer to these values as contrasts or effects. Economists and some other social scientists call them marginal or partial effects. The latter groups might be more comfortable if we avoided the whole concept of contrasts and instead estimated the effects by typing

```
margins agegrp, dydx(sex)
```

This will produce estimates that are identical to those shown above, and we can graph them by typing `marginsplot`.

The advantage of using the contrast notation and thinking in contrasts is most evident when we take marginal effects with respect to a categorical covariate with more than two levels. Marginal effects for each level of the covariate will be taken with respect to a specified base level. Contrasts are much more flexible. Using the `r.` operator, we can reproduce the marginal-effects results by taking derivatives with respect to a reference level (as we saw above.) We can also estimate the marginal effect of first moving from level 1 to level 2, then from level 2 to level 3, then from level 3 to level 4, ... using the `ar.` or “reverse adjacent” operator. Adjacent effects (marginal effects) can be valuable when evaluating an ordinal covariate, such as `agegrp` in our current model. For a discussion of contrasts, see `[R] contrast` and `[R] margins, contrast`.

### Three-way interactions

`marginsplot` can handle any number of covariates in your `margins` command. Consider the three-way ANOVA model that results from adding an indicator for whether an individual has been diagnosed with diabetes. We will fully interact the new covariate with the others in the model.

```
. anova bpsystol agegrp##sex##diabetes
```

```
Number of obs = 10349  R-squared = 0.2572
Root MSE = 20.131  Adj R-squared = 0.2556

Source | Partial SS | df | MS | F | Prob > F
------------- |------------ |---- |---- |---- |----------
Model       | 1448983.17  | 23 | 62999.2681 | 155.45 | 0.0000
  agegrp    | 107963.582  | 5  | 21592.7164 | 53.28  | 0.0000
  sex       | 1232.79267  | 1  | 1232.79267 | 3.04   | 0.0812
  agegrp#sex| 11679.5925  | 5  | 2335.91849 | 5.76   | 0.0000
  diabetes  | 7324.98924  | 1  | 7324.98924 | 18.07  | 0.0000
  agegrp#diabetes | 5484.54623 | 5  | 1096.90925 | 2.71   | 0.0189
  sex#diabetes | 102.988239 | 1  | 102.988239 | 0.25   | 0.6142
  agegrp#sex#diabetes | 4863.14971 | 5  | 972.629943 | 2.40   | 0.0349
Residual    | 4184296.88  | 10325 | 405.258778 |
Total       | 5633280.05  | 10348 | 544.38346 |
```

The three-way interaction is significant, as is the main effect of `diabetes` and its interaction with `agegrp`.

Again, if you are more comfortable with regression than ANOVA, you may type

```
. regress bpsystol agegrp##sex##diabetes
```

The `margins` and `marginsplot` results will be the same.
We estimate the expected cell means for each combination of agegrp, sex, and diabetes, and then graph the results by typing

```
  . margins agegrp#sex#diabetes
  (output omitted)
  . marginsplot
```
Variables that uniquely identify margins: agegrp sex diabetes

The graph is busy and difficult to interpret.

We can make it better by putting those with diabetes on one subgraph and those without on another:

```
  . marginsplot, by(diabetes)
```
Variables that uniquely identify margins: agegrp sex diabetes

We notice much larger CIs for diabetics. That is not surprising because our sample contains only 499 diabetics compared with 9,850 nondiabetics.
A more interesting way to arrange the plots is by grouping the subgraphs on `sex`:

```
. marginsplot, by(sex)
Variables that uniquely identify margins: agegrp sex diabetes
```

Aside from increased systolic blood pressure in the upper-age groups, which we saw earlier, it appears that those with diabetes are at greater risk of higher systolic blood pressure for many upper-age groups. We can check that by having `margins` estimate the differences between diabetics and nondiabetics, and graphing the results.

```
. margins r.diabetes@agegrp#sex
(output omitted)
. marginsplot, by(sex) yline(0)
Variables that uniquely identify margins: agegrp sex
```

With CIs above 0 for six of eight age groups over 40, this graph provides evidence that diabetes is related to higher blood pressure in those over 40.
Continuous covariates

margins and marginsplot are just as useful with continuous covariates as they are with factor variables. As a variation on our ANOVA/regression models, let’s move to a logistic regression, using as our dependent variable an indicator for whether a person has high blood pressure. We introduce a continuous covariate—body mass index (BMI), a measure of weight relative to height. High BMI is often associated with high blood pressure. We will allow the effect of BMI to vary across sexes, age groups, and sex/age combinations by fully interacting the covariates.

```
l. logistic highbp sex##agegrp##c.bmi
```

If we wished, we could perform all the analyses above on this model. Instead of estimating margins, contrasts, and marginal effects on the level of systolic blood pressure, we would be estimating margins, contrasts, and marginal effects on the probability of having high blood pressure. You can see those results by repeating any of the prior commands that involve sex and agegrp. In this section, we will focus on the continuous covariate bmi.

With continuous covariates, rather than specify them in the marginlist of margins, we specify the specific values at which we want the covariate evaluated in an at() option. at() options are very flexible, and there are many ways to specify values; see Syntax of at() in [R] margins.

BMI in our sample ranges from 12.4 to 61.1. Let’s estimate the predictive margins for males and females at levels of BMI from 10 through 65 at intervals of 5 and graph the results:

```
l. margins sex, at(bmi=(10(5)65))
(output omitted)
l. marginsplot, xlabel(10(10)60)
```

We added the xlabel(10(10)60) option to improve the labeling of the x axis. You may add any twoway_options (see [G-3] twoway_options) to the marginsplot command.

For a given BMI, males are generally more susceptible to high blood pressure, though the effect is attenuated by the logistic response when the probabilities approach 0 or 1.

Because bmi is continuous, we might prefer to see the response graphed using a line. We might also prefer that the CIs be plotted as areas. We change the plottype of the response by using the recast() option and the plottype of the CI by using the recastci() option:
The CIs are a little dark for our tastes. You can dim them a bit by reducing the intensity of their color. Adding \texttt{ciopts(color(*.8))} to our \texttt{marginsplot} command will do that. Any plot option accepted by \texttt{twoway rarea} (see [G-2] \texttt{graph twoway rarea}) may be specified in a \texttt{ciopts()} option.

Given their confidence regions, the male and female profiles appear to be statistically different over most of the range of BMI. As with the profiles of categorical covariates, we can check that assertion by contrasting the two profiles on \texttt{sex} and graphing the results. Let’s improve the smoothness of the response by specifying intervals of 1 instead of 5.

```stata
. margins r.sex, at(bmi=(10(1)65))
(output omitted)
. marginsplot, xlabel(10(10)60) recast(line) recastci(rarea)
```

Variables that uniquely identify margins: \texttt{bmi sex}

We see that the difference between the sexes is largest at a BMI of about 35 and that the sexes respond more similarly with very high and very low BMI. This shape is largely determined by the
response of the logistic function, which is attenuated near probabilities 0 and 1, combined with the
fact that the lowest measured BMIs are associated with low probabilities of high blood pressure and
the highest measured BMIs are associated with high probabilities of high blood pressure.

As when we contrasted profiles of categorical variables, different disciplines will think of this
graph differently. Those familiar with designed experiments will be comfortable with the terms used
above—this is a contrast of profiles, or a profile of effects, or a profile of a contrast. Many social
scientists will prefer to think of this as a graph of marginal or partial effects. For them, this is a plot
of the discrete marginal effect of being female for various levels of BMI. They can obtain an identical
graph, with labeling more appropriate for the marginal effect’s interpretation, by typing

```
  . margins, at(bmi=(10(1)65)) dydx(sex)
  . marginsplot, xlabel(10(10)60) recast(line) recastci(rarea)
```

We can also plot profiles of the response of BMI by levels of another continuous covariate (rather
than by the categorical variable sex). To do so, we will need another continuous variable in our
model. We have been using age groups as a covariate to emphasize the treatment of categorical
variables and to allow the effect of age to be flexible. Our dataset also has age recorded in integer
years. We replace `agegrp` with continuous `age` in our logistic regression.

```
  . logistic highbp sex##c.age##c.bmi
```

We can now obtain profiles of BMI for different ages by specifying ranges for both `bmi` and `age`
in a single `at()` option on the `margins` command:

```
  . margins sex, at(bmi=(10(5)60) age=(20(10)70))
```

With six ages specified, we have many profiles, so we will dispense with the CIs by adding the
`noci` option and also tidy up the graph by asking for three columns in the legend:

```
  . marginsplot, noci by(sex) legend(cols(3))

  Variables that uniquely identify margins: bmi age sex
```

Our model seems to indicate that males have a sharper reaction to body mass indices than do
dfemales. Likewise, younger subjects display a sharper response, while older subjects have a more
gradual response with earlier onset. That interpretation might be a result of our parametric treatment
of `age`. As it turns out, the interpretation holds if we allow age to take more flexible forms or return
to our use of age groups, which allows each of seven age groups to have unique BMI profiles. Here
are the commands to perform that analysis:
. logistic highbp sex##agegrp#c.bmi
(output omitted)
. margins sex##agegrp, at(bmi=(10(5)60))
(output omitted)
. marginsplot, noci by(sex) legend(cols(3))

Variables that uniquely identify margins: bmi sex agegrp

Plots at every value of a continuous covariate

In some cases, the specific values of a continuous covariate are important, and we want to plot the response at those specific values. Return to our logistic example with age treated as a continuous covariate.

. logistic highbp sex##age##c.bmi

We can use a programming trick to extract all the values of age and then supply them in an at() option, just as we would any list of values.

. levelsof age
. margins sex, at(age=('r(levels)'))

See [P] levelsof for a discussion of the levelsof command. levelsof returns in r(levels) the sorted list of unique values of the specified varlist, in our case, age.

We can then plot the results using marginsplot.

This is not a very interesting trick when using our age variable, which is recorded as integers from 20 to 74, but the approach will work with almost any continuous variable. In our model, bmi might seem more interesting, but there are 9,941 unique values of bmi in our dataset. A graph cannot resolve so many different values. For that reason, we usually recommend against plotting at every value of a covariate. Instead, graph at reasonable values over the range of the covariate by using the at() option, as we did earlier. This trick is best reserved for variables with a few, or at most a few dozen, unique values.
Contrasts of at() groups—discrete effects

We have previously contrasted across the values of factor variables in our model. Put another way, we have estimated the discrete marginal effects of factor variables. We can do the same for the levels of variables in at() specifications and across separate at() specifications.

Returning to one of our logistic models and its margins, we earlier estimated the predictive margins of BMI at 5-unit intervals for both sexes. These are the commands we typed:

```
.logistic highbp sex##agegrp##c.bmi
.margins sex, at(bmi=(10(5)65))
.marginsplot, xlabel(10(10)60)
```

We can estimate the discrete effects by sex of bmi moving from 10 to 15, then from 15 to 20, ..., and then from 60 to 65 by contrasting the levels of the at() groups using the reverse-adjacent contrast operator (ar.). We specify the operator within the atcontrast() suboption of the contrast() option. We need to specify one other option. By default, margins, contrast will apply a contrast to all variables in its marginlist when a contrast has been requested. In this case, we do not want to contrast across sexes but rather to contrast across the levels of BMI within each sex. To prevent margins from contrasting across the sexes, we specify the marginswithin option. Our margins command is

```
.margins sex, at(bmi=(10(5)65)) contrast(atcontrast(ar._at) marginswithin)
```

And we graph the results using marginsplot:

```
.marginsplot
```

Variables that uniquely identify margins: bmi sex

The graph shows the contrasts (or if you prefer, discrete changes) in the probability of high blood pressure by sex as one increases BMI in 5-unit increments.

We can even estimate contrasts (discrete effects) across at() options. To start, let’s compare the age-group profiles of the probability of high blood pressure for those in the 25th and 75th percentile of BMI.
For each age group, people whose BMI is at the 75th percentile have a much higher probability of high blood pressure than those at the 25th percentile. What is that difference in probability and its CI? To contrast across the percentiles of BMI within age groups, we again specify a contrast operator on the at() groups using atcontrast(), and we also tell margins to perform that contrast within the levels of the marginlist by using the marginswithin option.
The differences in probability between 25th and 75th BMI percentiles are clearly significantly greater than 0. The differences appear to be smallest for those in the youngest and oldest age groups.

Controlling the graph’s dimensions

Thus far, `marginsplot` has miraculously done almost exactly what we want in most cases. The things we want on the $x$ axis have been there, the choice of plots has made sense, etc. Some of that luck sprang from the relatively simple analyses we were performing, and some was from careful specification of our `margins` command. Sometimes, we will not be so lucky.
Consider the following `regress`, `margins`, and `marginsplot` commands:

```
. regress bpsystol agegrp##sex##c.bmi
(output omitted)
. margins agegrp, over(sex) at(bmi=(10(10)60))
(output omitted)
. marginsplot
```

Variables that uniquely identify margins: `agegrp _atopt`
Multiple `at()` options specified:
- `_atoption=1: (p25) bmi`
- `_atoption=2: (p75) bmi`

By default, `marginsplot` places the levels of the first multilevel `at()` specification on the x axis, and then usually plots the levels of all remaining variables as connected lines. That is what we see in the graph above—`bmi`, the `at()` variable, is on the x axis, and each combination of `agegrp` and `sex` is plotted as a separate connected line. If there is no multilevel `at()` specification, then the first variable in `marginlist` becomes the x axis. There are many more rules, but it is usually best to simply type `marginsplot` and see what happens. If you do not like `marginsplot`’s choices, change them.

What if we wanted `agegrp` on the x axis instead of `BMI`? We tell `marginsplot` to make that change by specifying `agegrp` in the `xdimension()` option:
. marginsplot, xdimension(agegrp)
Variables that uniquely identify margins: bmi agegrp sex

Predictive Margins of agegrp with 95% CIs

We have been suppressing the Results window output for marginsplot, but that output is helpful if we want to change how things are plotted. You may specify any variable used in your margins command in any of the dimension options—xdimension(), plotdimension(), bydimension(), and graphdimension(). (In fact, there are some pseudovariables that you may also specify in some cases; see Addendum: Advanced uses of dimlist for details.) marginsplot tries to help you narrow your choices by listing a set of variables that uniquely identify all your margins. You are not restricted to this list.

We have a different x axis and a different set of plots, but our graph is still busy and difficult to read. We can make it better by creating separate graph panels for each sex. We do that by adding a bydimension() option with sex as the argument.

. marginsplot, xdimension(agegrp) bydimension(sex)
Variables that uniquely identify margins: bmi agegrp sex

Predictive Margins of agegrp with 95% CIs

The patterns and the differences between males and females are now easier to see.
If our interest is in comparing males and females, we might even choose to create a separate panel for each level of BMI:

```
marginsplot, xdimension(agegrp) bydimension(bmi) xlabel(, angle(45))
```
Variables that uniquely identify margins: bmi agegrp sex

The $x$-axis labels did not fit, so we angled them.

We leave you to explore the use of the `graphdimension()` option. It is much like `bydimension()` but creates separate graphs rather than separate panels. Operationally, the `plotdimension()` option is rarely used. All variables not in the $x$ dimension and not specified elsewhere become the plotted connected lines.

You will likely use the dimension options frequently. This is one of the rare cases where we recommend using the minimal abbreviations of the options—`x()` for `xdimension()`, `plot()` for `plotdimension()`, `by()` for `bydimension()`, and `graph()` for `graphdimension()`). The abbreviations are easy to read and just as meaningful as the full option names. The full names exist to reinforce the relationship between the dimension options.

**Pairwise comparisons**

`marginsplot` can graph the results of `margins, pwcompare`; see [R] `margins, pwcompare`. We return to one of our ANOVA examples. Here we request pairwise comparisons with the `pwcompare` option of `margins`, and we request Bonferroni-adjusted CIs with the `mcompare()` option:
. anova bpsystol agegrp#sex
(output omitted)
. margins agegrp, pwcompare mcompare(bonferroni)
(output omitted)
. marginsplot

Variables that uniquely identify margins: _pw1 _pw0

_pw enumerates all pairwise comparisons; _pw0 enumerates the reference
categories; _pw1 enumerates the comparison categories.

Each connected line plot in the graph represents a reference age-group category for the pairwise
comparison. The ticks on the x axis represent comparison age-group categories. So, each plot is a
profile for a reference category showing its comparison to each other category.

**Horizontal is sometimes better**

Another interesting way to graph pairwise comparisons is to simply plot each comparison and
label the two categories being compared. This type of graph works better if it is oriented horizontally
rather than vertically.

Continuing with the example above, we will switch the graph to horizontal. We will also make
several changes to display the graph better. We specify that only unique comparisons be plotted. The
graph above plotted both 1 versus 2 and 2 versus 1, which are the same comparison with opposite
signs. We add a reference line at 0 because we are interested in comparisons that differ from 0. This
graph looks better without the connecting lines, so we add the option recast(scatter). We also
reverse the y scale so that the smallest levels of age group appear at the top of the axis.
. marginsplot, horizontal unique xline(0) recast(scatter) yscale(reverse)

Variables that uniquely identify margins: _pw1 _pw0

_pw enumerates all pairwise comparisons; _pw0 enumerates the reference
categories; _pw1 enumerates the comparison categories.

All the comparisons differ from 0, so all our age groups are statistically different from each other.

The horizontal option can be useful outside of pairwise comparisons. Profile plots are usually
oriented vertically. However, when your covariates have long labels or there are many levels at which
the margins are being evaluated, the graph may be easier to read when rendered horizontally.

Marginal effects

We have seen how to graph discrete effects for factor variables and continuous variables by using
contrasts, and optionally by using the dydx() option of margins: Contrasts of margins—effects
(discrete marginal effects) and Continuous covariates. Let’s now consider graphing instantaneous
marginal effects for continuous covariates. Begin by refitting our logistic model of high blood
pressure as a function of sex, age, and BMI:

. logistic highbp sex##agegrp##c.bmi
We estimate the average marginal effect of BMI on the probability of high blood pressure for each age group and then graph the results by typing

```
. margins agegrp, dydx(bmi)
(output omitted)
. marginsplot
```

Variables that uniquely identify margins: agegrp

These are the conditional expectations of the marginal effects treating everyone in the sample as though they were in each age group. We can estimate fully conditional marginal effects that do not depend on averaging over the sample by also margining on our one remaining covariate—sex.

```
. margins agegrp#sex, dydx(bmi)
(output omitted)
. marginsplot
```

Variables that uniquely identify margins: agegrp sex

The effect of BMI on the probability of high blood pressure looks to increase with age for females. The marginal effect is higher for males than females in the younger age groups but then decreases with age for males after the 40–49 age group.
You may want to test for differences in the marginal effect of BMI for males and females by contrasting across sexes within `agegrp`:

```
. margins r.sex@agegrp, dydx(bmi)
```

**Plotting a subset of the results from margins**

`marginsplot` plots all the margins produced by the preceding `margins` command. If you want a graph that does not include all the margins, then enter a `margins` command that produces a reduced set of margins. Obvious ways to reduce the number of margins include not specifying some factors or interactions in the `marginlist` of `margins`, not specifying some `at()` or `over()` options, or reducing the values specified in an `at()` option. A less obvious technique uses selection lists in factor operators to select specific sets of levels from factor variables specified in the `marginlist`.

Instead of typing

```
. margins agegrp
```

which will give you margins for all six age groups in our sample, type

```
. margins i(2/4).agegrp
```

which will give you only three margins—those for groups 2, 3, and 4. See [U] 11.4.3.4 Selecting levels.

**Advanced usage**

`margins` is incredibly flexible in the statistics it can estimate and in the grouping of those estimates. Many of the estimates that `margins` can produce do not make convincing graphs. `marginsplot` plots the results of any `margins` command, regardless of whether the resulting graph is easily interpreted. Here we demonstrate some options that can make complicated `margins` into graphs that are somewhat more useful than those produced by `marginsplot`'s defaults. Others may find truly useful applications for these approaches.

**Plots with multiple terms**

Margins plots are rarely interesting when you specify multiple terms on your `margins` command, for example, `margins a b`. Such plots often compare things that are not comparable. The defaults for `marginsplot` rarely produce useful plots with multiple terms. Perhaps the most interesting graph in such cases puts all the levels of all the terms together on the vertical axis and plots their margins on the horizontal axis. We do that by including the `marginlist` from `margins` in an `xdimension()` option on `marginsplot`. The long labels on such graphs look better with a horizontal orientation, and there is no need to connect the margin estimates, so we specify the `recast(scatter)` option.
Using one of our ANOVA examples from earlier,

\[
\begin{align*}
&. \texttt{anova bpsystol agegrp##sex} \\
& \quad (\text{output omitted}) \\
&. \texttt{margins agegrp sex} \\
& \quad (\text{output omitted}) \\
&. \texttt{marginsplot, xdimension(agegrp sex) horizontal recast(scatter)} \\
\end{align*}
\]

Variables that uniquely identify margins: agegrp sex

The “asobserved” notations in the $y$-axis labels are informing us that, for example, when the margin for females is evaluated, the values of age group are taken as they are observed in the dataset. The margin is computed as an average over those values.

### Plots with multiple at() options

Some disciplines like to compute margins at the means of other covariates in their model and others like to compute the response for each observation and then take the means of the response. These correspond to the \texttt{margins} options \texttt{at((mean) _all)} and \texttt{at((asobserved) _all)}. For responses that are linear functions of the coefficients, such as \texttt{predict} after \texttt{regress}, the two computations yield identical results. For responses that are nonlinear functions of the coefficients, the two computations estimate different things.

Using one of our logistic models of high blood pressure,

\[
. \texttt{logistic highbp sex##agegrp##c.bmi}
\]

and computing both sets of margins for each age group,

\[
. \texttt{margins agegrp, at((mean) _all) at((asobserved) _all)}
\]
we can use `marginsplot` to compare the approaches:

```
. marginsplot
Variables that uniquely identify margins: agegrp _atopt
Multiple at() options specified:
    _atoption=1: (mean) _all
    _atoption=2: (asobserved) _all
```

For the first three age groups, the probabilities of high blood pressure are lower at the means of `sex` and `bpi` than are the mean probabilities of high blood pressure averaged over the observed values of `sex` and `bpi`. The reverse is true for the last three age groups, although the values are very similar in these older age groups.
Such comparisons come up even more frequently when evaluating marginal effects. We can estimate the marginal effects of sex at each age group and graph the results by adding `dydx(sex)` to our `margins` command:

```
. margins agegrp, at((mean) _all) at((asobserved) _all) dydx(sex)
(output omitted)
. marginsplot
```

Variables that uniquely identify margins: agegrp _atopt
Multiple at() options specified:
_atoption=1: (mean) _all
_atoption=2: (asobserved) _all

The average marginal effect is smaller for most age groups, but the CIs for both sets of estimates are wide. Can we tell the difference between the estimates? To answer that, we use the now-familiar tactic of taking the contrast of our estimated marginal-effects profiles. That means adding `contrast(atjoint marginswithin)` to our `margins` command. We will also add `mcompare(bonferroni)` to account for the fact that we will be comparing six contrasts.

```
. margins agegrp, at((mean) _all) at((asobserved) _all) dydx(sex)
> contrast(atjoint marginswithin) mcompare(bonferroni)
```
We will also add the familiar reference line at 0 to our graph of the contrasts.

```
. marginsplot, yline(0)
```

Variables that uniquely identify margins: agegrp _atopt
Multiple at() options specified:
  _atoption=1: (mean)_all
  _atoption=2: (asobserved) _all

While the difference in the estimates of marginal effects is not large, we can distinguish the estimates for the 30–39 and 70+ age groups.

The `at()` option of `margins` provides far more flexibility than demonstrated above. It can be used to evaluate a response or marginal effect at almost any point of interest or combinations of such points. See *Syntax of at()* in [R] `margins`.

**Adding scatterplots of the data**

We can add scatterplots of the observed data to our plots of the margins. The NHANES II dataset is too large for this to be interesting, so for this example, we will use `auto.dta`. We fit mileage on whether the care is foreign and on a quadratic in the weight of the car. We convert the weight into tons (U.S. definition) to improve the scaling, and we format the new `tons` variable to improve its labels on the graph. For our graph, we create separate variables for mileage of domestic and of foreign cars. We fit a fully interacted model so that the effect of weight on mileage can be different for foreign and for domestic cars.

```
. use http://www.stata-press.com/data/r13/auto
. generate tons = weight/2000
. format tons %6.2f
. separate mpg, by(foreign)
. regress mpg foreign##c.tons##c.tons
```

We then estimate the margins over the range of tons, using the option `over(foreign)` to obtain separate estimates for foreign and domestic cars.

```
. margins, at(tons=(.8(.05)2.4)) over(foreign)
```
Adding scatterplots of mileage for domestic and foreign cars is easy. We insert into an `addplot()` option of `marginsplot` the same scatterplot syntax for `twoway` that we would type to produce a scatterplot of the data:

```
. marginsplot, addplot(scatter mpg0 tons || scatter mpg1 tons) recast(line) noci
  Variables that uniquely identify margins: tons foreign
```

![Predictive Margins](image)

Many will be surprised that the mileage profile is higher in 1978 for domestic (U.S. built) cars. Is the difference significant?

```
. margins, at(tons=(.8(.05)2.4)) over(r.for)
  (output omitted)
. marginsplot, yline(0)
  Variables that uniquely identify margins: tons
```

![Contrasts of Predictive Margins with 95% CIs](image)

As we did earlier, we contrast the two profiles. We can discern some difference between the two profiles for midweight vehicles, but otherwise there is insufficient information to believe mileage differs across domestic and foreign cars.

Profile plots and interaction plots, part 5: Interactions of two continuous variables

Addendum: Advanced uses of dimlist

dimlist specifies the dimensions from the immediately preceding margins command that are to be used for the marginsplot’s x axis, plots, subgraphs, and graphs. dimlist may contain:

<table>
<thead>
<tr>
<th>dim</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>varname</td>
<td>Any variable referenced in the preceding margins command.</td>
</tr>
<tr>
<td>at(varname)</td>
<td>If a variable is specified in both the marginlist or the over() option and in the at() option of margins, then the two uses can be distinguished in marginsplot by typing the at() variables as at(varname) in dimlist.</td>
</tr>
<tr>
<td>_deriv</td>
<td>If the preceding margins command included a dydx(), eyex(), dyex(), or eydx() option, dimlist may also contain _deriv to specify all the variables over which derivatives were taken.</td>
</tr>
<tr>
<td>_term</td>
<td>If the preceding margins command included multiple terms (for example, margins a b), then dimlist may contain _term to enumerate those terms.</td>
</tr>
<tr>
<td>_atopt</td>
<td>If the preceding margins command included multiple at() options, then dimlist may contain _atopt to enumerate those at() options.</td>
</tr>
</tbody>
</table>

When the pairwise option is specified on margins, you may specify dimensions that enumerate the pairwise comparisons.

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>_pw</td>
<td>enumerates all the pairwise comparisons</td>
</tr>
<tr>
<td>_pw0</td>
<td>enumerates the reference categories of the comparisons</td>
</tr>
<tr>
<td>_pw1</td>
<td>enumerates the comparison categories of the comparisons</td>
</tr>
</tbody>
</table>

Acknowledgments

We thank Philip B. Ender of UCLA Academic Technology Services for his programs that demonstrated what could be done in this area. We also thank Michael N. Mitchell, author of the Stata Press books Data Management Using Stata: A Practical Handbook and A Visual Guide to Stata Graphics, for his generous advice and comprehensive insight into the application of margins and their plots.

**matsize — Set the maximum number of variables in a model**

### Syntax

```
set matsize # [, permanently ]
```

where $10 \leq # \leq 11000$ for Stata/MP and Stata/SE and where $10 \leq # \leq 800$ for Stata/IC.

### Description

The `set matsize` command sets the maximum number of variables that can be included in any of Stata’s estimation commands.

For Stata/MP and Stata/SE, the default value is 400, but it may be changed upward or downward. The upper limit is 11,000.

For Stata/IC, the initial value is 400, but it may be changed upward or downward. The upper limit is 800.

This command may not be used with Small Stata; `matsize` is permanently frozen at 100. Changing `matsize` has no effect on Mata.

### Option

The `permanently` option specifies that, in addition to making the change right now, the `matsize` setting be remembered and become the default setting when you invoke Stata.

### Remarks and examples

The `set matsize` command controls the internal size of matrices that Stata uses. The default of 400 for Stata/IC, for instance, means that linear regression models are limited to 198 independent variables—198 because the constant uses one position and the dependent variable another, making a total of 200.

You may change `matsize` with data in memory, but increasing `matsize` increases the amount of memory consumed by Stata, increasing the probability of page faults and thus of making Stata run more slowly.

#### Example 1

We wish to fit a model of $y$ on the variables $x_1$ through $x_{400}$. Without thinking, we type

```
. regress y x1-x400
matsize too small
    You have attempted to create a matrix with more than 400 rows or columns
    or to fit a model with more than 400 variables plus ancillary parameters.
    You need to increase matsize by using the set matsize command; see help matsize.

r(908);
```
We realize that we need to increase `matsize`, so we type

```
. set matsize 450
. regress y x1-x400
(output omitted)
```

Programmers should note that the current setting of `matsize` is stored as the c-class value `c(matsize)`; see [P] `creturn`.

## Description

All Stata commands maximize likelihood functions using `moptimize()` and `optimize()`; see *Methods and formulas* below. Commands use the Newton–Raphson method with step halving and special fixups when they encounter nonconcave regions of the likelihood. For details, see [M-5] `moptimize()` and [M-5] `optimize()`. For more information about programming maximum likelihood estimators in ado-files and Mata, see [R] `ml` and the fourth edition of *Maximum Likelihood Estimation with Stata* (Gould, Pitblado, and Poi 2010).

*set maxiter* specifies the default maximum number of iterations for estimation commands that iterate. The initial value is 16000, and # can be 0 to 16000. To change the maximum number of iterations performed by a particular estimation command, you need not reset *maxiter*; you can specify the `iterate(#)` option. When `iterate(#)` is not specified, the *maxiter* value is used.

## Maximization options

*difficult* specifies that the likelihood function is likely to be difficult to maximize because of nonconcave regions. When the message “not concave” appears repeatedly, *ml*’s standard stepping algorithm may not be working well. *difficult* specifies that a different stepping algorithm be used in nonconcave regions. There is no guarantee that *difficult* will work better than the default; sometimes it is better and sometimes it is worse. You should use the *difficult* option only when the default stepper declares convergence and the last iteration is “not concave” or when the default stepper is repeatedly issuing “not concave” messages and producing only tiny improvements in the log likelihood.

*technique(algorithm_spec)* specifies how the likelihood function is to be maximized. The following algorithms are allowed. For details, see Gould, Pitblado, and Poi (2010).

*`technique(nr)`* specifies Stata’s modified Newton–Raphson (NR) algorithm.

*`technique(bhhh)`* specifies the Berndt–Hall–Hall–Hausman (BHHH) algorithm.

*`technique(dfp)`* specifies the Davidon–Fletcher–Powell (DFP) algorithm.

*`technique(bfgs)`* specifies the Broyden–Fletcher–Goldfarb–Shanno (BFGS) algorithm.

The default is `technique(nr)`.

You can switch between algorithms by specifying more than one in the `technique()` option. By default, an algorithm is used for five iterations before switching to the next algorithm. To specify a different number of iterations, include the number after the `technique` in the option. For example, specifying `technique(bhhh 10 nr 1000)` requests that *ml* perform 10 iterations with the BHHH algorithm followed by 1000 iterations with the NR algorithm, and then switch back to BHHH for 10 iterations, and so on. The process continues until convergence or until the maximum number of iterations is reached.
iterate(#) specifies the maximum number of iterations. When the number of iterations equals iterate(), the optimizer stops and presents the current results. If convergence is declared before this threshold is reached, it will stop when convergence is declared. Specifying iterate(0) is useful for viewing results evaluated at the initial value of the coefficient vector. Specifying iterate(0) and from() together allows you to view results evaluated at a specified coefficient vector; however, not all commands allow the from() option. The default value of iterate(#) for both estimators programmed internally and estimators programmed with ml is the current value of set maxiter, which is iterate(16000) by default.

log and nolog specify whether an iteration log showing the progress of the log likelihood is to be displayed. For most commands, the log is displayed by default, and nolog suppresses it. For a few commands (such as the svy maximum likelihood estimators), you must specify log to see the log.

trace adds to the iteration log a display of the current parameter vector.

gradient adds to the iteration log a display of the current gradient vector.

showstep adds to the iteration log a report on the steps within an iteration. This option was added so that developers at StataCorp could view the stepping when they were improving the ml optimizer code. At this point, it mainly provides entertainment.

hessian adds to the iteration log a display of the current negative Hessian matrix.

showtolerance adds to the iteration log the calculated value that is compared with the effective convergence criterion at the end of each iteration. Until convergence is achieved, the smallest calculated value is reported.

shownrtolerance is a synonym of showtolerance.

Below we describe the three convergence tolerances. Convergence is declared when the nrtolerance() criterion is met and either the tolerance() or the ltolerance() criterion is also met.

tolerance(#) specifies the tolerance for the coefficient vector. When the relative change in the coefficient vector from one iteration to the next is less than or equal to tolerance(), the tolerance() convergence criterion is satisfied.

tolerance(1e-4) is the default for estimators programmed with ml.

tolerance(1e-6) is the default.

ltolerance(#) specifies the tolerance for the log likelihood. When the relative change in the log likelihood from one iteration to the next is less than or equal to ltolerance(), the ltolerance() convergence is satisfied.

ltolerance(0) is the default for estimators programmed with ml.

ltolerance(1e-7) is the default.

nrtolerance(#) specifies the tolerance for the scaled gradient. Convergence is declared when $gH^{-1}g' < nrtolerance()$. The default is nrtolerance(1e-5).

qtolerance(#) when specified with algorithms bhhh, dfp, or bfgs uses the $q-H$ matrix as the final check for convergence rather than nrtolerance() and the $H$ matrix.

Beginning with Stata 12, by default, Stata now computes the $H$ matrix when the $q-H$ matrix passes the convergence tolerance, and Stata requires that $H$ be concave and pass the nrtolerance() criterion before concluding convergence has occurred.

qtolerance() provides a way for the user to obtain Stata’s earlier behavior.
nonrtolerance specifies that the default nrtolerance() criterion be turned off.

from() specifies initial values for the coefficients. Not all estimators in Stata support this option. You can specify the initial values in one of three ways: by specifying the name of a vector containing the initial values (for example, from(b0), where b0 is a properly labeled vector); by specifying coefficient names with the values (for example, from(age=2.1 /sigma=7.4)); or by specifying a list of values (for example, from(2.1 7.4, copy)). from() is intended for use when doing bootstraps (see [R] bootstrap) and in other special situations (for example, with iterate(0)). Even when the values specified in from() are close to the values that maximize the likelihood, only a few iterations may be saved. Poor values in from() may lead to convergence problems.

skip specifies that any parameters found in the specified initialization vector that are not also found in the model be ignored. The default action is to issue an error message.

copy specifies that the list of values or the initialization vector be copied into the initial-value vector by position rather than by name.

Option for set maxiter

permanently specifies that, in addition to making the change right now, the maxiter setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

Only in rare circumstances would you ever need to specify any of these options, except nolog. The nolog option is useful for reducing the amount of output appearing in log files.

The following is an example of an iteration log:

<table>
<thead>
<tr>
<th>Iteration</th>
<th>log likelihood</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>-3791.0251</td>
</tr>
<tr>
<td>1</td>
<td>-3761.738</td>
</tr>
<tr>
<td>2</td>
<td>-3758.0632 (not concave)</td>
</tr>
<tr>
<td>3</td>
<td>-3758.0447</td>
</tr>
<tr>
<td>4</td>
<td>-3757.5861</td>
</tr>
<tr>
<td>5</td>
<td>-3757.474</td>
</tr>
<tr>
<td>6</td>
<td>-3757.4613</td>
</tr>
<tr>
<td>7</td>
<td>-3757.4606</td>
</tr>
<tr>
<td>8</td>
<td>-3757.4606</td>
</tr>
</tbody>
</table>

At iteration 8, the model converged. The message “not concave” at the second iteration is notable. This example was produced using the heckman command; its likelihood is not globally concave, so it is not surprising that this message sometimes appears. The other message that is occasionally seen is “backed up”. Neither of these messages should be of any concern unless they appear at the final iteration.

If a “not concave” message appears at the last step, there are two possibilities. One is that the result is valid, but there is collinearity in the model that the command did not otherwise catch. Stata checks for obvious collinearity among the independent variables before performing the maximization, but strange collinearities or near collinearities can sometimes arise between coefficients and ancillary parameters. The second, more likely cause for a “not concave” message at the final step is that the optimizer entered a flat region of the likelihood and prematurely declared convergence.

If a “backed up” message appears at the last step, there are also two possibilities. One is that Stata found a perfect maximum and could not step to a better point; if this is the case, all is fine, but this is a highly unlikely occurrence. The second is that the optimizer worked itself into a bad concave spot where the computed gradient and Hessian gave a bad direction for stepping.
If either of these messages appears at the last step, perform the maximization again with the gradient option. If the gradient goes to zero, the optimizer has found a maximum that may not be unique but is a maximum. From the standpoint of maximum likelihood estimation, this is a valid result. If the gradient is not zero, it is not a valid result, and you should try tightening up the convergence criterion, or try ltol(0) tol(1e-7) to see if the optimizer can work its way out of the bad region.

If you get repeated “not concave” steps with little progress being made at each step, try specifying the difficult option. Sometimes difficult works wonderfully, reducing the number of iterations and producing convergence at a good (that is, concave) point. Other times, difficult works poorly, taking much longer to converge than the default stepper.

### Stored results

Maximum likelihood estimators store the following in e():

**Scalars**

- `e(N)` number of observations always stored
- `e(k)` number of parameters always stored
- `e(k_eq)` number of equations in e(b) usually stored
- `e(k_eq_model)` number of equations in overall model test usually stored
- `e(k_dv)` number of dependent variables usually stored
- `e(df_m)` model degrees of freedom always stored
- `e(r2_p)` pseudo-$R$-squared sometimes stored
- `e(ll)` log likelihood always stored
- `e(ll_0)` log likelihood, constant-only model stored when constant-only model is fit
- `e(N_clust)` number of clusters stored when vce(cluster clustvar) is specified; see [U] 20.21 Obtaining robust variance estimates
- `e(chi2)` $\chi^2$ usually stored
- `e(p)` significance of model of test usually stored
- `e(rank)` rank of e(V) always stored
- `e(rank0)` rank of e(V) for constant-only model stored when constant-only model is fit
- `e(ic)` number of iterations usually stored
- `e(rc)` return code usually stored
- `e(converged)` 1 if converged, 0 otherwise usually stored
Macros

- `e(cmd)` name of command always stored
- `e(cmdline)` command as typed always stored
- `e(depvar)` names of dependent variables always stored
- `e(wtype)` weight type stored when weights are specified or implied
- `e(wexp)` weight expression stored when weights are specified or implied
- `e(title)` title in estimation output usually stored by commands using `ml`
- `e(clustvar)` name of cluster variable stored when `vce(cluster clustvar)` is specified; see [U] 20.21 Obtaining robust variance estimates
- `e(chi2type)` Wald or LR; type of model \( \chi^2 \) test usually stored
- `e(vce)` vcetype specified in `vce()` stored when command allows (`vce()`) stored when command allows (`vce()`) always stored
- `e(vcetype)` title used to label Std. Err. sometimes stored
- `e(opt)` type of optimization always stored
- `e(which)` max or min; whether optimizer is to perform maximization or minimization always stored
- `e(ml_method)` type of ml method always stored by commands using `ml`
- `e(user)` name of likelihood-evaluator program always stored
- `e(technique)` from `technique()` option sometimes stored
- `e(singularH_method)` m-marquardt or hybrid; method sometimes stored\(^1\) used when Hessian is singular
- `e(crittype)` optimization criterion always stored\(^1\)
- `e(properties)` estimator properties always stored
- `e(predict)` program used to implement `predict` usually stored

Matrices

- `e(b)` coefficient vector always stored
- `e(Cns)` constraints matrix sometimes stored
- `e(ilog)` iteration log (up to 20 iterations) usually stored
- `e(gradient)` gradient vector usually stored
- `e(V)` variance–covariance matrix of the estimators always stored
- `e(V_modelbased)` model-based variance only stored when `e(V)` is neither the OIM nor OPG variance

Functions

- `e(sample)` marks estimation sample always stored

---

1. Type `ereturn list, all` to view these results; see [P] return.

See Stored results in the manual entry for any maximum likelihood estimator for a list of returned results.

Methods and formulas

Optimization is currently performed by `moptimize()` and `optimize()`, with the former implemented in terms of the latter; see [M-5] `moptimize()` and [M-5] `optimize()`. Some estimators use `moptimize()` and `optimize()` directly, and others use the `ml` ado-file interface to `moptimize()`.

Prior to Stata 11, Stata had three separate optimization engines: an internal one used by estimation commands implemented in C code; `ml` implemented in ado-code separately from `moptimize()` and used by most estimators; and `moptimize()` and `optimize()` used by a few recently written
estimators. These days, the internal optimizer and the old version of ml are used only under version control. In addition, arch and arima (see [TS] arch and [TS] arima) are currently implemented using the old ml.

Let $L_1$ be the log likelihood of the full model (that is, the log-likelihood value shown on the output), and let $L_0$ be the log likelihood of the “constant-only” model. The likelihood-ratio $\chi^2$ model test is defined as $2(L_1 - L_0)$. The pseudo-$R^2$ (McFadden 1974) is defined as $1 - L_1/L_0$. This is simply the log likelihood on a scale where 0 corresponds to the “constant-only” model and 1 corresponds to perfect prediction for a discrete model (in which case the overall log likelihood is 0).

Some maximum likelihood routines can report coefficients in an exponentiated form, for example, odds ratios in logistic. Let $b$ be the unexponentiated coefficient, $s$ its standard error, and $b_0$ and $b_1$ the reported confidence interval for $b$. In exponentiated form, the point estimate is $e^b$, the standard error $e^b s$, and the confidence interval $e^{b_0}$ and $e^{b_1}$. The displayed $Z$ (or $t$) statistics and $p$-values are the same as those for the unexponentiated results. This is justified because $e^b = 1$ and $b = 0$ are equivalent hypotheses, and normality is more likely to hold in the $b$ metric.

Statistics >> Summaries, tables, and tests >> Summary and descriptive statistics >> Means
Description

**mean** produces estimates of means, along with standard errors.

Options

```
Model

stdize(varname) specifies that the point estimates be adjusted by direct standardization across the strata identified by varname. This option requires the stdweight() option.

stdweight(varname) specifies the weight variable associated with the standard strata identified in the stdize() option. The standardization weights must be constant within the standard strata.

nostdrescale prevents the standardization weights from being rescaled within the over() groups. This option requires stdize() but is ignored if the over() option is not specified.

if/in/over

over(varlist [, nolabel]) specifies that estimates be computed for multiple subpopulations, which are identified by the different values of the variables in varlist.

When this option is supplied with one variable name, such as over(varname), the value labels of varname are used to identify the subpopulations. If varname does not have labeled values (or there are unlabeled values), the values themselves are used, provided that they are nonnegative integers. Noninteger values, negative values, and labels that are not valid Stata names are substituted with a default identifier.

When over() is supplied with multiple variable names, each subpopulation is assigned a unique default identifier.

nolabel requests that value labels attached to the variables identifying the subpopulations be ignored.

SE/Cluster

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (analytic), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

vce(analytic), the default, uses the analytically derived variance estimator associated with the sample mean.

Reporting

level(#) ; see [R] estimation options.

noheader prevents the table header from being displayed. This option implies nolegend.

nolegend prevents the table legend identifying the subpopulations from being displayed.

display_options: cformat(%,fmt) and nolstretch; see [R] estimation options.

The following option is available with mean but is not shown in the dialog box:

coeflegend; see [R] estimation options.
Remarks and examples

Example 1

Using the fuel data from example 3 of [R] ttest, we estimate the average mileage of the cars without the fuel treatment (mpg1) and those with the fuel treatment (mpg2).

```
. use http://www.stata-press.com/data/r13/fuel
. mean mpg1 mpg2
Mean estimation Number of obs = 12

<table>
<thead>
<tr>
<th></th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg1</td>
<td>21</td>
<td>.7881701</td>
<td>19.26525 22.73475</td>
</tr>
<tr>
<td>mpg2</td>
<td>22.75</td>
<td>.9384465</td>
<td>20.68449 24.81551</td>
</tr>
</tbody>
</table>
```

Using these results, we can test the equality of the mileage between the two groups of cars.

```
. test mpg1 = mpg2
( 1) mpg1 - mpg2 = 0
F( 1, 11) = 5.04
Prob > F = 0.0463
```

Example 2

In example 1, the joint observations of mpg1 and mpg2 were used to estimate a covariance between their means.

```
. matrix list e(V)
symmetric e(V)[2,2]
   mpg1    mpg2
mpg1 .62121212
mpg2 .4469697  .88068182
```

If the data were organized this way out of convenience but the two variables represent independent samples of cars (coincidentally of the same sample size), we should reshape the data and use the `over()` option to ensure that the covariance between the means is zero.

```
. use http://www.stata-press.com/data/r13/fuel
. stack mpg1 mpg2, into(mpg) clear
. mean mpg, over(_stack)
Mean estimation Number of obs = 24

<table>
<thead>
<tr>
<th>Over</th>
<th></th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>1:</td>
<td>_stack = 1</td>
<td>21</td>
<td>.7881701</td>
<td>19.36955 22.63045</td>
</tr>
<tr>
<td>2:</td>
<td>_stack = 2</td>
<td>22.75</td>
<td>.9384465</td>
<td>20.80868 24.69132</td>
</tr>
</tbody>
</table>
```
Now we can test the equality of the mileage between the two independent groups of cars.

```
> . test [mpg]1 = [mpg]2
  ( 1) [mpg]1 - [mpg]2 = 0
  F(  1,  23) = 2.04
  Prob > F = 0.1667
```

> Example 3: standardized means

Suppose that we collected the blood pressure data from example 2 of [R] dstdize, and we wish to obtain standardized high blood pressure rates for each city in 1990 and 1992, using, as the standard, the age, sex, and race distribution of the four cities and two years combined. Our rate is really the mean of a variable that indicates whether a sampled individual has high blood pressure. First, we generate the strata and weight variables from our standard distribution, and then use mean to compute the rates.

```
> . use http://www.stata-press.com/data/r13/hbp, clear
> . egen strata = group(age race sex) if inlist(year, 1990, 1992)
>  (675 missing values generated)
> . by strata, sort: gen stdw = _N
> . mean hbp, over(city year) stdize(strata) stdweight(stdw)

Mean estimation
N. of std strata = 24 Number of obs = 455
Over: city year
  _subpop_1: 1 1990
  _subpop_2: 1 1992
  _subpop_3: 2 1990
  _subpop_4: 2 1992
  _subpop_5: 3 1990
  _subpop_6: 3 1992
  _subpop_7: 5 1990
  _subpop_8: 5 1992

<table>
<thead>
<tr>

</tbody>
</table>
```

The standard error of the high blood pressure rate estimate is missing for city 5 in 1992 because there was only one individual with high blood pressure; that individual was the only person observed in the stratum of white males 30–35 years old.
By default, `mean` rescales the standard weights within the `over()` groups. In the following, we use the `nostdrescale` option to prevent this, thus reproducing the results in [R] `dstdize`.

```
. mean hbp, over(city year) nolegend stdize(strata) stdweight(stdw)
> nostdrescale

**Video example**

Descriptive statistics in Stata

**Stored results**

`mean` stores the following in `e()`:

Scalars
- `e(N)` number of observations
- `e(N_over)` number of subpopulations
- `e(N_stdize)` number of standard strata
- `e(N_clust)` number of clusters
- `e(k_eq)` number of equations in `e(b)`
- `e(df_r)` sample degrees of freedom
- `e(rank)` rank of `e(V)`

Macros
- `e(cmd)` `mean`
- `e(cmdline)` command as typed
- `e(varlist)` `varlist`
- `e(stdize)` `varname` from `stdize()`
- `e(stdweight)` `varname` from `stdweight()`
- `e(vtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(cluster)` name of cluster variable
- `e(over)` `varlist` from `over()`
- `e(over_labels)` labels from `over()` variables
- `e(over_namelist)` names from `e(over_labels)`
- `e(vce)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(properties)` `b V`
- `e(estat_cmd)` program used to implement `estat`
- `e(marginsnotok)` predictions disallowed by `margins`
Matrices
- \( e(b) \) vector of mean estimates
- \( e(V) \) (co)variance estimates
- \( e(_N) \) vector of numbers of nonmissing observations
- \( e(_N\_stdsum) \) number of nonmissing observations within the standard strata
- \( e(_p\_stdize) \) standardizing proportions
- \( e(error) \) error code corresponding to \( e(b) \)

Functions
- \( e(sample) \) marks estimation sample

Methods and formulas

Methods and formulas are presented under the following headings:

- The mean estimator
- Survey data
- The survey mean estimator
- The standardized mean estimator
- The poststratified mean estimator
- The standardized poststratified mean estimator
- Subpopulation estimation

The mean estimator

Let \( y \) be the variable on which we want to calculate the mean and \( y_j \) an individual observation on \( y \), where \( j = 1, \ldots, n \) and \( n \) is the sample size. Let \( w_j \) be the weight, and if no weight is specified, define \( w_j = 1 \) for all \( j \). For \textit{aweights}, the \( w_j \) are normalized to sum to \( n \). See The survey mean estimator for \textit{pweighted} data.

Let \( W \) be the sum of the weights

\[
W = \sum_{j=1}^{n} w_j
\]

The mean is defined as

\[
\bar{y} = \frac{1}{W} \sum_{j=1}^{n} w_j y_j
\]

The default variance estimator for the mean is

\[
\hat{V}(\bar{y}) = \frac{1}{W(W-1)} \sum_{j=1}^{n} w_j (y_j - \bar{y})^2
\]

The standard error of the mean is the square root of the variance.

If \( x, x_j, \) and \( \bar{x} \) are similarly defined for another variable (observed jointly with \( y \)), the covariance estimator between \( \bar{x} \) and \( \bar{y} \) is

\[
\hat{\text{Cov}}(\bar{x}, \bar{y}) = \frac{1}{W(W-1)} \sum_{j=1}^{n} w_j (x_j - \bar{x})(y_j - \bar{y})
\]
Survey data

See [SVY] variance estimation, [SVY] direct standardization, and [SVY] poststratification for discussions that provide background information for the following formulas. The following formulas are derived from the fact that the mean is a special case of the ratio estimator where the denominator variable is one, \( x_j = 1 \); see [R] ratio.

The survey mean estimator

Let \( Y_j \) be a survey item for the \( j \)th individual in the population, where \( j = 1, \ldots, M \) and \( M \) is the size of the population. The associated population mean for the item of interest is \( \bar{Y} = Y/M \) where

\[
Y = \sum_{j=1}^{M} Y_j
\]

Let \( y_j \) be the survey item for the \( j \)th sampled individual from the population, where \( j = 1, \ldots, m \) and \( m \) is the number of observations in the sample.

The estimator for the mean is \( \bar{y} = \hat{Y}/\hat{M} \), where

\[
\hat{Y} = \sum_{j=1}^{m} w_j y_j \quad \text{and} \quad \hat{M} = \sum_{j=1}^{m} w_j
\]

and \( w_j \) is a sampling weight. The score variable for the mean estimator is

\[
z_j(\bar{y}) = \frac{y_j - \bar{y}}{\bar{M}} = \frac{\hat{M} y_j - \hat{Y}}{\hat{M}^2}
\]

The standardized mean estimator

Let \( D_g \) denote the set of sampled observations that belong to the \( g \)th standard stratum and define \( I_{D_g}(j) \) to indicate if the \( j \)th observation is a member of the \( g \)th standard stratum; where \( g = 1, \ldots, L_D \) and \( L_D \) is the number of standard strata. Also, let \( \pi_g \) denote the fraction of the population that belongs to the \( g \)th standard stratum, thus \( \pi_1 + \cdots + \pi_{L_D} = 1 \). \( \pi_g \) is derived from the stdweight() option.

The estimator for the standardized mean is

\[
\bar{y}_D = \sum_{g=1}^{L_D} \pi_g \frac{\hat{Y}_g}{\hat{M}_g}
\]

where

\[
\hat{Y}_g = \sum_{j=1}^{m} I_{D_g}(j) w_j y_j \quad \text{and} \quad \hat{M}_g = \sum_{j=1}^{m} I_{D_g}(j) w_j
\]

The score variable for the standardized mean is

\[
z_j(\bar{y}_D) = \sum_{g=1}^{L_D} \pi_g I_{D_g}(j) \frac{\hat{M}_g y_j - \hat{Y}_g}{\hat{M}_g^2}
\]
The poststratified mean estimator

Let $P_k$ denote the set of sampled observations that belong to poststratum $k$ and define $I_{P_k}(j)$ to indicate if the $j$th observation is a member of poststratum $k$; where $k = 1, \ldots, L_P$ and $L_P$ is the number of poststrata. Also let $M_k$ denote the population size for poststratum $k$. $P_k$ and $M_k$ are identified by specifying the poststrata() and postweight() options on svyset; see [SVY] svyset.

The estimator for the poststratified mean is

$$\bar{y}^P = \frac{\hat{Y}^P}{M^P} = \frac{\hat{Y}^P}{M}$$

where

$$\hat{Y}^P = \sum_{k=1}^{L_P} \frac{M_k}{M} \hat{Y}_k = \sum_{k=1}^{L_P} \frac{M_k}{M} \sum_{j=1}^{m} I_{P_k}(j) w_j y_j$$

and

$$M^P = \sum_{k=1}^{L_P} \frac{M_k}{M} M_k = \sum_{k=1}^{L_P} M_k = M$$

The score variable for the poststratified mean is

$$z_j(\bar{y}^P) = \frac{z_j(\hat{Y}^P)}{M} = \frac{1}{M} \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{M_k} \left( y_j - \hat{Y}_k \right)$$

The standardized poststratified mean estimator

The estimator for the standardized poststratified mean is

$$\bar{y}^{DP} = \sum_{g=1}^{L_D} \pi_g \frac{\hat{Y}_g^P}{M_g^P}$$

where

$$\hat{Y}_g^P = \sum_{k=1}^{L_p} \frac{M_k}{M} \hat{Y}_{g,k} = \sum_{k=1}^{L_p} \frac{M_k}{M} \sum_{j=1}^{m} I_{D_g}(j) I_{P_k}(j) w_j y_j$$

and

$$M_g^P = \sum_{k=1}^{L_p} \frac{M_k}{M} M_{g,k} = \sum_{k=1}^{L_p} M_k \sum_{j=1}^{m} I_{D_g}(j) I_{P_k}(j) w_j$$

The score variable for the standardized poststratified mean is

$$z_j(\bar{y}^{DP}) = \sum_{g=1}^{L_D} \pi_g \frac{\hat{M}_g^P z_j(\hat{Y}_g^P) - \hat{Y}_g^P z_j(\hat{M}_g^P)}{(\hat{M}_g^P)^2}$$

where

$$z_j(\hat{Y}_g^P) = \sum_{k=1}^{L_p} I_{P_k}(j) \frac{M_k}{M_k} \left\{ I_{D_g}(j) y_j - \frac{\hat{Y}_{g,k}}{M_k} \right\}$$

and

$$z_j(\hat{M}_g^P) = \sum_{k=1}^{L_p} I_{P_k}(j) \frac{M_k}{M_k} \left\{ I_{D_g}(j) - \frac{\hat{M}_{g,k}}{M_k} \right\}$$
Subpopulation estimation

Let $S$ denote the set of sampled observations that belong to the subpopulation of interest, and define $I_S(j)$ to indicate if the $j$th observation falls within the subpopulation.

The estimator for the subpopulation mean is $\tilde{Y}^S = \hat{Y}^S / \hat{M}^S$, where

$$\hat{Y}^S = \sum_{j=1}^{m} I_S(j) w_j y_j \quad \text{and} \quad \hat{M}^S = \sum_{j=1}^{m} I_S(j) w_j$$

Its score variable is

$$z_j(\tilde{Y}^S) = I_S(j) \frac{y_j - \bar{y}^S}{\bar{M}^S} = I_S(j) \frac{\hat{M}^S y_j - \hat{Y}^S}{(\bar{M}^S)^2}$$

The estimator for the standardized subpopulation mean is

$$\bar{y}^{DS} = \sum_{g=1}^{L_D} \pi_g \frac{\hat{Y}^S_g}{\hat{M}^S_g}$$

where

$$\hat{Y}^S_g = \sum_{j=1}^{m} I_{D_g}(j) I_S(j) w_j y_j \quad \text{and} \quad \hat{M}^S_g = \sum_{j=1}^{m} I_{D_g}(j) I_S(j) w_j$$

Its score variable is

$$z_j(\bar{y}^{DS}) = \sum_{g=1}^{L_D} \pi_g I_{D_g}(j) I_S(j) \frac{\hat{M}^S_g y_j - \hat{Y}^S_g}{(\hat{M}^S_g)^2}$$

The estimator for the poststratified subpopulation mean is

$$\bar{y}^{PS} = \frac{\hat{Y}^{PS}}{\hat{M}^{PS}}$$

where

$$\hat{Y}^{PS} = \sum_{k=1}^{L_P} \frac{M_k}{\hat{M}_k} \hat{Y}_k^S = \sum_{k=1}^{L_P} \frac{M_k}{\hat{M}_k} \sum_{j=1}^{m} I_{P_k}(j) I_S(j) w_j y_j$$

and

$$\hat{M}^{PS} = \sum_{k=1}^{L_P} \frac{M_k}{\hat{M}_k} \hat{M}_k^S = \sum_{k=1}^{L_P} \frac{M_k}{\hat{M}_k} \sum_{j=1}^{m} I_{P_k}(j) I_S(j) w_j$$

Its score variable is

$$z_j(\bar{y}^{PS}) = \frac{\hat{M}^{PS} z_j(\hat{Y}^{PS}) - \hat{Y}^{PS} z_j(\hat{M}^{PS})}{(\hat{M}^{PS})^2}$$

where

$$z_j(\hat{Y}^{PS}) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{\hat{M}_k} \left\{ I_S(j) y_j - \frac{\hat{Y}_k^S}{\hat{M}_k} \right\}$$
and

\[
    z_j(\widehat{M}^{PS}) = \sum_{k=1}^{L_p} I_{P_k}(j) \frac{M_k}{M} \left\{ I_S(j) - \frac{\widehat{M}^{S}}{M_k} \right\}
\]

The estimator for the standardized poststratified subpopulation mean is

\[
    \overline{y}_{DPS} = \sum_{g=1}^{L_D} \pi_g \frac{\widehat{Y}_{PS}^g}{\overline{M}^{PS}_g}
\]

where

\[
    \widehat{Y}_{g}^{PS} = \sum_{k=1}^{L_p} \frac{M_k}{M} \widehat{Y}_{g,k}^S = \sum_{k=1}^{L_p} \frac{M_k}{M_k} \sum_{j=1}^{m} I_{D_g}(j) I_{P_k}(j) I_S(j) \cdot w_j \cdot y_j
\]

and

\[
    \overline{M}^{PS}_g = \sum_{k=1}^{L_p} \frac{M_k}{M} \overline{M}^{S}_{g,k} = \sum_{k=1}^{L_p} \frac{M_k}{M_k} \sum_{j=1}^{m} I_{D_g}(j) I_{P_k}(j) I_S(j) \cdot w_j
\]

Its score variable is

\[
    z_j(\overline{y}^{DPS}) = \sum_{g=1}^{L_D} \pi_g \frac{\overline{M}^{PS}_g z_j(\widehat{Y}_{g}^{PS}) - \widehat{Y}_{g}^{PS} z_j(\overline{M}^{PS}_g)}{(\overline{M}^{PS}_g)^2}
\]

where

\[
    z_j(\widehat{Y}_{g}^{PS}) = \sum_{k=1}^{L_p} I_{P_k}(j) \frac{M_k}{M} \left\{ I_{D_g}(j) I_S(j) \cdot y_j - \frac{\widehat{Y}_{g,k}^S}{M_k} \right\}
\]

and

\[
    z_j(\overline{M}^{PS}_g) = \sum_{k=1}^{L_p} I_{P_k}(j) \frac{M_k}{M} \left\{ I_{D_g}(j) I_S(j) - \frac{\overline{M}^{S}_{g,k}}{M_k} \right\}
\]

Title

**mean postestimation** — Postestimation tools for mean

**Description**

The following postestimation commands are available after `mean`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>lincom</code></td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td><code>nlcom</code></td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

**Remarks and examples**

**Example 1**

We have a dataset with monthly rates of returns on the Dow and NASDAQ stock indices. We can use `mean` to compute the average quarterly rates of return for the two indices separately:

```
. use http://www.stata-press.com/data/r13/rates
. mean dow nasdaq
```

<table>
<thead>
<tr>
<th>Mean estimation</th>
<th>Number of obs = 357</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Mean</td>
</tr>
<tr>
<td>Dow</td>
<td>.2489137</td>
</tr>
<tr>
<td>Nasdaq</td>
<td>10.78477</td>
</tr>
</tbody>
</table>

If you chose just one of the indices for your portfolio, you either did rather well or rather poorly, depending on which one you picked. However, as we now show with the postestimation command `lincom`, if you diversified your portfolio, you would have earned a respectable 5.5% rate of return without having to guess which index would be the better performer.
. lincom .5*dow + .5*nasdaq
( 1) .5*dow + .5*nasdaq = 0

|    | Coef. | Std. Err. | t    | P>|t| | [95% Conf. Interval] |
|----|-------|-----------|------|-----|---------------------|
| (1)| 5.51684 | 4.262673 | 1.29 | 0.196 | -2.866347 to 13.90003 |

Remarks and examples

Stata does not have a meta-analysis command. Stata users, however, have developed an excellent suite of commands for performing meta-analysis, including commands for performing standard and cumulative meta-analysis, commands for producing forest plots and contour-enhanced funnel plots, and commands for nonparametric analysis of publication bias.

Many articles describing these commands have been published in the *Stata Technical Bulletin* and the *Stata Journal*. These articles were updated and published in a cohesive collection: *Meta-Analysis in Stata: An Updated Collection from the Stata Journal*.

In this collection, editor Jonathan Sterne discusses how these articles relate to each other and how they fit in the overall literature of meta-analysis. Sterne has organized the collection into four areas: classic meta-analysis; meta-regression; graphical and analytic tools for detecting bias; and recent advances such as meta-analysis for dose–response curves, diagnostic accuracy, multivariate analysis, and studies containing missing values.

All meta-analysis commands discussed in this collection may be downloaded by visiting [http://www.stata-press.com/books/mais.html](http://www.stata-press.com/books/mais.html).

We highly recommend that Stata users interested in meta-analysis read this book. Since the publication of the meta-analysis collection, Kontopantelis and Reeves (2010) published an article in the *Stata Journal* describing a new command *metaan* that performs fixed- or random-effects meta-analysis.

Please also see the following FAQ on the Stata website:

What meta-analysis features are available in Stata?

All weight types supported by `regression_cmd` are allowed; see [U] 11.1.6 weight.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
`fp generate` may be used to create new variables containing fractional polynomial powers. See [R] fp.
mfp — Multivariable fractional polynomial models

where

\textit{regression\_cmd} may be \texttt{clogit}, \texttt{glm}, \texttt{intreg}, \texttt{logistic}, \texttt{logit}, \texttt{mlogit}, \texttt{nbreg}, \texttt{ologit}, \texttt{oprobit}, \texttt{poisson}, \texttt{probit}, \texttt{qreg}, \texttt{regress}, \texttt{rreg}, \texttt{stcox}, \texttt{stcrreg}, \texttt{streg}, or \texttt{xtgee}.

\texttt{yvar} \texttt{1} is not allowed for \texttt{streg}, \texttt{stcrreg}, and \texttt{stcox}. For these commands, you must first \texttt{stset} your data.

\texttt{yvar} \texttt{1} and \texttt{yvar} \texttt{2} must both be specified when \textit{regression\_cmd} is \texttt{intreg}.

\texttt{xvarlist} has elements of type \texttt{varlist} and/or (\texttt{varlist}), for example, x1 x2 (x3 x4 x5). Elements enclosed in parentheses are tested jointly for inclusion in the model and are not eligible for fractional polynomial transformation.

\section*{Menu}

Statistics > Linear models and related > Fractional polynomials > Multivariable fractional polynomial models

\section*{Description}

\texttt{mfp} selects the multivariable fractional polynomial (MFP) model that best predicts the outcome variable from the right-hand-side variables in \texttt{xvarlist}.

For univariate fractional polynomials, \texttt{fp} can be used to fit a wider range of models than \texttt{mfp}. See \texttt{[R] fp} for more details.

\section*{Options}

\begin{itemize}
  \item \texttt{sequential} chooses the sequential fractional polynomial (FP) selection algorithm (see \textit{Methods of FP model selection}).
  \item \texttt{cycles(\#)} sets the maximum number of iteration cycles permitted. \texttt{cycles(5)} is the default.
  \item \texttt{dfdefault(\#)} determines the default maximum degrees of freedom (df) for a predictor. The default is \texttt{dfdefault(4)} (second-degree FP).
  \item \texttt{center(cent\_list)} defines the centering of the covariates \texttt{xvar} \texttt{1}, \texttt{xvar} \texttt{2}, \ldots{} of \texttt{xvarlist}. The default is \texttt{center(mean)}, except for binary covariates, where it is \texttt{center(#)}, with \# being the lower of the two distinct values of the covariate. A typical item in \texttt{cent\_list} is \texttt{varlist:\{mean\mid #\mid no\}}. Items are separated by commas. The first item is special in that \texttt{varlist} is optional, and if it is omitted, the default is reset to the specified value (\texttt{mean}, \#, or \texttt{no}). For example, \texttt{center(no, age:mean)} sets the default to \texttt{no} (that is, no centering) and the centering of \texttt{age} to \texttt{mean}.
  \item \texttt{alpha(alpha\_list)} sets the significance levels for testing between FP models of different degrees. The rules for \texttt{alpha\_list} are the same as those for \texttt{df\_list} in the \texttt{df()} option (see below). The default nominal \(p\)-value (significance level, selection level) is 0.05 for all variables.
    \begin{itemize}
      \item Example: \texttt{alpha(0.01)} specifies that all variables have an FP selection level of 1%.
      \item Example: \texttt{alpha(0.05, weight:0.1)} specifies that all variables except \texttt{weight} have an FP selection level of 5%; \texttt{weight} has a level of 10%.
    \end{itemize}
\end{itemize}
df(df_list) sets the df for each predictor. The df (not counting the regression constant, _cons) is twice the degree of the FP, so, for example, an xvar fit as a second-degree FP (FP²) has 4 df. The first item in df_list may be either # or varlist:#. Subsequent items must be varlist:#. Items are separated by commas, and varlist is specified in the usual way for variables. With the first type of item, the df for all predictors is taken to be #. With the second type of item, all members of varlist (which must be a subset of xvarlist) have # df.

The default number of degrees of freedom for a predictor of type varlist specified in xvarlist but not in df_list is assigned according to the number of distinct (unique) values of the predictor, as follows:

<table>
<thead>
<tr>
<th># of distinct values</th>
<th>Default df</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>(invalid predictor)</td>
</tr>
<tr>
<td>2–3</td>
<td>1</td>
</tr>
<tr>
<td>4–5</td>
<td>min(2, dfdefault())</td>
</tr>
<tr>
<td>≥ 6</td>
<td>dfdefault()</td>
</tr>
</tbody>
</table>

Example: df(4)
All variables have 4 df.

Example: df(2, weight displ:4)
weight and displ have 4 df; all other variables have 2 df.

Example: df(weight displ:4, mpg:2)
weight and displ have 4 df, mpg has 2 df; all other variables have default df.

powers(numlist) is the set of FP powers to be used. The default set is −2, −1, −0.5, 0, 0.5, 1, 2, 3 (0 means log).

xorder(+ | − | n) determines the order of entry of the covariates into the model-selection algorithm. The default is xorder(+), which enters them in decreasing order of significance in a multiple linear regression (most significant first). xorder(−) places them in reverse significance order, whereas xorder(n) respects the original order in xvarlist.

select(select_list) sets the nominal p-values (significance levels) for variable selection by backward elimination. A variable is dropped if its removal causes a nonsignificant increase in deviance. The rules for select_list are the same as those for df_list in the df() option (see above). Using the default selection level of 1 for all variables forces them all into the model. Setting the nominal p-value to be 1 for a given variable forces it into the model, leaving others to be selected or not. The nominal p-value for elements of xvarlist bound by parentheses is specified by including (varlist) in select_list.

Example: select(0.05)
All variables have a nominal p-value of 5%.

Example: select(0.05, weight:1)
All variables except weight have a nominal p-value of 5%; weight is forced into the model.

Example: select(a (b c):0.05)
All variables except a, b, and c are forced into the model. b and c are tested jointly with 2 df at the 5% level, and a is tested singly at the 5% level.
`xpowers(xp_list)` sets the permitted FP powers for covariates individually. The rules for `xp_list` are the same as for `df_list` in the `df()` option. The default selection is the same as that for the `powers()` option.

Example: `xpowers(-1 0 1)`
All variables have powers $-1, 0, 1$.

Example: `xpowers(x5:-1 0 1)`
All variables except `x5` have default powers; `x5` has powers $-1, 0, 1$.

`zero(varlist)` treats negative and zero values of members of `varlist` as zero when FP transformations are applied. By default, such variables are subjected to a preliminary linear transformation to avoid negative and zero values, as described in the `scale` option of `fp`. `varlist` must be part of `xvarlist`.

`catzero(varlist)` is a variation on `zero()`; see Zeros and zero categories below. `varlist` must be part of `xvarlist`.

`regression_cmd_options` may be any of the options appropriate to `regression_cmd`.

`all` includes out-of-sample observations when generating the FP variables. By default, the generated FP variables contain missing values outside the estimation sample.

---

`level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [U] 20.7 Specifying the width of confidence intervals.

`display_options`: `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] estimation options.

**Remarks and examples**

Remarks are presented under the following headings:

- Iteration report
- Estimation algorithm
- Methods of FP model selection
- Zeros and zero categories

For elements in `xvarlist` not enclosed in parentheses, `mfp` leaves variables in the data named `Ixvar__1`, `Ixvar__2`, ..., where `xvar` represents the first four letters of the name of `xvar1`, and so on, for `xvar2`, `xvar3`, etc. The new variables contain the best-fitting FP powers of `xvar1`, `xvar2`, ....

**Iteration report**

By default, for each continuous predictor, `x`, `mfp` compares null, linear, and FP1 models for `x` with an FP2 model. The deviance for each of these nested submodels is given in the column labeled “Deviance”. The line labeled “Final” gives the deviance for the selected model and its powers. All the other predictors currently selected are included, with their transformations (if any). For models specified as having 1 df, the only choice is whether the variable enters the model.
Estimation algorithm

The estimation algorithm in \texttt{mfp} processes the \texttt{xvars} in turn. Initially, \texttt{mfp} silently arranges \texttt{xvarlist} in order of increasing \textit{p}-value (that is, of decreasing statistical significance) for omitting each predictor from the model comprising \texttt{xvarlist}, with each term linear. The aim is to model relatively important variables before unimportant ones. This approach may help to reduce potential model-fitting difficulties caused by collinearity or, more generally, “concurvity” among the predictors. See the \texttt{xorder()} option above for details on how to change the ordering.

At the initial cycle, the best-fitting FP function for \texttt{xvar}$_1$ (the first of \texttt{xvarlist}) is determined, with all the other variables assumed to be linear. Either the default or the alternative procedure is used (see \textit{Methods of FP model selection} below). The functional form (but not the estimated regression coefficients) for \texttt{xvar}$_1$ is kept, and the process is repeated for \texttt{xvar}$_2$, \texttt{xvar}$_3$, etc. The first iteration concludes when all the variables have been processed in this way. The next cycle is similar, except that the functional forms from the initial cycle are retained for all variables except the one currently being processed.

A variable whose functional form is prespecified to be linear (that is, to have 1 df) is tested for exclusion within the above procedure when its nominal \textit{p}-value (selection level) according to \texttt{select()} is less than 1; otherwise, it is included.

Updating of FP functions and candidate variables continues until the functions and variables included in the overall model do not change (convergence). Convergence is usually achieved within 1–4 cycles.

Methods of FP model selection

\texttt{mfp} includes two algorithms for FP model selection, both of which combine backward elimination with the selection of an FP function. For each continuous variable in turn, they start from a most-complex permitted FP model and attempt to simplify the model by reducing the degree. The default algorithm resembles a closed-test procedure, a sequence of tests maintaining the overall type I error rate at a prespecified nominal level, such as 5%. All significance tests are approximate; therefore, the algorithm is not precisely a closed-test procedure (Royston and Sauerbrei 2008, chap. 6).

The closed-test algorithm for choosing an FP model with maximum permitted degree $m = 2$ (that is, an FP2 model with 4 df) for one continuous predictor, \texttt{x}, is as follows:

1. Inclusion: Test FP2 against the null model for \texttt{x} on 4 df at the significance level determined by \texttt{select()}. If \texttt{x} is significant, continue; otherwise, drop \texttt{x} from the model.
2. Nonlinearity: Test FP2 against a straight line in \texttt{x} on 3 df at the significance level determined by \texttt{alpha()}. If significant, continue; otherwise, stop, with the chosen model for \texttt{x} being a straight line.
3. Simplification: Test FP2 against FP1 on 2 df at the significance level determined by \texttt{alpha()}. If significant, the final model is FP2; otherwise, it is FP1.

The first step is omitted if \texttt{x} is to be retained in the model, that is, if its nominal \textit{p}-value, according to the \texttt{select()} option, is 1.

An alternative algorithm is available with the \texttt{sequential} option, as originally suggested by Royston and Altman (1994):

1. Test FP2 against FP1 on 2 df at the \texttt{alpha()} significance level. If significant, the final model is FP2; otherwise, continue.
2. Test FP1 against a straight line on 1 df at the \texttt{alpha()} level. If significant, the final model is FP1; otherwise, continue.
3. Test a straight line against omitting $x$ on 1 df at the `select()` level. If significant, the final model is a straight line; otherwise, drop $x$.

The final step is omitted if $x$ is to be retained in the model, that is, if its nominal $p$-value, according to the `select()` option, is 1.

If $x$ is uninfluential, the overall type I error rate of this procedure is about double that of the closed-test procedure, for which the rate is close to the nominal value. This inflated type I error rate confers increased apparent power to detect nonlinear relationships.

Zeros and zero categories

The `zero()` option permits fitting an FP model to the positive values of a covariate, taking nonpositive values as zero. An application is the assessment of the effect of cigarette smoking as a risk factor in an epidemiological study. Nonsmokers may be qualitatively different from smokers, so the effect of smoking (regarded as a continuous variable) may not be continuous between one and zero cigarettes. To allow for this, the risk may be modeled as constant for the nonsmokers and as an FP function of the number of cigarettes for the smokers:

```stata
. generate byte nonsmkr = cond(n_cigs==0, 1, 0) if n_cigs != .
. mfp, zero(n_cigs) df(4, nonsmkr:1): logit case n_cigs nonsmkr age
```

Omission of `zero(n_cigs)` would cause `n_cigs` to be transformed before analysis by the addition of a suitable constant, probably 1.

A closely related approach involves the `catzero()` option. The command

```stata
. mfp, catzero(n_cigs): logit case n_cigs age
```

would achieve a similar result to the previous command but with important differences. First, `mfp` would create the equivalent of the binary variable `nonsmkr` automatically and include it in the model. Second, the two smoking variables would be treated as one predictor in the model. With the `select()` option active, the two variables would be tested jointly for inclusion in the model. A modified version is described in Royston and Sauerbrei (2008, sec. 4.15).

Example 1

We illustrate two of the analyses performed by Sauerbrei and Royston (1999). We use `brcancer.dta`, which contains prognostic factors data from the German Breast Cancer Study Group of patients with node-positive breast cancer. The response variable is recurrence-free survival time (`rectime`), and the censoring variable is `censrec`. There are 686 patients with 299 events. We use Cox regression to predict the log hazard of recurrence from prognostic factors of which five are continuous (`x1`, `x3`, `x5`, `x6`, `x7`) and three are binary (`x2`, `x4a`, `x4b`). Hormonal therapy (`hormon`) is known to reduce recurrence rates and is forced into the model. We use `mfp` to build a model from the initial set of eight predictors by using the backfitting model-selection algorithm. We set the nominal $p$-value for variable and FP selection to 0.05 for all variables except hormon, which it is set to 1:

```stata
. use http://www.stata-press.com/data/r13/brcancer
   (German breast cancer data)
. stset rectime, fail(censrec)
   (output omitted)
```
. mfp, alpha(.05) select(.05, hormon:1): stcox x1 x2 x3 x4a x4b x5 x6 x7 hormon,
> nohr

| hormon  | -0.402419| .1280843 | -3.14 | 0.002| -.6534575 -.1513763 |

Deviance: 3420.724.

Some explanation of the output from the model-selection algorithm is desirable. Consider the first few lines of output in the iteration log:

1. Deviance for model with all terms untransformed = 3471.637, 686 observations

   Variable | Model (vs.) | Deviance | Dev diff. | P     | Powers (vs.) |
   ---------|-------------|----------|-----------|-------|--------------|
   x5       | null FP2    | 3503.610 | 61.366    | 0.000*| .5            |
   x4a      | lin.        | 3471.637 | 29.393    | 0.000+| 1             |
   x4b      | FP1         | 3449.203 | 6.959     | 0.031+| 0             |
   x5       | Final       | 3442.244 |           |       | .5            |

Line 1 gives the deviance ($-2 \times \log$ partial likelihood) for the Cox model with all terms linear, the place where the algorithm starts. The model is modified variable by variable in subsequent steps. The most significant linear term turns out to be x5, which is therefore processed first. Line 2 compares the best-fitting FP2 for x5 with a model omitting x5. The FP has powers (0.5, 3), and the test for inclusion of x5 is highly significant. The reported deviance of 3,503.610 is of the null model, not for the FP2 model. The deviance for the FP2 model may be calculated by subtracting the deviance
difference (Dev diff.) from the reported deviance, giving 3,503.610 − 61.366 = 3,442.244. Line 3 shows that the FP2 model is also a significantly better fit than a straight line (lin.) and line 4 that FP2 is also somewhat better than FP1 \((p = 0.031)\). Thus at this stage in the model-selection procedure, the final model for \(x5\) (line 5) is FP2 with powers \((0.5, 3)\). The overall model with an FP2 for \(x5\) and all other terms linear has a deviance of 3,442.244.

After all the variables have been processed (cycle 1) and reprocessed (cycle 2) in this way, convergence is achieved because the functional forms (FP powers and variables included) after cycle 2 are the same as they were after cycle 1. The model finally chosen is Model II as given in tables 3 and 4 of Sauerbrei and Royston (1999). Because of scaling of variables, the regression coefficients reported there are different, but the model and its deviance are identical. The model includes \(x1\) with powers \((-2, -0.5)\), \(x4a\), \(x5\) with powers \((-2, -1)\), and \(x6\) with power 0.5. There is strong evidence of nonlinearity for \(x1\) and for \(x5\), the deviance differences for comparison with a straight-line model (FP2 vs lin.) being, respectively, 19.3 and 31.1 at convergence (cycle 2). Predictors \(x2\), \(x3\), \(x4b\), and \(x7\) are dropped, as may be seen from their status out in the table Final multivariable fractional polynomial model for \(t\) (the assumed depvar when using stcox).

All predictors except \(x4a\) and hormon, which are binary, have been centered on the mean of the original variable. For example, the mean of \(x1\) (age) is 53.05 years. The first FP-transformed variable for \(x1\) is \(x1^{-2}\) and is created by the expression `gen double Ix1__1 = X^-2-.0355 if e(sample)` The value 0.0355 is obtained from \((53.05/10)^{-2}\). The division by 10 is applied automatically to improve the scaling of the regression coefficient for \(Ix1__1\).

According to Sauerbrei and Royston (1999), medical knowledge dictates that the estimated risk function for \(x5\) (number of positive nodes), which was based on the above FP with powers \((-2, -1)\), should be monotonic, but it was not. They improved Model II by estimating a preliminary exponential transformation, \(x5e = \exp(-0.12 \cdot x5)\), for \(x5\) and fitting a degree 1 FP for \(x5e\), thus obtaining a monotonic risk function. The value of \(-0.12\) was estimated univariately using nonlinear Cox regression with the ado-file `boxtid` (Royston and Ambler 1999b, 1999d). To ensure a negative exponent, Sauerbrei and Royston (1999) restricted the powers for \(x5e\) to be positive. Their Model III may be fit by using the following command:

```
. mfp, alpha(.05) select(.05, hormon:1) df(x5e:2) xpowers(x5e:0.5 1 2 3):
> stcox x1 x2 x3 x4a x4b x5e x6 x7 hormon
```

Other than the customization for \(x5e\), the command is the same as it was before. The resulting model is as reported in table 4 of Sauerbrei and Royston (1999):
. use http://www.stata-press.com/data/r13/brcancer, clear
(German breast cancer data)
. stset rectime, fail(censrec)
(output omitted)
. mfp, alpha(.05) select(.05, hormon:1) df(x5e:2) xpowers(x5e:0.5 1 2 3):
> stcox x1 x2 x3 x4a x4b x5e x6 x7 hormon, nohr
(output omitted)

Stored results

In addition to what `regression_cmd` stores, `mfp` stores the following in `e()`:

Scalars
- `e(fp_nx)` number of predictors in `xvarlist`
- `e(fp_dev)` deviance of final model fit
- `e(Fp_id#)` initial degrees of freedom for the `#`th element of `xvarlist`
- `e(Fp_fd#)` final degrees of freedom for the `#`th element of `xvarlist`
- `e(Fp_al#)` FP selection level for the `#`th element of `xvarlist`
- `e(Fp_se#)` backward elimination selection level for the `#`th element of `xvarlist`

Macros
- `e(fp_cmd)` `fracpoly`
- `e(fp_cmd2)` `mfp`
- `e(cmdline)` command as typed
- `e(fracpoly)` command used to fit the selected model using `fracpoly`
- `e(fp_fvl)` variables in final model
- `e(fp_depv)` `yvar1` (`yvar2`)
- `e(fp_opts)` estimation command options
- `e(fp_x1)` first variable in `xvarlist`
- `e(fp_x2)` second variable in `xvarlist`
- `...`
- `e(fp_xN)` last variable in `xvarlist`, `N=e(fp_nx)`
- `e(fp_k1)` power for first variable in `xvarlist` (*)
- `e(fp_k2)` power for second variable in `xvarlist` (*)
- `...`
- `e(fp_kN)` power for last var. in `xvarlist` (*), `N=e(fp_nx)`

Note: (*) contains ‘.’ if the variable is not selected in the final model.

Acknowledgments

`mfp` is an update of `mfracpol` by Royston and Ambler (1998).

**Special-interest postestimation commands**

`fracplot` plots the data and fit, with 95% confidence limits, from the most recently fit fractional polynomial (FP) model. The data and fit are plotted against `varname`, which may be `xvar_1` or another of the covariates (`xvar_2`, ..., or a variable from `xvarlist`). If `varname` is not specified, `xvar_1` is assumed.

`fracpred` creates `newvar` containing the fitted index or deviance residuals for the whole model, or the fitted index or its standard error for `varname`, which may be `xvar_1` or another covariate.
Syntax for fracplot and fracpred

Plot data and fit from most recently fit fractional polynomial model

```
fracplot [varname] [if] [in] [, fracplot_options]
```

Create variable containing the prediction, deviance residuals, or SEs of fitted values

```
fracpred newvar [, fracpred_options]
```

Statistics > Linear models and related > Fractional polynomials > Multivariable fractional polynomial prediction

Options for fracplot

Plot
marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.

marker_label_options specify if and how the markers are to be labeled; see [G-3] marker_label_options.

Fitted line
lineopts(cline_options) affect the rendition of the fitted line; see [G-3] cline_options.

CI plot
ciopts(area_options) affect the rendition of the confidence bands; see [G-3] area_options.

Add plots
addplot(plot) provides a way to add other plots to the generated graph. See [G-3] addplot_option.

Y axis, X axis, Titles, Legend, Overall
twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Options for fracpred

for(varname) specifies (partial) prediction for variable varname. The fitted values are adjusted to the value specified by the center() option in mfp.

dresid specifies that deviance residuals be calculated.

stdp specifies calculation of the standard errors of the fitted values varname, adjusted for all the other predictors at the values specified by center().

Remarks and examples

fracplot actually produces a component-plus-residual plot. For normal-error models with constant weights and one covariate, this amounts to a plot of the observations with the fitted line inscribed. For other normal-error models, weighted residuals are calculated and added to the fitted values.

For models with additional covariates, the line is the partial linear predictor for the variable in question (xvar_1 or a covariate) and includes the intercept $\beta_0$. 
For generalized linear and Cox models, the fitted values are plotted on the scale of the “index” (linear predictor). Deviance residuals are added to the (partial) linear predictor to give component-plus-residual values. These values are plotted as small circles.

**Example 1**

In example 1 of [R] mfp, we used Cox regression to predict the log hazard of breast cancer recurrence from prognostic factors of which five are continuous (x1, x3, x5, x6, x7) and three are binary (x2, x4a, x4b). We also controlled for hormonal therapy (hormon). We used mfp to build a model from the initial set of eight predictors by using the backfitting model-selection algorithm. The nominal p-value for variable and FP selection was set to 0.05 for all variables except hormon, which is set to 1.

```
. use http://www.stata-press.com/data/r13/brcancer
   (German breast cancer data)
. stset rectime, fail(censrec)
   (output omitted)
. mfp, alpha(.05) select(.05, hormon:1): stcox x1 x2 x3 x4a x4b x5 x6 x7 hormon,
    > nohr
   (output omitted)
```

We can use fracplot to produce component-plus-residual plots of the continuous variables. We produce the component-plus-residual plot for x1 with fracplot by specifying x1 after the command name.

```
. fracplot x1
```

![Fractional Polynomial plot](image)

We use fracpred with the stdp option to predict the standard error of the fractional polynomial prediction for x1. The standard error prediction will be stored in variable sepx1. We specify that prediction is made for x1 with the for() option. After prediction, we use summarize to show how the standard error estimate varies over different values of x1.

```
. fracpred sepx1, stdp for(x1)
. summarize sepx1
```

Methods and formulas

The general definition of an FP, accommodating possible repeated powers, may be written for functions $H_1(x), \ldots, H_m(x)$ as

$$
\beta_0 + \sum_{j=1}^{m} \beta_j H_j(x)
$$

where $H_1(x) = x^{(p_1)}$ and for $j = 2, \ldots, m$,

$$
H_j(x) = \begin{cases} 
  x^{(p_j)} & \text{if } p_j \neq p_j-1 \\
  H_{j-1}(x) \log x & \text{if } p_j = p_j-1
\end{cases}
$$

For example, an FP of degree 3 with powers $(1, 3, 3)$ has $H_1(x) = x$, $H_2(x) = x^3$, and $H_3(x) = x^3 \log x$ and equals $\beta_0 + \beta_1 x + \beta_2 x^3 + \beta_3 x^3 \log x$.

The component-plus-residual values graphed by `fracplot` are calculated as follows: Let the data consist of triplets $(y_i, x_i, z_i)$, $i = 1, \ldots, n$, where $z_i$ is the vector of covariates for the $i$th observation, after applying possible fractional polynomial transformation and adjustment as described earlier. Let $\hat{\eta}_i = \hat{\beta}_0 + \{\textbf{H}(x_i) - \textbf{H}(x_0)\}'\hat{\beta} + z_i'\hat{\gamma}$ be the linear predictor from the FP model, as given by the `fracpred` command or, equivalently, by the `predict` command with the `xb` option, following `mfp`. Here $\textbf{H}(x_i) = \{H_1(x_i), \ldots, H_m(x_i)\}'$ is the vector of FP functions described above, $\textbf{H}(x_0) = \{H_1(x_0), \ldots, H_m(x_0)\}'$ is the vector of adjustments to $x_0$ (often, $x_0$ is chosen to be the mean of the $x_i$), $\hat{\beta}$ is the estimated parameter vector, and $\hat{\gamma}$ is the estimated parameter vector for the covariates. The values $\hat{\eta}_i^* = \hat{\beta}_0 + \{\textbf{H}(x_i) - \textbf{H}(x_0)\}'\hat{\beta}$ represent the behavior of the FP model for $x$ at fixed values $z = 0$ of the (adjusted) covariates. The $i$th component-plus-residual is defined as $\hat{\eta}_i^* + d_i$, where $d_i$ is the deviance residual for the $i$th observation. For normal-errors models, $d_i = \sqrt{w_i}(y_i - \hat{\eta}_i)$, where $w_i$ is the case weight (or 1, if `weight` is not specified). For logistic, Cox, and generalized linear regression models, see [R] logistic, [R] probit, [ST] stcox, and [R] glm for the formula for $d_i$. The formula for poisson models is the same as that for glm with `family(poisson)`. For stcox, $d_i$ is the partial martingale residual (see [ST] stcox_postestimation).

`fracplot` plots the values of $d_i$ and the curve represented by $\hat{\eta}_i^*$ against $x_i$. The confidence interval for $\hat{\eta}_i^*$ is obtained from the variance–covariance matrix of the entire model and takes into account the uncertainty in estimating $\beta_0$, $\beta$, and $\gamma$ (but not in estimating the FP powers for $x$).

`fracpred` with the `for(varname)` option calculates the predicted index at $x_i = x_0$ and $z_i = 0$; that is, $\hat{\eta}_i = \hat{\beta}_0 + \{\textbf{H}(x_i) - \textbf{H}(x_0)\}'\hat{\beta}$. The standard error is calculated from the variance–covariance matrix of $(\hat{\beta}_0, \hat{\beta})$, again ignoring estimation of the powers.

In addition, programmer's option `nopreserve` is allowed with all syntaxes; see [P] `nopreserve` option.

**Menu**

Statistics > Summaries, tables, and tests > Other tables > Tabulate missing values

**Description**

`misstable` makes tables that help you understand the pattern of missing values in your data.

**Options**

Options are presented under the following headings:

- Options for `misstable summarize`
- Options for `misstable patterns`
- Options for `misstable tree`
- Option for `misstable nested`
- Common options

**Options for misstable summarize**

- `all` specifies that the table should include all the variables specified or all the variables in the dataset. The default is to include only numeric variables that contain missing values.
- `showzeros` specifies that zeros in the table should display as 0 rather than being omitted.
- `generate(stub [, exok])` requests that a missing-value indicator `newvar`, a new binary variable containing 0 for complete observations and 1 for incomplete observations, be generated for every numeric variable in `varlist` containing missing values. If the `all` option is specified, missing-value indicators are created for all the numeric variables specified or for all the numeric variables in the dataset. If `exok` is specified within `generate()`, the extended missing values `.a, .b, ..., .z` are treated as if they do not designate missing.

  For each variable in `varlist`, `newvar` is the corresponding variable name `varname` prefixed with `stub`. If the total length of `stub` and `varname` exceeds 32 characters, `newvar` is abbreviated so that its name does not exceed 32 characters.

**Options for misstable patterns**

- `asis`, `frequency`, and `exok` – see Common options below.
- `replace` specifies that the data in memory be replaced with a dataset corresponding to the table just displayed; see misstable patterns under Remarks and examples below.
- `clear` is for use with `replace`; it specifies that it is okay to change the data in memory even if they have not been saved to disk.
bypatterns specifies the table be ordered by pattern rather than by frequency. That is, bypatterns specifies that patterns containing one incomplete variable be listed first, followed by those for two incomplete variables, and so on. The default is to list the most frequent pattern first, followed by the next most frequent pattern, etc.

Options for misstable tree

asis, frequency, and exok – see Common options below.

Option for misstable nested

exok – see Common options below.

Common options

asis specifies that the order of the variables in the table be the same as the order in which they are specified on the misstable command. The default is to order the variables by the number of missing values, and within that, by the amount of overlap of missing values.

frequency specifies that the table should report frequencies instead of percentages.

exok specifies that the extended missing values .a, .b, ..., .z should be treated as if they do not designate missing. Some users use extended missing values to designate values that are missing for a known and valid reason.

nopreserve is a programmer’s option allowed with all misstable commands; see [P] nopreserve option.

Remarks and examples

Remarks are presented under the following headings:

misstable summarize
misstable patterns
misstable tree
misstable nested
Execution time of misstable nested

In what follows, we will use data from a 125-observation, fictional, student-satisfaction survey:

. use http://www.stata-press.com/data/r13/studentsurvey
(Student Survey)
. summarize

<table>
<thead>
<tr>

<td>0</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The m1 and m2 variables record the student’s satisfaction with teaching and with academics. comment is a string variable recording any comments the student might have had.
misstable summarize

Example 1

misstable summarize reports counts of missing values:

```
. misstable summarize

  Variable | Obs=. | Obs> | Obs< | Unique values | Min | Max
-----------|-------|------|------|---------------|-----|-----
   age     |  3    | 122  |  5   | 5             |  17 | 21
  female  |  3    | 122  |  2   | 2             |  0  |  1
     dept  |  9    | 116  |  4   | 4             |  1  |  4
```

Stata provides 27 different missing values, namely, ., .a, .b, .c, .d, ..., .z. The first of those, ., is often called system missing. The remaining missing values are called extended missings. The nonmissing and missing values are ordered `nonmissing < . < .a < .b < ... < .z`. Thus reported in the column “Obs=.” are counts of system missing values; in the column “Obs>.”, extended missing values; and in the column “Obs<.”, nonmissing values.

The rightmost portion of the table is included to remind you how the variables are encoded.

Our data contain seven variables and yet misstable reported only three of them. The omitted variables contain no missing values or are string variables. Even if we specified the varlist explicitly, those variables would not appear in the table unless we specified the `all` option.

We can also create missing-value indicators for each of the variables above using the `generate()` option:

```
. quietly misstable summarize, generate(miss_)
. describe miss_*
```

<table>
<thead>
<tr>
<th>variable name</th>
<th>storage</th>
<th>display</th>
<th>value</th>
</tr>
</thead>
<tbody>
<tr>
<td>miss_age</td>
<td>byte</td>
<td>%8.0g</td>
<td>(age&gt;=.)</td>
</tr>
<tr>
<td>miss_female</td>
<td>byte</td>
<td>%8.0g</td>
<td>(female&gt;=.)</td>
</tr>
<tr>
<td>miss_dept</td>
<td>byte</td>
<td>%8.0g</td>
<td>(dept&gt;=.)</td>
</tr>
</tbody>
</table>

For each variable containing missing values, the `generate()` option creates a new binary variable containing 0 for complete observations and 1 for incomplete observations. In our example, three new missing-value indicators are generated, one for each of the incomplete variables age, female, and dept. The naming convention of `generate()` is to prefix the corresponding variable names with the specified `stub`, which is `miss_` in this example.

Missing-value indicators are useful, for example, for checking whether data are missing completely at random. They are also often used within the multiple-imputation context to identify the observed and imputed data; see [MI] intro substantive for a general introduction to multiple imputation. Within Stata’s multiple-imputation commands, an incomplete value is identified by the system missing value, a dot. By default, misstable summarize, generate() marks the extended missing values as incomplete values, as well. You can use exok within generate() to treat extended missing values as complete when creating missing-value identifiers.
misstable patterns

Example 2

misstable patterns reports the pattern of missing values:

```
. misstable patterns

Missing-value patterns
(1 means complete)

<table>
<thead>
<tr>
<th>Percent</th>
<th>Pattern</th>
</tr>
</thead>
<tbody>
<tr>
<td>93%</td>
<td>1 1 1</td>
</tr>
<tr>
<td>5</td>
<td>1 1 0</td>
</tr>
<tr>
<td>2</td>
<td>0 0 0</td>
</tr>
</tbody>
</table>

Variables are (1) age (2) female (3) dept
```

There are three patterns in these data: (1,1,1), (1,1,0), and (0,0,0). By default, the rows of the table are ordered by frequency. In larger tables that have more patterns, it is sometimes useful to order the rows by pattern. We could have obtained that by typing `mi misstable patterns, bypatterns`.

In a pattern, 1 indicates that all values of the variable are nonmissing and 0 indicates that all values are missing. Thus pattern (1,1,1) means no missing values, and 93% of our data have that pattern. There are two patterns in which variables are missing, (1,1,0) and (0,0,0). Pattern (1,1,0) means that age is nonmissing, female is nonmissing, and dept is missing. The order of the variables in the patterns appears in the key at the bottom of the table. Five percent of the observations have pattern (1,1,0). The remaining 2% have pattern (0,0,0), meaning that all three variables contain missing.

As with `misstable summarize`, only numeric variables that contain missing are listed, so had we typed `misstable patterns comments age female offcampus dept`, we still would have obtained the same table. Variables that are automatically omitted contain no missing values or are string variables.

The variables in the table are ordered from lowest to highest frequency of missing values, although you cannot see that from the information presented in the table. The variables are ordered this way even if you explicitly specify the varlist with a different ordering. Typing `misstable patterns dept female age` would produce the same table as above. Specify the `asis` option if you want the variables in the order in which you specify them.

You can obtain a dataset of the patterns by specifying the `replace` option:

```
. misstable patterns, replace clear

Missing-value patterns
(1 means complete)

<table>
<thead>
<tr>
<th>Percent</th>
<th>Pattern</th>
</tr>
</thead>
<tbody>
<tr>
<td>93%</td>
<td>1 1 1</td>
</tr>
<tr>
<td>5</td>
<td>1 1 0</td>
</tr>
<tr>
<td>2</td>
<td>0 0 0</td>
</tr>
</tbody>
</table>

Variables are (1) age (2) female (3) dept
```

(summary data now in memory)
The differences between the dataset and the printed table are that 1) the dataset always records frequency and 2) the rows are reversed.

misstable tree

Example 3

misstable tree presents a tree view of the pattern of missing values:

```stata
. use http://www.stata-press.com/data/r13/studentsurvey, clear
(Student Survey)
. misstable tree, frequency
```

Nested pattern of missing values

<table>
<thead>
<tr>
<th>dept</th>
<th>age</th>
<th>female</th>
</tr>
</thead>
<tbody>
<tr>
<td>9</td>
<td>3</td>
<td>3</td>
</tr>
<tr>
<td></td>
<td>0</td>
<td></td>
</tr>
<tr>
<td>6</td>
<td>0</td>
<td></td>
</tr>
<tr>
<td>6</td>
<td></td>
<td></td>
</tr>
<tr>
<td>116</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>116</td>
<td>0</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td>116</td>
</tr>
</tbody>
</table>

(number missing listed first)

In this example, we specified the `frequency` option to see the table in frequency rather than percentage terms. In the table, each column sums to the total number of observations in the data, 125. Variables are ordered from those with the most missing values to those with the least. Start with the first column. The `dept` variable is missing in 9 observations and, farther down, the table reports that it is not missing in 116 observations.

Go back to the first row and read across, but only to the second column. The `dept` variable is missing in 9 observations. Within those 9, `age` is missing in 3 of them and is not missing in the remaining 6. Reading down the second column, within the 116 observations that `dept` is not missing, `age` is missing in 0 and not missing in 116.

Reading straight across the first row again, `dept` is missing in 9 observations, and within the 9, `age` is missing in 3, and within the 3, `female` is also missing in 3. Skipping down just a little, within the 6 observations for which `dept` is missing and `age` is not missing, `female` is not missing, too.
**misstable nested**

Example 4

`misstable nested` lists the nesting rules that describe the missing-value pattern,

```
1. female(3) <-> age(3) -> dept(9)
```

This line says that in observations in which `female` is missing, so is `age` missing, and vice versa, and in observations in which `age` (or `female`) is missing, so is `dept`. The numbers in parentheses are counts of the missing values. The `female` variable happens to be missing in 3 observations, and the same is true for `age`; the `dept` variable is missing in 9 observations. Thus `dept` is missing in the 3 observations for which `age` and `female` are missing, and in 6 more observations, too.

In these data, it turns out that the missing-value pattern can be summarized in one statement. In a larger dataset, you might see something like this:

```
1. female(50) <-> age(50) -> dept(120)
2. female(50) -> m1(58)
3. offcampus(11)
```

`misstable nested` accounts for every missing value. In the above, in addition to `female <-> age -> dept`, we have that `female -> m1`, and we have `offcampus`, the last all by itself. The last line says that the 11 missing values in `offcampus` are not themselves nested in the missing value of any other variable, nor do they imply the missing values in another variable. In some datasets, all the statements will be of this last form.

In our data, however, we have one statement:

```
1. female(3) <-> age(3) -> dept(9)
```

When the missing-value pattern can be summarized in one `misstable nested` statement, the pattern of missing values in the data is said to be monotone.

---

**Execution time of misstable nested**

The execution time of `misstable nested` is affected little by the number of observations but can grow quickly with the number of variables, depending on the fraction of missing values within variable. The execution time of the example above, which has 3 variables containing missing, is instant. In worst-case scenarios, with 500 variables, the time might be 25 seconds; with 1,000 variables, the execution time might be closer to an hour.

In situations where `misstable nested` takes a long time to complete, it will produce thousands of rules that will defy interpretation. A 523-variable dataset we have seen ran in 20 seconds and produced 8,040 rules. Although we spotted a few rules in the output that did not surprise us, such as the year of the date being missing implied that the month and the day were also missing, mostly the output was not helpful.

If you have such a dataset, we recommend you run `misstable` on groups of variables that you have reason to believe the pattern of missing values might be related.
Stored results

misstable summarize stores the following values of the last variable summarized in r():

Scalars
- \( r(N_{eq\_dot}) \) number of observations containing \( . \)
- \( r(N_{gt\_dot}) \) number of observations containing \( .a, .b, \ldots, .z \)
- \( r(N_{lt\_dot}) \) number of observations containing nonmissing
- \( r(K_{uniq}) \) number of unique, nonmissing values
- \( r(min) \) variable’s minimum value
- \( r(max) \) variable’s maximum value

Macros
- \( r(vartype) \) numeric, string, or none

\( r(K_{uniq}) \) contains \( . \) if the number of unique, nonmissing values is greater than 500. \( r(vartype) \) contains none if no variables are summarized, and in that case, the value of the scalars are all set to missing (\( . \)). Programmers intending to access results after misstable summarize should specify the all option.

misstable patterns stores the following in r():

Scalars
- \( r(N_{complete}) \) number of complete observations
- \( r(N_{incomplete}) \) number of incomplete observations
- \( r(K) \) number of patterns

Macros
- \( r(vars) \) variables used in order presented

\( r(N_{complete}) \) and \( r(N_{incomplete}) \) are defined with respect to the variables specified if variables were specified and otherwise, defined with respect to all the numeric variables in the dataset. \( r(N_{complete}) \) is the number of observations that contain no missing values.

misstable tree stores the following in r():

Macros
- \( r(vars) \) variables used in order presented

misstable nested stores the following in r():

Scalars
- \( r(K) \) number of statements

Macros
- \( r(stmt1) \) first statement
- \( r(stmt2) \) second statement
- \( \ldots \)
- \( r(stmt'R(K))' \) last statement
- \( r(stmt1wc) \) \( r(stmt1) \) with missing-value counts
- \( r(vars) \) variables considered

A statement is encoded “\( varname \), “\( varname \ op \ varname \)”, or “\( varname \ op \ varname \ op \ varname \ op \ varname \)”, and so on; \( op \) is either “\( -> \)” or “\( <-> \)”.

</tr>
</tbody>
</table>

**Syntax**

Linear spline with knots at specified points

```
mkspline newvar1 #1 [newvar2 #2 [...]] newvark = oldvar [if] [in] [, marginal displayknots]
```

Linear spline with knots equally spaced or at percentiles of data

```
mkspline stubname # = oldvar [if] [in] [weight] [, marginal pctl displayknots]
```

Restricted cubic spline

```
mkspline stubname = oldvar [if] [in] [weight], cubic [nknots(#) knots(numlist) displayknots]
```

*Weights* are allowed with the second and third syntax; see [U] 11.1.6 weight.

**Menu**

Data > Create or change data > Other variable-creation commands > Linear and cubic spline construction

**Description**

*mkspline* creates variables containing a linear spline or a restricted cubic spline of *oldvar*.

In the first syntax, *mkspline* creates *newvar1*, ..., *newvark* containing a linear spline of *oldvar* with knots at the specified #1, ..., #k−1.

In the second syntax, *mkspline* creates # variables named *stubname1*, ..., *stubname#* containing a linear spline of *oldvar*. The knots are equally spaced over the range of *oldvar* or are placed at the percentiles of *oldvar*.

In the third syntax, *mkspline* creates variables containing a restricted cubic spline of *oldvar*. This is also known as a natural spline. The location and spacing of the knots is determined by the specification of the *nknots()* and *knots()* options.
Options

`mkspline` allows with the first or second syntax. It specifies that the new variables be constructed so that, when used in estimation, the coefficients represent the change in the slope from the preceding interval. The default is to construct the variables so that, when used in estimation, the coefficients measure the slopes for the interval.

`displayknots` displays the values of the knots that were used in creating the linear or restricted cubic spline.

`pctile` is allowed only with the second syntax. It specifies that the knots be placed at percentiles of the data rather than being equally spaced over the range.

`nknots(#)` is allowed only with the third syntax. It specifies the number of knots that are to be used for a restricted cubic spline. This number must be between 3 and 7 unless the knot locations are specified using `knots()`. The default number of knots is 5.

`knots(numlist)` is allowed only with the third syntax. It specifies the exact location of the knots to be used for a restricted cubic spline. The values of these knots must be given in increasing order. When this option is omitted, the default knot values are based on Harrell’s recommended percentiles with the additional restriction that the smallest knot may not be less than the fifth-smallest value of `oldvar` and the largest knot may not be greater than the fifth-largest value of `oldvar`. If both `nknots()` and `knots()` are given, they must specify the same number of knots.

Remarks and examples

Remarks are presented under the following headings:

* Linear splines
  * Restricted cubic splines

**Linear splines**

Linear splines allow estimating the relationship between `y` and `x` as a piecewise linear function, which is a function composed of linear segments—straight lines. One linear segment represents the function for values of `x` below `x_0`, another linear segment handles values between `x_0` and `x_1`, and so on. The linear segments are arranged so that they join at `x_0`, `x_1`, ..., which are called the knots. An example of a piecewise linear function is shown below.

![A piecewise linear function](image)
Example 1

We wish to fit a model of log income on education and age by using a piecewise linear function for age:

\[ \lninc = b_0 + b_1 \text{educ} + f(\text{age}) + u \]

The knots are to be placed at 10-year intervals: 20, 30, 40, 50, and 60.

\[ \text{use http://www.stata-press.com/data/r13/mksp1} \]
\[ \text{mkspline age1 20 age2 30 age3 40 age4 50 age5 60 age6 = age, marginal} \]
\[ \text{regress lninc educ age1-age6} \]
\[ \text{(output omitted)} \]

Because we specified the \text{marginal} option, we could test whether the age effect is the same in the 30–40 and 40–50 intervals by asking whether the \text{age}4 coefficient is zero. With the \text{marginal} option, coefficients measure the change in slope from the preceding group. Specifying \text{marginal} changes only the interpretation of the coefficients; the same model is fit in either case. Without the \text{marginal} option, the interpretation of the coefficients would have been

\[
\frac{dy}{d\text{age}} = \begin{cases} 
  a_1 & \text{if } \text{age} < 20 \\
  a_2 & \text{if } 20 \leq \text{age} < 30 \\
  a_3 & \text{if } 30 \leq \text{age} < 40 \\
  a_4 & \text{if } 40 \leq \text{age} < 50 \\
  a_5 & \text{if } 50 \leq \text{age} < 60 \\
  a_6 & \text{otherwise}
\end{cases}
\]

With the \text{marginal} option, the interpretation is

\[
\frac{dy}{d\text{age}} = \begin{cases} 
  a_1 & \text{if } \text{age} < 20 \\
  a_1 + a_2 & \text{if } 20 \leq \text{age} < 30 \\
  a_1 + a_2 + a_3 & \text{if } 30 \leq \text{age} < 40 \\
  a_1 + a_2 + a_3 + a_4 & \text{if } 40 \leq \text{age} < 50 \\
  a_1 + a_2 + a_3 + a_4 + a_5 & \text{if } 50 \leq \text{age} < 60 \\
  a_1 + a_2 + a_3 + a_4 + a_5 + a_6 & \text{otherwise}
\end{cases}
\]

Example 2

Say that we have a binary outcome variable called \text{outcome}. We are beginning an analysis and wish to parameterize the effect of dosage on outcome. We wish to divide the data into five equal-width groups of dosage for the piecewise linear function.

\[ \text{use http://www.stata-press.com/data/r13/mksp2, clear} \]
\[ \text{mkspline dose 5 = dosage, displayknots} \]
\[ \begin{array}{cccc}
  \text{dosage} & \text{knot1} & \text{knot2} & \text{knot3} & \text{knot4} \\
  20 & 40 & 60 & 80 \\
\end{array} \]
\[ \text{(output omitted)} \]
mkspline dose 5 = dosage creates five variables—dose1, dose2, ..., dose5—equally spacing the knots over the range of dosage. Because dosage varied between 0 and 100, the mkspline command above has the same effect as typing

```
mkspline dose1 20 dose2 40 dose3 60 dose4 80 dose5 = dosage
```

The pctile option sets the knots to divide the data into five equal sample-size groups rather than five equal-width ranges. Typing

```
mkspline pctdose 5 = dosage, pctile displayknots
```

places the knots at the 20th, 40th, 60th, and 80th percentiles of the data.

### Restricted cubic splines

A linear spline can be used to fit many functions well. However, a restricted cubic spline may be a better choice than a linear spline when working with a very curved function. When using a restricted cubic spline, one obtains a continuous smooth function that is linear before the first knot, a piecewise cubic polynomial between adjacent knots, and linear again after the last knot.

#### Example 3

Returning to the data from example 1, we may feel that a curved function is a better fit. First, we will use the knots() option to specify the five knots that we used previously.

```
use http://www.stata-press.com/data/r13/mksp1, clear
mkspline agesp = age, cubic knots(20 30 40 50 60)
regress lninc educ agesp*
```

Output omitted

Harrell (2001, 23) recommends placing knots at equally spaced percentiles of the original variable’s marginal distribution. If we do not specify the knots() option, variables will be created containing a restricted cubic spline with five knots determined by Harrell’s default percentiles.

```
use http://www.stata-press.com/data/r13/mksp1, clear
mkspline agesp = age, cubic displayknots
regress lninc educ agesp*
```

Output omitted

---

### Methods and formulas

Methods and formulas are presented under the following headings:

- Linear splines
- Restricted cubic splines
**Linear splines**

Let $V_i, i = 1, \ldots, n$, be the variables to be created; $k_i, i = 1, \ldots, n-1$, be the corresponding knots; and $V$ be the original variable (the command is `mkspline V_1 k_1 V_2 k_2 \ldots V_n = V$). Then

$$V_1 = \min(V, k_1)$$
$$V_i = \max\left\{\min(V, k_i), k_{i-1}\right\} - k_{i-1} \quad i = 2, \ldots, n-1$$
$$V_n = \max(V, k_{n-1}) - k_{n-1}$$

If the marginal option is specified, the definitions are

$$V_1 = V$$
$$V_i = \max(0, V - k_{i-1}) \quad i = 2, \ldots, n$$

In the second syntax, `mkspline stubname # = V`, so let $m$ and $M$ be the minimum and maximum of $V$. Without the `pctile` option, knots are set at $m + (M - m)(i/n)$ for $i = 1, \ldots, n-1$. If `pctile` is specified, knots are set at the 100$(i/n)$ percentiles, for $i = 1, \ldots, n-1$. Percentiles are calculated by `centile`; see [R] `centile`.

**Restricted cubic splines**

Let $k_i, i = 1, \ldots, n$, be the knot values; $V_i, i = 1, \ldots, n-1$, be the variables to be created; and $V$ be the original variable. Then

$$V_1 = V$$
$$V_{i+1} = \frac{(V - k_i)^3_+ - (k_n - k_{n-1})^{-1}\{(V - k_{n-1})^3_+ (k_n - k_i) - (V - k_n)^3_+ (k_{n-1} - k_i)\}}{(k_n - k_1)^2} \quad i = 1, \ldots, n-2$$

where

$$(u)_+ = \begin{cases} u, & \text{if } u > 0 \\ 0, & \text{if } u \leq 0 \end{cases}$$

Without the `knots()` option, the locations of the knots are determined by the percentiles recommended in Harrell (2001, 23). These percentiles are based on the chosen number of knots as follows:

<table>
<thead>
<tr>
<th>No. of knots</th>
<th>Percentiles</th>
</tr>
</thead>
<tbody>
<tr>
<td>3</td>
<td>10</td>
</tr>
<tr>
<td>4</td>
<td>5</td>
</tr>
<tr>
<td>5</td>
<td>5</td>
</tr>
<tr>
<td>6</td>
<td>5</td>
</tr>
<tr>
<td>7</td>
<td>2.5</td>
</tr>
</tbody>
</table>
Harrell provides default percentiles when the number of knots is between 3 and 7. When using a number of knots outside this range, the location of the knots must be specified in \texttt{knots()}. 

\section*{Acknowledgment}

The restricted cubic spline portion of \texttt{mkspline} is based on the \texttt{rc_spline} command by William Dupont of the Department of Biostatistics at Vanderbilt University.

fweights, aweights, iweights, and pweights are allowed; see [U] 11.1.6 weight. With all but method lf, you must write your likelihood-evaluation program carefully if pweights are to be specified, and pweights may not be specified with method d0, d1, d1debug, d2, or d2debug. See Gould, Pitblado, and Poi (2010, chap. 6) for details.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

To redisplay results, type `ml display`.

### Syntax of subroutines for use by evaluator programs

- **mleval**
  - `newvar = vecname [, eq(#)]`
- **mlsum**
  - `scalarname = vecname, scalar [eq(#)]`
  - `lnf = exp [if] [, noweight]`
- **mlvecsum**
  - `scalarname[rowvecname] = exp [if] [, eq(#)]`
- **mlmatsum**
  - `scalarname[matrixname] = exp [if] [, eq(#)]`
- **mlmatbysum**
  - `scalarname[matrixname varname] = exp [if] [varname]`, `by(varname) [eq(#)]`

### Syntax of user-written evaluator

#### Summary of notation

The log-likelihood function is $\ln L(\theta_{1j}, \theta_{2j}, \ldots, \theta_{Ej})$, where $\theta_{ij} = x_{ij} b_i$, $j = 1, \ldots, N$ indexes observations, and $i = 1, \ldots, E$ indexes the linear equations defined by `ml model`. If the likelihood satisfies the linear-form restrictions, it can be decomposed as $\ln L = \sum_{j=1}^{N} \ln \ell(\theta_{1j}, \theta_{2j}, \ldots, \theta_{Ej})$.

#### Method-lf evaluators

```plaintext

    ... // if you need to create any intermediate results:
    tempvar tmp1 tmp2 ...
    gen double `tmp1' = ...
    ...
    quietly replace `lnfj' = ...
    if (`todo'==0) exit
    quietly replace `g1' = formula for \partial \ln \ell_j / \partial \theta_{1j}
    quietly replace `g2' = formula for \partial \ln \ell_j / \partial \theta_{2j}
    ... end
```

where

- `todo' contains 0 or 1
  - 0⇒`lnfj' to be filled in;
  - 1⇒`lnfj', `g1', `g2' ..., to be filled in
- `b' full parameter row vector \( b=(b_1,b_2,...,b_E)\)
- `lnfj' variable to be filled in with observation-by-observation values of \( \ln \ell_j \)
- `g1' variable to be filled in with \( \partial \ln \ell_j / \partial \theta_{1j} \)
- `g2' variable to be filled in with \( \partial \ln \ell_j / \partial \theta_{2j} \)

Method-lf2 evaluators

```stata
program proname
    version 13
    args todo b lnfj g1 g2 ... H
    tempvar theta1 theta2 ...
    mleval `theta1' = `b', eq(1)
    mleval `theta2' = `b', eq(2) // if there is a \theta_2
    ... // if you need to create any intermediate results:
    tempvar tmp1 tmp2 ...
    gen double `tmp1' = ...
    ...
    quietly replace `lnfj' = ...
    if (`todo'==0) exit
    quietly replace `g1' = formula for \partial \ln \ell_j / \partial \theta_{1j}
    quietly replace `g2' = formula for \partial \ln \ell_j / \partial \theta_{2j}
    ... if (`todo'==1) exit
    tempname d11 d12 d22 lnf ...
    mlmatsum `lnf' `d11' = formula for \partial^2 \ln \ell_j / \partial \theta_{1j}^2, eq(1)
    mlmatsum `lnf' `d12' = formula for \partial^2 \ln \ell_j / \partial \theta_{1j} \partial \theta_{2j}, eq(1,2)
    mlmatsum `lnf' `d22' = formula for \partial^2 \ln \ell_j / \partial \theta_{2j}^2, eq(2)
    ... matrix `H'={({`d11'},`d12', ..., \`d12'),`d22', ...)
end
```
where

\[ \text{‘todo’} \]

contains 0 or 1

\[ 0 \Rightarrow \text{‘lnfj’} \text{to be filled in;} \]

\[ 1 \Rightarrow \text{‘lnfj’, ‘g1’, ‘g2’, ... , to be filled in} \]

\[ 2 \Rightarrow \text{‘lnfj’, ‘g1’, ‘g2’, ... , and ‘H’ to be filled in} \]

\[ \text{‘b’} \]

full parameter row vector \( b = (b_1, b_2, ..., b_E) \)

\[ \text{‘lnfj’} \]

scalar to be filled in with observation-by-observation \( \ln L \)

\[ \text{‘g1’} \]

variable to be filled in with \( \frac{\partial \ln L_j}{\partial \theta_1} \)

\[ \text{‘g2’} \]

variable to be filled in with \( \frac{\partial \ln L_j}{\partial \theta_2} \)

\[ ... \]

\[ \text{‘H’} \]

matrix to be filled in with overall Hessian \( H = \frac{\partial^2 \ln L}{\partial b \partial b'} \)

### Method-gf0 evaluators

```
program proname
    version 13
    args todo b lnfj
    tempvar theta1 theta2 ...
    mleval 'theta1' = 'b', eq(1)
    mleval 'theta2' = 'b', eq(2) // if there is a \( \theta_2 \)
    ...
    // if you need to create any intermediate results:
    tempvar tmp1 tmp2 ...
    gen double 'tmp1' = ...
    ...
    quietly replace 'lnfj' = ...
end
```

where

\[ \text{‘todo’} \]

always contains 0 (may be ignored)

\[ \text{‘b’} \]

full parameter row vector \( b = (b_1, b_2, ..., b_E) \)

\[ \text{‘lnfj’} \]

variable to be filled in with the values of the log-likelihood \( \ln L_j \)

### Global macros for use by all evaluators

\[ $ML_y1 \]

name of first dependent variable

\[ $ML_y2 \]

name of second dependent variable, if any

\[ ...
\]

\[ $ML_samp \]

variable containing 1 if observation to be used; 0 otherwise

\[ $ML_w \]

variable containing weight associated with observation or 1 if no weights specified

Method-Iff evaluators can ignore \( $ML_samp \), but restricting calculations to the \( $ML_samp == 1 \) subsample will speed execution. Method-Iff evaluators must ignore \( $ML_w \); application of weights is handled by the method itself.

Methods d0, d1, d2, lf0, lf1, lf2, and gf0 can ignore \( $ML_samp \) as long as \textit{ml model}’s \textit{nopreserve} option is not specified. These methods will run more quickly if \textit{nopreserve} is specified. These evaluators can ignore \( $ML_w \) only if they use \textit{mlsum}, \textit{mlvecsum}, \textit{mlmatsum}, and \textit{mlmatbysum} to produce all final results.

### Description

\textit{ml model} defines the current problem.

\textit{ml clear} clears the current problem definition. This command is rarely used because when you type 
\textit{ml model}, any previous problem is automatically cleared.

\textit{ml query} displays a description of the current problem.

\textit{ml check} verifies that the log-likelihood evaluator you have written works. We strongly recommend using this command.
ml search searches for (better) initial values. We recommend using this command.

ml plot provides a graphical way of searching for (better) initial values.

ml init provides a way to specify initial values.

ml report reports \( \ln L \)'s values, gradient, and Hessian at the initial values or current parameter estimates, \( b_0 \).

ml trace traces the execution of the user-defined log-likelihood evaluation program.

ml count counts the number of times the user-defined log-likelihood evaluation program is called; this command is seldom used. ml count clear clears the counter. ml count on turns on the counter. ml count without arguments reports the current values of the counter. ml count off stops counting calls.

ml maximize maximizes the likelihood function and reports results. Once ml maximize has successfully completed, the previously mentioned ml commands may no longer be used unless noclear is specified. ml graph and ml display may be used whether or not noclear is specified.

ml graph graphs the log-likelihood values against the iteration number.

ml display redisplay results.

ml footnote displays a warning message when the model did not converge within the specified number of iterations.

ml score creates new variables containing the equation-level scores. The variables generated by ml score are equivalent to those generated by specifying the score() option of ml maximize (and ml model ... , ... maximize).

\texttt{prognname} is the name of a Stata program you write to evaluate the log-likelihood function.

\texttt{funcname()} is the name of a Mata function you write to evaluate the log-likelihood function.

In this documentation, \texttt{prognname} and \texttt{funcname()} are referred to as the user-written evaluator, the likelihood evaluator, or sometimes simply as the evaluator. The program you write is written in the style required by the method you choose. The methods are lf, d0, d1, d2, lf0, lf1, lf2, and gf0. Thus, if you choose to use method lf, your program is called a method-lf evaluator.

Method-lf evaluators are required to evaluate the observation-by-observation log likelihood \( \ln \ell_j, j = 1, \ldots, N \).

Method-d0 evaluators are required to evaluate the overall log likelihood \( \ln L \). Method-d1 evaluators are required to evaluate the overall log likelihood and its gradient vector \( g = \partial \ln L / \partial b \). Method-d2 evaluators are required to evaluate the overall log likelihood, its gradient, and its Hessian matrix \( H = \partial^2 \ln L / \partial b \partial b' \).

Method-lf0 evaluators are required to evaluate the observation-by-observation log likelihood \( \ln \ell_j, j = 1, \ldots, N \). Method-lf1 evaluators are required to evaluate the observation-by-observation log likelihood and its equation-level scores \( g_{ji} = \partial \ln \ell / \partial x_{ji}b_i \). Method-lf2 evaluators are required to evaluate the observation-by-observation log likelihood, its equation-level scores, and its Hessian matrix \( H = \partial^2 \ln \ell / \partial b \partial b' \).

Method-gf0 evaluators are required to evaluate the summable pieces of the log likelihood \( \ln \ell_k, k = 1, \ldots, K \).

\texttt{mleval} is a subroutine used by evaluators of methods d0, d1, d2, lf0, lf1, lf2, and gf0 to evaluate the coefficient vector, \( b \), that they are passed.

\texttt{mlsum} is a subroutine used by evaluators of methods d0, d1, and d2 to define the value, \( \ln L \), that is to be returned.
mlvecsum is a subroutine used by evaluators of methods d1 and d2 to define the gradient vector, \( g \), that is to be returned. It is suitable for use only when the likelihood function meets the linear-form restrictions.

mlmatsum is a subroutine used by evaluators of methods d2 and lf2 to define the Hessian matrix, \( H \), that is to be returned. It is suitable for use only when the likelihood function meets the linear-form restrictions.

mlmatbysum is a subroutine used by evaluator of method d2 to help define the Hessian matrix, \( H \), that is to be returned. It is suitable for use when the likelihood function contains terms made up of grouped sums, such as in panel-data models. For such models, use mlmatsum to compute the observation-level outer products and mlmatbysum to compute the group-level outer products. mlmatbysum requires that the data be sorted by the variable identified in the by() option.

Options

Options are presented under the following headings:

Options for use with ml model in interactive or noninteractive mode
Options for use with ml model in noninteractive mode
Options for use when specifying equations
Options for use with ml search
Option for use with ml plot
Options for use with ml init
Options for use with ml maximize
Option for use with ml graph
Options for use with ml display
Options for use with mleval
Option for use with ml sum
Option for use with mlvecsum
Option for use with mlmatsum
Options for use with mlmatbysum
Options for use with ml score

Options for use with ml model in interactive or noninteractive mode

group(varname) specifies the numeric variable that identifies groups. This option is typically used to identify panels for panel-data models.

vce(vcetype) specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that are derived from asymptotic theory (oim, opg); see [R] vce_option.

vce(robust), vce(cluster clustvar), pweight, and svy will work with evaluators of methods lf, lf0, lf1, lf2, and gf0; all you need do is specify them.

These options will not work with evaluators of methods d0, d1, or d2, and specifying these options will produce an error message.

constraints(numlist | matname) specifies the linear constraints to be applied during estimation.

constraints(numlist) specifies the constraints by number. Constraints are defined by using the constraint command; see [R] constraint. constraint(matname) specifies a matrix that contains the constraints.

nocnsnotes prevents notes from being displayed when constraints are dropped. A constraint will be dropped if it is inconsistent, contradicts other constraints, or causes some other error when the constraint matrix is being built. Constraints are checked in the order in which they are specified.
**title(string)** specifies the title for the estimation output when results are complete.

**nopreserve** specifies that `ml` need not ensure that only the estimation subsample is in memory when the user-written likelihood evaluator is called. **nopreserve** is irrelevant when you use method lf.

For the other methods, if **nopreserve** is not specified, `ml` saves the data in a file (preserves the original dataset) and drops the irrelevant observations before calling the user-written evaluator. This way, even if the evaluator does not restrict its attentions to the $ML_{\text{samp}}==1$ subsample, results will still be correct. Later, `ml` automatically restores the original dataset.

`ml` need not go through these machinations for method lf because the user-written evaluator calculates observation-by-observation values, and `ml` itself sums the components.

`ml` goes through these machinations if and only if the estimation sample is a subsample of the data in memory. If the estimation sample includes every observation in memory, `ml` does not preserve the original dataset. Thus programmers must not alter the original dataset unless they preserve the data themselves.

We recommend that interactive users of `ml` not specify **nopreserve**; the speed gain is not worth the possibility of getting incorrect results.

We recommend that programmers specify **nopreserve**, but only after verifying that their evaluator really does restrict its attentions solely to the $ML_{\text{samp}}==1$ subsample.

**collinear** specifies that `ml` not remove the collinear variables within equations. There is no reason to leave collinear variables in place, but this option is of interest to programmers who, in their code, have already removed collinear variables and do not want `ml` to waste computer time checking again.

**missing** specifies that observations containing variables with missing values not be eliminated from the estimation sample. There are two reasons you might want to specify **missing**:

Programmers may wish to specify **missing** because, in other parts of their code, they have already eliminated observations with missing values and do not want `ml` to waste computer time looking again.

You may wish to specify **missing** if your model explicitly deals with missing values. Stata’s `heckman` command is a good example of this. In such cases, there will be observations where missing values are allowed and other observations where they are not—where their presence should cause the observation to be eliminated. If you specify **missing**, it is your responsibility to specify an `if exp` that eliminates the irrelevant observations.

**lf0(#k #ll)** is typically used by programmers. It specifies the number of parameters and log-likelihood value of the constant-only model so that `ml` can report a likelihood-ratio test rather than a Wald test. These values may have been analytically determined, or they may have been determined by a previous fitting of the constant-only model on the estimation sample.

Also see the **continue** option directly below.

If you specify **lf0()**, it must be safe for you to specify the **missing** option, too, else how did you calculate the log likelihood for the constant-only model on the same sample? You must have identified the estimation sample, and done so correctly, so there is no reason for `ml` to waste time rechecking your results. All of which is to say, do not specify **lf0()** unless you are certain your code identifies the estimation sample correctly.

**lf0()**, even if specified, is ignored if **vce(robust)**, **vce(cluster clustvar)**, **pweight**, or **svy** is specified because, in that case, a likelihood-ratio test would be inappropriate.
continue is typically specified by programmers and does two things:

First, it specifies that a model has just been fit by either ml or some other estimation command, such as \texttt{logit}, and that the likelihood value stored in \texttt{e(11)} and the number of parameters stored in \texttt{e(b)} as of that instant are the relevant values of the constant-only model. The current value of the log likelihood is used to present a likelihood-ratio test unless \texttt{vce(robust)}, \texttt{vce(cluster clustvar)}, \texttt{pweight}, \texttt{svy}, or \texttt{constraints()} is specified. A likelihood-ratio test is inappropriate when \texttt{vce(robust)}, \texttt{vce(cluster clustvar)}, \texttt{pweight}, or \texttt{svy} is specified. We suggest using \texttt{lrtest} when \texttt{constraints()} is specified; see \texttt{[R] lrtest}.

Second, \texttt{continue} sets the initial values, \(b_0\), for the model about to be fit according to the \texttt{e(b)} currently stored.

The comments made about specifying \texttt{missing} with \texttt{lf0()} apply equally well here.

\texttt{waldtest(\#)} is typically specified by programmers. By default, \texttt{ml} presents a Wald test, but that is overridden if the \texttt{lf0()} or \texttt{continue} option is specified. A Wald test is performed if \texttt{vce(robust)}, \texttt{vce(cluster clustvar)}, or \texttt{pweight} is specified.

\texttt{waldtest(0)} prevents even the Wald test from being reported.

\texttt{waldtest(-1)} is the default. It specifies that a Wald test be performed by constraining all coefficients except the intercept to 0 in the first equation. Remaining equations are to be unconstrained. A Wald test is performed if neither \texttt{lf0()} nor \texttt{continue} was specified, and a Wald test is forced if \texttt{vce(robust)}, \texttt{vce(cluster clustvar)}, or \texttt{pweight} was specified.

\texttt{waldtest(k)} for \(k \leq -1\) specifies that a Wald test be performed by constraining all coefficients except intercepts to 0 in the first \(|k|\) equations; remaining equations are to be unconstrained. A Wald test is performed if neither \texttt{lf0()} nor \texttt{continue} was specified, and a Wald test is forced if \texttt{vce(robust)}, \texttt{vce(cluster clustvar)}, or \texttt{pweight} was specified.

\texttt{waldtest(k)} for \(k \geq 1\) works like the options above, except that it forces a Wald test to be reported even if the information to perform the likelihood-ratio test is available and even if none of \texttt{vce(robust)}, \texttt{vce(cluster clustvar)}, or \texttt{pweight} was specified. \texttt{waldtest(k)}, \(k \geq 1\), may not be specified with \texttt{lf0()}.

\texttt{obs(\#)} is used mostly by programmers. It specifies that the number of observations reported and ultimately stored in \texttt{e(N)} be \#. Ordinarily, \texttt{ml} works that out for itself. Programmers may want to specify this option when, for the likelihood evaluator to work for \(N\) observations, they first had to modify the dataset so that it contained a different number of observations.

\texttt{crittype(string)} is used mostly by programmers. It allows programmers to supply a string (up to 32 characters long) that describes the criterion that is being optimized by \texttt{ml}. The default is "log likelihood" for nonrobust and "log pseudolikelihood" for robust estimation.

\texttt{svy} indicates that \texttt{ml} is to pick up the \texttt{svy} settings set by \texttt{svyset} and use the robust variance estimator. This option requires the data to be \texttt{svyset}; see \texttt{[SVY] svyset}. \texttt{svy} may not be specified with \texttt{vce()} or \texttt{weights}.

\texttt{subpop(varname)} specifies that estimates be computed for the single subpopulation defined by the observations for which \texttt{varname} \neq 0. Typically, \texttt{varname = 1} defines the subpopulation, and \texttt{varname = 0} indicates observations not belonging to the subpopulation. For observations whose subpopulation status is uncertain, \texttt{varname} should be set to missing (‘.’). This option requires the \texttt{svy} option.

\texttt{nosvyadjust} specifies that the model Wald test be carried out as \(W/k \sim F(k,d)\), where \(W\) is the Wald test statistic, \(k\) is the number of terms in the model excluding the constant term, \(d\) is the total number of sampled PSUs minus the total number of strata, and \(F(k,d)\) is an \(F\) distribution with \(k\) numerator degrees of freedom and \(d\) denominator degrees of freedom. By default, an adjusted
Wald test is conducted: \((d - k + 1)W/(kd) \sim F(k, d - k + 1)\). See Korn and Graubard (1990) for a discussion of the Wald test and the adjustments thereof. This option requires the \texttt{svy} option. 

\texttt{technique(algorithm\_spec)} specifies how the likelihood function is to be maximized. The following algorithms are currently implemented in \texttt{ml}. For details, see Gould, Pitblado, and Poi (2010).

\texttt{technique(nr)} specifies Stata’s modified Newton–Raphson (NR) algorithm.

\texttt{technique(bhhh)} specifies the Berndt–Hall–Hall–Hausman (BHHH) algorithm.

\texttt{technique(dfpm)} specifies the Davidon–Fletcher–Powell (DFP) algorithm.

\texttt{technique(bfgs)} specifies the Broyden–Fletcher–Goldfarb–Shanno (BFGS) algorithm.

The default is \texttt{technique(nr)}.

You can switch between algorithms by specifying more than one in the \texttt{technique()} option. By default, \texttt{ml} will use an algorithm for five iterations before switching to the next algorithm. To specify a different number of iterations, include the number after the \texttt{technique} in the option. For example, \texttt{technique(bhhh 10 nr 1000)} requests that \texttt{ml} perform 10 iterations using the BHHH algorithm, followed by 1,000 iterations using the NR algorithm, and then switch back to BHHH for 10 iterations, and so on. The process continues until convergence or until reaching the maximum number of iterations.

### Options for use with \texttt{ml model} in noninteractive mode

The following extra options are for use with \texttt{ml model} in noninteractive mode. Noninteractive mode is for programmers who use \texttt{ml} as a subroutine and want to issue one command that will carry forth the estimation from start to finish.

\texttt{maximize} is required. It specifies noninteractive mode.

\texttt{init(ml\_init\_args)} sets the initial values, \(b_0\). \texttt{ml\_init\_args} are whatever you would type after the \texttt{ml init} command.

\texttt{search(on | norescale | quietly | off)} specifies whether \texttt{ml search} is to be used to improve the initial values. \texttt{search(on)} is the default and is equivalent to separately running \texttt{ml search}, \texttt{repeat(0)}. \texttt{search(norescale)} is equivalent to separately running \texttt{ml search}, \texttt{repeat(0) norescale}. \texttt{search(quietly)} is equivalent to \texttt{search(on)}, except that it suppresses \texttt{ml search’s} output. \texttt{search(off)} prevents calling \texttt{ml search}.

\texttt{repeat(#)} is \texttt{ml search’s} \texttt{repeat()} option. \texttt{repeat(0)} is the default.

\texttt{bounds(ml\_search\_bounds)} specifies the search bounds. \texttt{ml\_search\_bounds} is specified as

\[
[eqn\_name] \ lower\_bound \ upper\_bound \ ... \ [eqn\_name] \ lower\_bound \ upper\_bound
\]

for instance, \texttt{bounds(100 100 lnsigma 0 10)}. The \texttt{ml model} command issues \texttt{ml search ml\_search\_bounds, repeat(#)}. Specifying search bounds is optional.

\texttt{nowarning}, \texttt{novce}, \texttt{negh}, and \texttt{score()} are \texttt{ml maximize’s} equivalent options.

\texttt{maximize\_options: difficult, technique(algorithm\_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init\_specs); see \texttt{[R maximize}}. These options are seldom used.
Options for use when specifying equations

noconstant specifies that the equation not include an intercept.

offset(varname_o) specifies that the equation be $xb + varname_o$—that it include $varname_o$ with coefficient constrained to be 1.

exposure(varname_e) is an alternative to offset(varname_o); it specifies that the equation be $xb + \ln(varname_e)$. The equation is to include $\ln(varname_e)$ with coefficient constrained to be 1.

Options for use with ml search

repeat(#) specifies the number of random attempts that are to be made to find a better initial-value vector. The default is repeat(10).

repeat(0) specifies that no random attempts be made. More precisely, repeat(0) specifies that no random attempts be made if the first initial-value vector is a feasible starting point. If it is not, ml search will make random attempts, even if you specify repeat(0), because it has no alternative. The repeat() option refers to the number of random attempts to be made to improve the initial values. When the initial starting value vector is not feasible, ml search will make up to 1,000 random attempts to find starting values. It stops when it finds one set of values that works and then moves into its improve-initial-values logic.

repeat(k), k > 0, specifies the number of random attempts to be made to improve the initial values.

restart specifies that random actions be taken to obtain starting values and that the resulting starting values not be a deterministic function of the current values. Generally, you should not specify this option because, with restart, ml search intentionally does not produce as good a set of starting values as it could. restart is included for use by the optimizer when it gets into serious trouble. The random actions ensure that the optimizer and ml search, working together, do not cause an endless loop.

restart implies norescale, which is why we recommend that you do not specify restart. In testing, sometimes rescale worked so well that, even after randomization, the rescaler would bring the starting values right back to where they had been the first time and thus defeat the intended randomization.

norescale specifies that ml search not engage in its rescaling actions to improve the parameter vector. We do not recommend specifying this option because rescaling tends to work so well.

maximize_options: [no]log and trace; see [R] maximize. These options are seldom used.

Option for use with ml plot

saving(filename[, replace]) specifies that the graph be saved in filename.gph.

Options for use with ml init

copy specifies that the list of numbers or the initialization vector be copied into the initial-value vector by position rather than by name.

skip specifies that any parameters found in the specified initialization vector that are not also found in the model be ignored. The default action is to issue an error message.
Options for use with ml maximize

nowarning is allowed only with iterate(0). nowarning suppresses the “convergence not achieved” message. Programmers might specify iterate(0) nowarning when they have a vector \( \mathbf{b} \) already containing the final estimates and want ml to calculate the variance matrix and postestimation results. Then specify init(b) search(off) iterate(0) nowarning nolog.

novce is allowed only with iterate(0). novce substitutes the zero matrix for the variance matrix, which in effect posts estimation results as fixed constants.

negh indicates that the evaluator returns the negative Hessian matrix. By default, ml assumes \( d2 \) and \( lf2 \) evaluators return the Hessian matrix.

score(newvars | stub*) creates new variables containing the contributions to the score for each equation and ancillary parameter in the model; see [U] 20.22 Obtaining scores.

If score(newvars) is specified, the newvars must contain \( k \) new variables. For evaluators of methods \( lf, lf0, lf1, \) and \( lf2 \), \( k \) is the number of equations. For evaluators of method \( gf0 \), \( k \) is the number of parameters. If score(stub*) is specified, variables named \( stub1, stub2, \ldots, stubk \) are created.

For evaluators of methods \( lf, lf0, lf1, \) and \( lf2 \), the first variable contains \( \frac{\partial \ln \ell_j}{\partial (x_{1j} b_1)} \), the second variable contains \( \frac{\partial \ln \ell_j}{\partial (x_{2j} b_2)} \), and so on.

For evaluators of method \( gf0 \), the first variable contains \( \frac{\partial \ln \ell_j}{\partial b_1} \), the second variable contains \( \frac{\partial \ln \ell_j}{\partial b_2} \), and so on.

nnooutput suppresses display of results. This option is different from prefixing ml maximize with quietly in that the iteration log is still displayed (assuming that nolog is not specified).

noclear specifies that the ml problem definition not be cleared after the model has converged. Perhaps you are having convergence problems and intend to run the model to convergence. If so, use ml search to see if those values can be improved, and then restart the estimation.

maximize_options: difficult, iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance; see [R] maximize. These options are seldom used.

display_options; see Options for use with ml display below.

eform_options; see Options for use with ml display below.

Option for use with ml graph

saving(filename[, replace]) specifies that the graph be saved in filename.gph.

Options for use with ml display

noheader suppresses the header display above the coefficient table that displays the final log-likelihood value, the number of observations, and the model significance test.

nofootnote suppresses the footnote display below the coefficient table, which displays a warning if the model fit did not converge within the specified number of iterations. Use ml footnote to display the warning if 1) you add to the coefficient table using the plus option or 2) you have your own footnotes and want the warning to be last.
level(#) is the standard confidence-level option. It specifies the confidence level, as a percentage, for confidence intervals of the coefficients. The default is level(95) or as set by set level; see \[20.7\] Specifying the width of confidence intervals.

first displays a coefficient table reporting results for the first equation only, and the report makes it appear that the first equation is the only equation. This option is used by programmers who estimate ancillary parameters in the second and subsequent equations and who wish to report the values of such parameters themselves.

neq(#) is an alternative to first. neq(#) displays a coefficient table reporting results for the first # equations. This option is used by programmers who estimate ancillary parameters in the # + 1 and subsequent equations and who wish to report the values of such parameters themselves.

showeqns is a seldom-used option that displays the equation names in the coefficient table. ml display uses the numbers stored in e(k_eq) and e(k_aux) to determine how to display the coefficient table. e(k_eq) identifies the number of equations, and e(k_aux) identifies how many of these are for ancillary parameters. The first option is implied when showeqns is not specified and all but the first equation are for ancillary parameters.

plus displays the coefficient table, but rather than ending the table in a line of dashes, ends it in dashes–plus-sign–dashes. This is so that programmers can write additional display code to add more results to the table and make it appear as if the combined result is one table. Programmers typically specify plus with the first or neq() options. This option implies nofootnote.

nocnsreport suppresses the display of constraints above the coefficient table. This option is ignored if constraints were not used to fit the model.

noomitted specifies that variables that were omitted because of collinearity not be displayed. The default is to include in the table any variables omitted because of collinearity and to label them as “(omitted)”.

vsquish specifies that the blank space separating factor-variable terms or time-series–operated variables from other variables in the model be suppressed.

noemptycells specifies that empty cells for interactions of factor variables not be displayed. The default is to include in the table interaction cells that do not occur in the estimation sample and to label them as “(empty)”.

baselevels and allbaselevels control whether the base levels of factor variables and interactions are displayed. The default is to exclude from the table all base categories.

baselevels specifies that base levels be reported for factor variables and for interactions whose bases cannot be inferred from their component factor variables.

allbaselevels specifies that all base levels of factor variables and interactions be reported.

cformat(\%fmt) specifies how to format coefficients, standard errors, and confidence limits in the coefficient table.

pformat(\%fmt) specifies how to format p-values in the coefficient table.

sformat(\%fmt) specifies how to format test statistics in the coefficient table.

nolstretch specifies that the width of the coefficient table not be automatically widened to accommodate longer variable names. The default, lstretch, is to automatically widen the coefficient table up to the width of the Results window. To change the default, use set lstretch off. nolstretch is not shown in the dialog box.

coflegend specifies that the legend of the coefficients and how to specify them in an expression be displayed rather than displaying the statistics for the coefficients.
**ml — Maximum likelihood estimation**

**eform_option:** `eform(string)`, `eform`, `hr`, `shr`, `irr`, `or`, and `rrr` display the coefficient table in exponentiated form: for each coefficient, \( \exp(b) \) rather than \( b \) is displayed, and standard errors and confidence intervals are transformed. `string` is the table header that will be displayed above the transformed coefficients and must be 11 characters or shorter in length—for example, `eform("Odds Ratio")`. The options `eform`, `hr`, `shr`, `irr`, `or`, and `rrr` provide a default `string` equivalent to “\( \exp(b) \)”, “Haz. Ratio”, “SHR”, “IRR”, “Odds Ratio”, and “RRR”, respectively. These options may not be combined.

`ml display` looks at `e(k eform)` to determine how many equations are affected by an `eform_option`; by default, only the first equation is affected. Type `ereturn list, all` to view `e(k eform)`; see `[P] ereturn`.

**Options for use with mleval**

- `eq(#)` specifies the equation number, \( i \), for which \( \theta_{ij} = x_{ij} b_i \) is to be evaluated. `eq(1)` is assumed if `eq()` is not specified.
- `scalar` asserts that the \( i \)th equation is known to evaluate to a constant, meaning that the equation was specified as `( )`, `(name:)`, or `/name` on the `ml model` statement. If you specify this option, the new variable created is created as a scalar. If the \( i \)th equation does not evaluate to a scalar, an error message is issued.

**Option for use with mlsum**

- `noweight` specifies that weights (`$ML_w`) be ignored when summing the likelihood function.

**Option for use with mlvecsum**

- `eq(#)` specifies the equation for which a gradient vector \( \partial \ln L / \partial b_i \) is to be constructed. The default is `eq(1)`.

**Option for use with mlmatsum**

- `eq(# [, #])` specifies the equations for which the Hessian matrix is to be constructed. The default is `eq(1)`, which is the same as `eq(1, 1)`, which means \( \partial^2 \ln L / \partial b_1 \partial b'_1 \). Specifying `eq(i, j)` results in \( \partial^2 \ln L / \partial b_i \partial b'_j \).

**Options for use with mlmatbysum**

- `by(varname)` is required and specifies the group variable.
- `eq(# [, #])` specifies the equations for which the Hessian matrix is to be constructed. The default is `eq(1)`, which is the same as `eq(1, 1)`, which means \( \partial^2 \ln L / \partial b_1 \partial b'_1 \). Specifying `eq(i, j)` results in \( \partial^2 \ln L / \partial b_i \partial b'_j \).

**Options for use with ml score**

- `equation(eqname)` identifies from which equation the observation scores are to come. This option may be used only when generating one variable.
- `missing` specifies that observations containing variables with missing values not be eliminated from the estimation sample.
Remarks and examples

For a thorough discussion of \texttt{ml}, see the fourth edition of *Maximum Likelihood Estimation with Stata* (Gould, Pitblado, and Poi 2010). The book provides a tutorial introduction to \texttt{ml}, notes on advanced programming issues, and a discourse on maximum likelihood estimation from both theoretical and practical standpoints. See *Survey options and ml* at the end of Remarks and examples for examples of the new \texttt{svy} options. For more information about survey estimation, see \texttt{[SVY] survey}, \texttt{[SVY] svy estimation}, and \texttt{[SVY] variance estimation}.

\texttt{ml} requires that you write a program that evaluates the log-likelihood function and, possibly, its first and second derivatives. The style of the program you write depends upon the method you choose. Methods \texttt{lf}, \texttt{lf0}, \texttt{d0}, and \texttt{gf0} require that your program evaluate the log likelihood only. Methods \texttt{d1} and \texttt{lf1} require that your program evaluate the log likelihood and its first derivatives. Methods \texttt{d2} and \texttt{lf2} require that your program evaluate the log likelihood and its first and second derivatives. Methods \texttt{lf}, \texttt{lf0}, \texttt{d0}, and \texttt{gf0} differ from each other in that, with methods \texttt{lf} and \texttt{lf0}, your program is required to produce observation-by-observation log-likelihood values $ln \ell_j$ and it is assumed that $ln L = \sum_j ln \ell_j$; with method \texttt{d0}, your program is required to produce only the overall value $ln L$; and with method \texttt{gf0}, your program is required to produce the summable pieces of the log likelihood, such as those in panel-data models.

Once you have written the program—called an evaluator—you define a model to be fit using \texttt{ml model} and obtain estimates using \texttt{ml maximize}. You might type

\begin{verbatim}
. ml model ...
. ml maximize
\end{verbatim}

but we recommend that you type

\begin{verbatim}
. ml model ...
. ml check
. ml search
. ml maximize
\end{verbatim}

\texttt{ml check} verifies your evaluator has no obvious errors, and \texttt{ml search} finds better initial values.

You fill in the \texttt{ml model} statement with 1) the method you are using, 2) the name of your program, and 3) the “equations”. You write your evaluator in terms of $\theta_1$, $\theta_2$, $\ldots$, each of which has a linear equation associated with it. That linear equation might be as simple as $\theta_i = b_0$, it might be $\theta_i = b_1 mpg + b_2 weight + b_3$, or it might omit the intercept $b_3$. The equations are specified in parentheses on the \texttt{ml model} line.

Suppose that you are using method \texttt{lf} and the name of your evaluator program is \texttt{myprog}. The statement

\begin{verbatim}
. ml model lf myprog (mpg weight)
\end{verbatim}

would specify one equation with $\theta_i = b_1 mpg + b_2 weight + b_3$. If you wanted to omit $b_3$, you would type

\begin{verbatim}
. ml model lf myprog (mpg weight, nocons)
\end{verbatim}

and if all you wanted was $\theta_i = b_0$, you would type

\begin{verbatim}
. ml model lf myprog ()
\end{verbatim}

With multiple equations, you list the equations one after the other; so, if you typed

\begin{verbatim}
. ml model lf myprog (mpg weight) ()
\end{verbatim}
you would be specifying $\theta_1 = b_1 \text{mpg} + b_2 \text{weight} + b_3$ and $\theta_2 = b_4$. You would write your likelihood in terms of $\theta_1$ and $\theta_2$. If the model was linear regression, $\theta_1$ might be the $x_b$ part and $\theta_2$ the variance of the residuals.

When you specify the equations, you also specify any dependent variables. If you typed

```
.ml model lf myprog (price = mpg weight) ()
```

price would be the one and only dependent variable, and that would be passed to your program in $\text{ML}_y1$. If your model had two dependent variables, you could type

```
.ml model lf myprog (price displ = mpg weight) ()
```

Then $\text{ML}_y1$ would be price and $\text{ML}_y2$ would be displ. You can specify however many dependent variables are necessary and specify them on any equation. It does not matter on which equation you specify them; the first one specified is placed in $\text{ML}_y1$, the second in $\text{ML}_y2$, and so on.

### Example 1: Method If

Using method If, we want to produce observation-by-observation values of the log likelihood. The probit log-likelihood function is

$$
\ln \ell_j = \begin{cases} 
\ln \Phi(\theta_{1j}) & \text{if } y_j = 1 \\
\ln \Phi(-\theta_{1j}) & \text{if } y_j = 0 
\end{cases}
$$

\[ \theta_{1j} = x_j b_1 \]

The following is the method-lf evaluator for this likelihood function:

```
program myprobit
    version 13
    args lnf theta1
    quietly replace `lnf' = ln(normal(`theta1')) if $ML_y1==1
    quietly replace `lnf' = ln(normal(-`theta1')) if $ML_y1==0
end
```

If we wanted to fit a model of foreign on mpg and weight, we would type the following commands. The `foreign =' part specifies that $y$ is foreign. The `mpg weight' part specifies that $\theta_{1j} = b_1 \text{mpg}_j + b_2 \text{weight}_j + b_3$. 
Example 2: Method lf for two-equation, two-dependent-variable model

A two-equation, two-dependent-variable model is a little different. Rather than receiving one \( \theta \), our program will receive two. Rather than there being one dependent variable in \$ML_y1, there will be dependent variables in \$ML_y1 and \$ML_y2. For instance, the Weibull regression log-likelihood function is

\[
\ln \ell_j = -(t_j e^{-\theta_{1j}})^{\exp(\theta_{2j})} + d_j \{\theta_{2j} - \theta_{1j} + (e^{\theta_{2j}} - 1)(\ln t_j - \theta_{1j})\}
\]

\[
\theta_{1j} = x_j b_1
\]

\[
\theta_{2j} = s
\]

where \( t_j \) is the time of failure or censoring and \( d_j = 1 \) if failure and 0 if censored. We can make the log likelihood a little easier to program by introducing some extra variables:

\[
p_j = \exp(\theta_{2j})
\]

\[
M_j = \{t_j \exp(-\theta_{1j})\}^{p_j}
\]

\[
R_j = \ln t_j - \theta_{1j}
\]

\[
\ln \ell_j = -M_j + d_j \{\theta_{2j} - \theta_{1j} + (p_j - 1)R_j\}
\]

The method-lf evaluator for this is

```stata
program myweib
version 13
args lnf theta1 theta2
tempvar p M R
quietly gen double `p' = exp(`theta2')
quietly gen double `M' = ($ML_y1*exp(-`theta1'))^`p'
quietly gen double `R' = ln($ML_y1)-`theta1'
quietly replace `lnf' = `-`M' + $ML_y2*(`theta2'-`theta1') + (`p'-1)*`R'
end
```
We can fit a model by typing

```
  . ml model lf myweib (studytime died = i.drug age) ()
  . ml maximize
```

Note that we specified ‘()’ for the second equation. The second equation corresponds to the Weibull shape parameter \( s \), and the linear combination we want for \( s \) contains just an intercept. Alternatively, we could type

```
  . ml model lf myweib (studytime died = i.drug age) /s
```

Typing /s means the same thing as typing \((s:)\), and both really mean the same thing as (). The \( s \), either after a slash or in parentheses before a colon, labels the equation. It makes the output look prettier, and that is all:

```
  . use http://www.stata-press.com/data/r13/cancer, clear
  (Patient Survival in Drug Trial)
  . ml model lf myweib (studytime died = i.drug age) /s
  . ml maximize

  initial: log likelihood =  -744

```

Example 3: Method d0

Method-d0 evaluators receive \( \mathbf{b} = (b_1, b_2, \ldots, b_E) \), the coefficient vector, rather than the already evaluated \( \theta_1, \theta_2, \ldots, \theta_E \), and they are required to evaluate the overall log-likelihood \( \ln L \) rather than \( \ln \ell_j, j = 1, \ldots, N \).

Use `mleval` to produce the thetas from the coefficient vector.

Use `mlsum` to sum the components that enter into \( \ln L \).
In the case of Weibull, \( \ln L = \sum \ln \ell_j \), and our method-d0 evaluator is

```stata
program weib0
    version 13
    args todo b lnf
    tempvar theta1 theta2
    mleval `theta1' = `b', eq(1)
    mleval `theta2' = `b', eq(2)
    local t "\$ML_y1" // this is just for readability
    local d "\$ML_y2"
    tempvar p M R
    quietly gen double `p' = exp(`theta2')
    quietly gen double `M' = (`t'*exp(-`theta1'))^`p'
    quietly gen double `R' = ln(`t')-`theta1'
    mlsum `lnf' = -`M' + `d'*(`theta2'-`theta1' + (`p'-1)*`R')
end
```

To fit our model using this evaluator, we would type

```
.ml model d0 weib0 (studytime died = i.drug age) /s
.ml maximize
```

- **Technical note**

  Method d0 does not require \( \ln L = \sum_j \ln \ell_j, j = 1, \ldots, N \), as method lf does. Your likelihood function might have independent components only for groups of observations. Panel-data estimators have a log-likelihood value \( \ln L = \sum_i \ln L_i \), where \( i \) indexes the panels, each of which contains multiple observations. Conditional logistic regression has \( \ln L = \sum_k \ln L_k \), where \( k \) indexes the risk pools. Cox regression has \( \ln L = \sum_{(t)} \ln L_{(t)} \), where \( (t) \) denotes the ordered failure times.

To evaluate such likelihood functions, first calculate the within-group log-likelihood contributions. This usually involves `generate` and `replace` statements prefixed with `by`, as in

```stata
    tempvar sumd
    by group: gen double `sumd' = sum($ML_y1)
```

Structure your code so that the log-likelihood contributions are recorded in the last observation of each group. Say that a variable is named `cont`. To sum the contributions, code

```stata
    tempvar last
    quietly by group: gen byte `last' = (_n==_N)
    mlsum `lnf' = `cont' if `last'
```

You must inform `mlsum` which observations contain log-likelihood values to be summed. First, you do not want to include intermediate results in the sum. Second, `mlsum` does not skip missing values. Rather, if `mlsum` sees a missing value among the contributions, it sets the overall result, `lnf`, to missing. That is how `ml maximize` is informed that the likelihood function could not be evaluated at the particular value of `b`. `ml maximize` will then take action to escape from what it thinks is an infeasible area of the likelihood function.

When the likelihood function violates the linear-form restriction \( \ln L = \sum_j \ln \ell_j, j = 1, \ldots, N \), with \( \ln \ell_j \) being a function solely of values within the \( j \)th observation, use method d0. In the following examples, we will demonstrate methods d1 and d2 with likelihood functions that meet this linear-form restriction. The d1 and d2 methods themselves do not require the linear-form restriction, but the utility routines `mlvecsum` and `mlmatsum` do. Using method d1 or d2 when the restriction is violated is difficult; however, `mlmatbysum` may be of some help for method-d2 evaluators.
Example 4: Method d1

Method-d1 evaluators are required to produce the gradient vector $\mathbf{g} = \partial \ln L/\partial \mathbf{b}$, as well as the overall log-likelihood value. Using `mlvecsum`, we can obtain $\partial \ln L/\partial \mathbf{b}$ from $\partial \ln L/\partial \theta_i$, $i = 1, \ldots, E$. The derivatives of the Weibull log-likelihood function are

$$
\frac{\partial \ln \ell_j}{\partial \theta_{1j}} = p_j (M_j - d_j)
$$

$$
\frac{\partial \ln \ell_j}{\partial \theta_{2j}} = d_j - R_j p_j (M_j - d_j)
$$

The method-d1 evaluator for this is

```plaintext
program weib1
    version 13
    args todo b lnf g
    tempvar t1 t2
    mleval 't1' = 'b', eq(1)
    mleval 't2' = 'b', eq(2)
    local t "$ML_y1"
    local d "$ML_y2"
    tempvar p M R
    quietly gen double 'p' = exp('t2')
    quietly gen double 'M' = ('t'*exp(-'t1'))^'p'
    quietly gen double 'R' = ln('t')-'t1'
    mlsum 'lnf' = -'M' + 'd'*(-'t2'+'t1' + ('p'-1)*'R')
    if ('todo'==0 | 'lnf'>=.) exit /* <-- new */
    tempname d1 d2 /* <-- new */
    mlvecsum 'lnf' 'd1' = 'p'*('M'-'d'), eq(1) /* <-- new */
    mlvecsum 'lnf' 'd2' = 'd' - 'R'*(p*(M-'d'), eq(2) /* <-- new */
    matrix 'g' = ('d1','d2') /* <-- new */
end
```

We obtained this code by starting with our method-d0 evaluator and then adding the extra lines that method d1 requires. To fit our model using this evaluator, we could type

```
    . ml model d1 weib1 (studytime died = drug2 drug3 age) /s
    . ml maximize
```

but we recommend substituting method d1debug for method d1 and typing

```
    . ml model d1debug weib1 (studytime died = drug2 drug3 age) /s
    . ml maximize
```

Method d1debug will compare the derivatives we calculate with numerical derivatives and thus verify that our program is correct. Once we are certain the program is correct, then we would switch from method d1debug to method d1.

Example 5: Method d2

Method-d2 evaluators are required to produce $\mathbf{H} = \partial^2 \ln L/\partial \mathbf{b} \partial \mathbf{b}'$, the Hessian matrix, as well as the gradient and log-likelihood value. `mlmatsum` will help calculate $\partial^2 \ln L/\partial \mathbf{b} \partial \mathbf{b}'$ from the second derivatives with respect to $\theta$. For the Weibull model, these second derivatives are
\[ \frac{\partial^2 \ln \ell_j}{\partial \theta_{1j}^2} = -p_j^2 M_j \]
\[ \frac{\partial^2 \ln \ell_j}{\partial \theta_{1j} \partial \theta_{2j}} = p_j (M_j - d_j + R_j p_j M_j) \]
\[ \frac{\partial^2 \ln \ell_j}{\partial \theta_{2j}^2} = -p_j R_j (R_j p_j M_j + M_j - d_j) \]

The method-d2 evaluator is

```plaintext
program weib2
    version 13
    args todo b lnf g H    // H added
    tempvar t1 t2
    mleval 't1' = 'b', eq(1)
    mleval 't2' = 'b', eq(2)
    local t "$ML_y1"
    local d "$ML_y2"
    tempvar p M R
    quietly gen double 'p' = exp('t2')
    quietly gen double 'M' = ('t'*exp(-'t1'))^'p'
    quietly gen double 'R' = ln('t')-'t1'
    mlsum 'lnf' = -'M' + 'd'*(('t2'-'t1') + ('p'-1)*'R')
    if ('todo'==0 | 'lnf'>=.) exit
    tempname d1 d2
    mlvecsum 'lnf' 'd1' = 'p'*('M'-'d'), eq(1)
    mlvecsum 'lnf' 'd2' = 'd' - 'R'*'p'*('M'-'d'), eq(2)
    matrix 'g' = ('d1','d2')
    if ('todo'==1 | 'lnf'>=.) exit    // new from here down
    tempname d11 d12 d22
    mlmatsum 'lnf' 'd11' = -'p'^2 * 'M', eq(1)
    mlmatsum 'lnf' 'd12' = 'p'*(('M'-'d') + 'R'*(p*'M'), eq(1,2)
    mlmatsum 'lnf' 'd22' = -'p'*(R*(p*'M' + 'M' - 'd') , eq(2)
    matrix 'H' = ('d11','d12' \ 'd12','d22')
end
```

We started with our previous method-d1 evaluator and added the lines that method d2 requires. We could now fit a model by typing

```
. ml model d2 weib2 (studytime died = drug2 drug3 age) /s
. ml maximize
```

but we would recommend substituting method d2debug for method d2 and typing

```
. ml model d2debug weib2 (studytime died = drug2 drug3 age) /s
. ml maximize
```

Method d2debug will compare the first and second derivatives we calculate with numerical derivatives and thus verify that our program is correct. Once we are certain the program is correct, then we would switch from method d2debug to method d2.

As we stated earlier, to produce the robust variance estimator with method lf, there is nothing to do except specify `vce(robust)`, `vce(cluster clustvar)`, or `pweight`. For methods d0, d1, and d2, these options do not work. If your likelihood function meets the linear-form restrictions, you can use methods lf0, lf1, and lf2, then these options will work. The equation scores are defined as

\[ \frac{\partial \ln \ell_j}{\partial \theta_{1j}}, \frac{\partial \ln \ell_j}{\partial \theta_{2j}}, \ldots \]
Your evaluator will be passed variables, one for each equation, which you fill in with the equation scores. For both method lf1 and lf2, these variables are passed in the fourth and subsequent positions of the argument list. That is, you must process the arguments as

    args todo b lnf g1 g2 ... H

Note that for method lf1, the ‘H’ argument is not used and can be ignored.

Example 6: Robust variance estimates

If you have used `mlvecsum` in your evaluator of method d1 or d2, it is easy to turn it into evaluator of method lf1 or lf2 that allows the computation of the robust variance estimator. The expression that you specified on the right-hand side of `mlvecsum` is the equation score.

Here we turn the program that we gave earlier in the method-d1 example into a method-lf1 evaluator that allows `vce(robust)`, `vce(cluster clustvar)`, or `pweight`.

    program weib1
    version 13
    args todo b lnfj g1 g2 // g1 and g2 are new
    tempvar t1 t2
    mleval 't1' = 'b', eq(1)
    mleval 't2' = 'b', eq(2)
    local t "$ML_y1"
    local d "$ML_y2"
    tempvar p M R
    quietly gen double 'p' = exp('t2')
    quietly gen double 'M' = ('t'*exp(-'t1'))*'p'
    quietly gen double 'R' = ln('t')-'t1'
    quietly replace 'lnfj' = -'M' + 'd'*(t2-t1 + (p-1)*R)
    if ('todo'==0) exit
    quietly replace 'g1' = 'p'*(M-'d') /* <-- new */
    quietly replace 'g2' = 'd' - 'R'*(p*(M-'d')) /* <-- new */
    end

To fit our model and get the robust variance estimates, we type

    . ml model lf1 weib1 (studytime died = drug2 drug3 age) /s, vce(robust)
    . ml maximize

Survey options and ml

`ml` can handle stratification, poststratification, multiple stages of clustering, and finite population corrections. Specifying the `svy` option implies that the data come from a survey design and also implies that the survey linearized variance estimator is to be used; see [SVY] variance estimation.

Example 7

Suppose that we are interested in a probit analysis of data from a survey in which q1 is the answer to a yes/no question and x1, x2, x3 are demographic responses. The following is a lf2 evaluator for the probit model that meets the requirements for `vce(robust)` (linear form and computes the scores).
To fit a model, we `svyset` the data, then use `svy` with `ml`.

```
. svyset psuid [pw=w], strata(strid)
. ml model lf2 mylf2probit (q1 = x1 x2 x3), svy
. ml maximize
```

We could also use the `subpop()` option to make inferences about the subpopulation identified by the variable `sub`:

```
. svyset psuid [pw=w], strata(strid)
. ml model lf2 mylf2probit (q1 = x1 x2 x3), svy subpop(sub)
. ml maximize
```

### Stored results

For results stored by `ml` without the `svy` option, see [R] `maximize`.

For results stored by `ml` with the `svy` option, see [SVY] `svy`.

### Methods and formulas

`ml` is implemented using `moptimize()`; see [M-5] `moptimize()`.

<lexp> may contain time-series operators; see [U] 13.9 Time-series operators.
bootstrap, by, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
aweights are not allowed with the jackknife prefix; see [R] jackknife.
aweights, fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.
coeflegend does not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

<lexp> and <dexp> are extensions of valid Stata expressions that also contain parameters to be estimated. The parameters are enclosed in curly braces and must otherwise satisfy the naming requirements for variables; {beta} is an example of a parameter. Also allowed is a notation of the
form \{<eqname>: varlist\} for linear combinations of multiple covariates and their parameters. For example, \{xb: mpg price turn\} defines a linear combination of the variables mpg, price, and turn. See \textit{Substitutable expressions} under \textit{Remarks and examples} below.

**Menu**

Statistics $>$ Other $>$ Maximum likelihood estimation of expression

**Description**

\texttt{mlexp} performs maximum likelihood estimation of models that satisfy the linear-form restrictions, which is to say models for which you can write down the log likelihood for an individual observation and for which the overall log likelihood is simply the sum of the individual observations’ log likelihoods.

You express the observation-level log-likelihood function by using a substitutable expression. Unlike models fit using \texttt{ml}, you do not need to do any programming. However, \texttt{ml} can fit classes of models that cannot be fit by \texttt{mlexp}.

**Options**

<table>
<thead>
<tr>
<th>Model</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{variables(varlist)} specifies the variables in the model. \texttt{mlexp} ignores observations for which any of these variables has missing values. If you do not specify \texttt{variables()}, then \texttt{mlexp} assumes all the observations are valid. If the log likelihood cannot be calculated at the initial values for any observation, \texttt{mlexp} will exit with an error message.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Derivatives</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{from(initial_values)} specifies the initial values to begin the estimation. You can specify a $1 \times k$ matrix, where $k$ is the number of parameters in the model, or you can specify parameter names and values. For example, to initialize alpha to 1.23 and delta to 4.57, you would type \texttt{mlexp ... , from(alpha=1.23 delta=4.57) ...}</td>
</tr>
</tbody>
</table>

Initial values declared using this option override any that are declared within substitutable expressions. If you specify a parameter that does not appear in your model, \texttt{mlexp} exits with an error. If you specify a matrix, the values must be in the same order in which the parameters are declared in your model. \texttt{mlexp} ignores the row and column names of the matrix.

<table>
<thead>
<tr>
<th>Derivatives</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{derivative(/name = &lt;dexp&gt;)} specifies the derivative of the observation-level log-likelihood function with respect to parameter name.</td>
</tr>
</tbody>
</table>

\texttt{<dexp>} uses the same substitutable expression syntax as is used to specify the log-likelihood function. If you declare a linear combination in the log-likelihood function, you provide the derivative for the linear combination; \texttt{mlexp} then applies the chain rule for you. See \textit{Specifying derivatives} under \textit{Remarks and examples} below for examples.

If you do not specify the \texttt{derivative()} option, \texttt{mlexp} calculates derivatives numerically. You must either specify no derivatives or specify all the derivatives; you cannot specify some analytic derivatives and have \texttt{mlexp} compute the rest numerically.

If you are estimating multiple parameters, you supply derivatives using multiple \texttt{derivative()} specifications.
vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#) ; see [R] estimation options.

title(string) specifies an optional title that will be displayed just above the table of parameter estimates.

title2(string) specifies an optional subtitle that will be displayed between the title specified in title() and the table of parameter estimates. If title2() is specified but title() is not, then title2() has the same effect as title().

display_options: cformat(%fmt), pformat(%fmt), and sformat(%fmt); see [R] estimation options.

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), and nonrtolerance; see [R] maximize. These options are seldom used.

The following option is available with mlexp but is not shown in the dialog box:

coefflegend; see [R] estimation options.

Remarks and examples

Remarks are presented under the following headings:

Introduction
Substitutable expressions
Parameter constraints
Specifying derivatives

Introduction

mlexp performs maximum likelihood estimation of models that satisfy the linear-form restrictions, which is to say models for which you can write down the log likelihood for a single observation and for which the overall log likelihood is simply the sum of the individual observations’ log likelihoods. Models designed for use with cross-sectional data usually meet the linear-form restrictions, including linear regression, many discrete-choice models, limited-dependent-variable models, and selection models. Examples of models that do not satisfy the linear-form restrictions are random-effects panel-data models (because the likelihood function is defined at the panel level) and Cox proportional hazards models (because the likelihood function is defined for risk sets).

Because of its straightforward syntax and accessibility from the menu system, mlexp is particularly suited to users who are new to Stata and to those using Stata for pedagogical purposes. You express the observation-level log-likelihood function by using a substitutable expression, which we explain below. Unlike models fit using ml, you do not need to do any programming. However, ml can fit classes of models that cannot be fit by mlexp, including those that do not meet the linear-form restrictions.
Substitutable expressions

You specify the log-likelihood function that `mlexp` is to maximize by using substitutable expressions that are similar to those used by `nl`, `nlsur`, and `gmm`. You specify substitutable expressions just as you would specify any other mathematical expression involving scalars and variables, such as those expressions you would use with Stata’s `generate` command, except that the parameters to be estimated are bound in braces. See [U] 13.2 Operators and [U] 13.3 Functions for more information on expressions. Parameter names must follow the same conventions as variable names. See [U] 11.3 Naming conventions.

For example, say that you have observations on variable $x$, and the log likelihood for the $i$th observation is

$$\ln \ell_i = \ln \lambda - \lambda x_i$$

where $\lambda$ is a parameter to be estimated. Then you would type

```
.mlexp (ln({lambda}) - {lambda}*x)
```

Because $\lambda$ is a parameter, we enclosed it in braces. To specify initial values for a parameter, you can include an equal sign and the initial value after the parameter; for example,

```
.mlexp (ln({lambda = 0.75}) - {lambda}*x)
```

would initialize $\lambda$ to be 0.75. If you do not initialize a parameter, `mlexp` initializes it to zero.

Frequently, even nonlinear functions contain linear combinations of variables. Continuing the previous example, say that we want to parameterize $\lambda$ as

$$\lambda_i = \alpha_1 u_i + \alpha_2 v_i$$

where $u$ and $v$ are variables in the dataset. Instead of typing

```
.mlexp (ln({alpha1}*u + {alpha2}*v) - ({alpha1}*u + {alpha2}*v)*x)
```

you can instead type

```
.mlexp (ln({lambda: u v}) - {lambda:}*x)
```

The notation `{lambda: u v}` indicates to `mlexp` that you want a linear combination of the variables $u$ and $v$. We named the linear combination `lambda`, so `mlexp` will name the parameters for the two variables `lambda_u` and `lambda_v`, respectively. Once you have declared a linear combination, you can subsequently refer to the linear combination by specifying its name and a colon inside braces, as we did with this example. You cannot use the same name for both an individual parameter and a linear combination. However, after a linear combination has been declared, you can refer to the parameter of an individual variable within that linear combination by using the notation `{lc_z}`, where `lc` is the name of the linear combination and `z` is the variable whose parameter you want to reference. Linear combinations do not include a constant term.

There are three rules to follow when defining substitutable expressions:

1. Parameters of the model are bound in braces: `{b0}`, `{param}`, etc.
2. Initial values for parameters are given by including an equal sign and the initial value inside the braces: `{b0=1}`, `{param=3.571}`, etc.
3. Linear combinations of variables can be included using the notation `{eqname:varlist}`: `{xb: mpg price weight}`, `{score: w x z}`, etc. Parameters of linear combinations are initialized to zero.
If you specify initial values by using the from() option, they override whatever initial values are given within the substitutable expression. Substitutable expressions are so named because once values are assigned to the parameters, the resulting expressions can be handled by generate and replace.

Regardless of whether you specify initial values, mlexp performs a search procedure for better starting values before commencing the first iteration of the maximization routine. If you specify initial values, the search procedure tries to improve upon those values. Otherwise, the search procedure begins with all parameters set to zero.

Example 1: The gamma density function

The two-parameter gamma density function for \( y \geq 0 \) is

\[
f(y) = \frac{\lambda^P}{\Gamma(P)} \exp(-\lambda y) y^{P-1} \quad \lambda > 0, \ P > 0
\]

so that the log likelihood for the \( i \)th observation is

\[
\ln \ell_i = P \ln \lambda - \ln \Gamma(P) - \lambda y_i + (P-1) \ln y_i
\]

The dataset greenegamma.dta, based on Greene (2012, 460–461), contains 20 observations drawn randomly from the two-parameter gamma distribution. We want to estimate the parameters of that distribution. We type

```
. use http://www.stata-press.com/data/r13/greenegamma
. mlexp ({P}*ln({lambda}) - lngamma({P}) - {lambda}*y + ({P}-1)*ln(y))
```

| Initial: log likelihood = -<inf> (could not be evaluated) |
| Rescale: log likelihood = -363.37264 |
| Rescale eq: log likelihood = -153.09898 |
| Feasible: log likelihood = -88.863468 |
| Iteration 0: log likelihood = -88.863468 |
| Iteration 1: log likelihood = -85.405011 |
| Iteration 2: log likelihood = -85.375857 |
| Iteration 3: log likelihood = -85.375669 |
| Iteration 4: log likelihood = -85.375669 |

Maximum likelihood estimation

| Log likelihood = -85.375669 | Number of obs = 20 |
| Coef. Std. Err. z P>|z| [95% Conf. Interval] |
|---|---|---|---|---|---|
| /P | 2.410602 | .7158452 | 3.37 | 0.001 | 1.007571 3.813633 |
| /lambda | .0770702 | .0254361 | 3.03 | 0.002 | .0272164 .1269241 |

In our substitutable expression for the log-likelihood function, we enclosed the two parameters of our model, \( P \) and \( \lambda \), in curly braces. We used the lngamma() function to compute \( \ln \Gamma(P) \) because Stata (unlike Mata) does not have a built-in function to compute \( \Gamma(P) \), and numerical algorithms for computing \( \ln \Gamma(P) \) directly are more accurate than taking the natural logarithm of \( \Gamma(P) \), anyway.

Because we did not specify initial values, mlexp initialized \( P \) and \( \lambda \) to be zero. When both parameters are zero, the log-likelihood function cannot be evaluated because \( \ln(0) \) is undefined. Therefore, in the iteration log above the coefficient table, we see that mlexp reported the initial log likelihood to be -<inf> (could not be evaluated). mlexp uses a search routine to find alternative initial values that do allow the log-likelihood function to be calculated.
Example 2: Obtaining alternative VCEs

In example 1, by default `mlexp` reported standard errors based on the observed information matrix of the log-likelihood function. See [R] `vce_option` for an overview or Gould, Pitblado, and Poi (2010) for an in-depth discussion of different ways of obtaining the VCE in maximum likelihood estimation. With `mlexp`, we can use the `vce()` option to obtain standard errors based on alternative VCEs. For example, to obtain the outer product of gradients (OPG) standard errors, we type

```bash
. mlexp ({P}*ln({lambda}) - lngamma({P}) - {lambda}*y + ({P}-1)*ln(y)), vce(opg)
```

```
initial: log likelihood = -<inf> (could not be evaluated)
feasible: log likelihood = -363.37264
rescale: log likelihood = -153.09898
rescale eq: log likelihood = -88.863468
Iteration 0: log likelihood = -88.863468
Iteration 1: log likelihood = -85.405011
Iteration 2: log likelihood = -85.375857
Iteration 3: log likelihood = -85.375669
Iteration 4: log likelihood = -85.375669
```

Maximum likelihood estimation

Log likelihood = -85.375669  Number of obs = 20

Parameter constraints

In examples 1 and 2, we were lucky. The two-parameter gamma density function is defined only when both $\lambda$ and $P$ are positive. However, `mlexp` does not know this; when maximizing the log-likelihood function, it will consider all real values for the parameters. Rather than relying on luck, we should instead reparameterize our model so that we avoid having to directly estimate parameters that are restricted.

For example, consider the parameter $\lambda > 0$, and suppose we define the new parameter $\theta = \ln(\lambda)$ so that $\lambda = \exp(\theta)$. With this parameterization, for any real value of $\theta$ that `mlexp` might try to use when evaluating the log-likelihood function, $\lambda$ is guaranteed to be positive.

Example 3: Classical normal regression

In the classical normal variant of linear regression (Goldberger 1991, chap. 19), we assume not only that $y_i = x_i'\beta + \epsilon_i$ but also that $x_i$ is nonstochastic and that $\epsilon_i$ is distributed independently and identically normal with mean zero and variance $\sigma^2$. This is equivalent to assuming that

$$y_i|x_i \sim N(x_i'\beta, \sigma^2)$$

Using the properties of the normal distribution, we could write the log likelihood for the $i$th observation as

$$\ln l_i = \ln \left\{ \frac{1}{\sigma} \phi \left( \frac{y_i - x_i'\beta}{\sigma} \right) \right\}$$
where $\phi(\cdot)$ is the standard normal density function. In Stata, we use the three-argument version of the `normalden()` function and directly specify the conditional mean ($x_i'\beta$) and standard deviation ($\sigma$) as the additional arguments.

The normal density function is defined only for $\sigma > 0$, so instead of estimating $\sigma$ directly, we will instead estimate the unconstrained parameter $\theta$ and let $\sigma = \exp(\theta)$. For any real value of $\theta$, this transformation ensures that $\sigma > 0$.

Using `auto.dta`, say that we want to fit the classical normal regression

$$mpg_i = \beta_0 + \beta_1 weight_i + \epsilon_i$$

We type

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. mlexp (ln(normalden(mpg, {b0} + {b1}*weight, exp({theta}))))
```

```
initial: log likelihood = -<inf> (could not be evaluated)
feasible: log likelihood = -882.02886
rescale: log likelihood = -882.02886
rescale eq: log likelihood = -274.09391
Iteration 0: log likelihood = -274.09391 (not concave)
(output omitted)
Iteration 13: log likelihood = -195.38869
Maximum likelihood estimation
Log likelihood = -195.38869 Number of obs = 74

| Coef. Std. Err. | z    | P>|z|  | [95% Conf. Interval]    |
|-----------------|------|------|------------------------|
| /b0             | 39.44028 | 1.592043 | 24.77 | 0.000 | 36.31993 | 42.56063 |
| /b1             | -0.0060087 | 0.0005108 | -11.76 | 0.000 | -0.0070099 | -0.0050075 |
| /theta          | 1.221449 | 0.0821995 | 14.86 | 0.000 | 1.060341 | 1.382557 |
```

To recover our estimate of $\sigma$, we can use `nlcom`:

```
. nlcom (sigma: exp(_b[/theta]))
```

```
| Coef. Std. Err. | z    | P>|z|  | [95% Conf. Interval]    |
|-----------------|------|------|------------------------|
| sigma           | 3.392099 | 0.2788288 | 12.17 | 0.000 | 2.845605 | 3.938594 |
```

In the previous example, we named the unconstrained parameter $\theta$ `theta`. In actual practice, however, we would generally name that parameter `lnsigma` to indicate that it is $\ln(\sigma)$.

Two other parameter restrictions often appear in maximum likelihood estimation. Consider the correlation coefficient $\rho$. In general, it must be true that $-1 < \rho < 1$. Define the parameter $\eta = \tanh^{-1}(\rho)$, where $\tanh^{-1}(\cdot)$ is the hyperbolic arctangent function. Then $\rho = \tanh(\eta)$, and by the properties of the hyperbolic tangent function, for any real value of $\eta$, we will have $-1 < \rho < 1$. Stata has the built-in function `tanh()`, so recovering $\rho$ from $\eta$ is easy. In practice, instead of naming the unconstrained parameter `eta` in our likelihood expression, we would name it `atanhrho` to remind us that it is the hyperbolic arctangent of $\rho$. 
Other parameters, such as those that represent probabilities or ratios of variances, are often restricted to be between 0 and 1. Say that we have the restriction $0 < \kappa < 1$. Consider the parameter $\psi = \ln \{\kappa/(1 - \kappa)\}$. Then $\kappa = e^{\psi}/(1 + e^{\psi})$ and for any real value of $\psi$, we have $0 < \kappa < 1$. The formula for $\kappa$ in terms of $\psi$ is known as the inverse logit transformation and is available as `invlogit()` in Stata. Thus in our likelihood expression, we would code `invlogit({logitk})` to map the unconstrained parameter $\logitk$ into the $(0, 1)$ interval.

### Specifying derivatives

By default, `mlexp` calculates derivatives of the log-likelihood function numerically using a sophisticated algorithm that produces accurate results. However, `mlexp` will fit your model more quickly (and even more accurately) if you specify analytic derivatives.

You specify derivatives by using substitutable expressions in much the same way as you specify the log-likelihood function. If you specify a linear combination in your log-likelihood function, then you supply a derivative with respect to that linear combination; `mlexp` then uses the chain rule to obtain the derivatives with respect to the individual parameters.

We will illustrate how to specify derivatives using the probit model for dichotomous outcomes. The log likelihood for the probit model is often written as

$$
\ln \ell_i = \begin{cases} 
\ln \Phi(x'_i \beta) & y_i = 1 \\
\ln \Phi(-x'_i \beta) & y_i = 0 
\end{cases}
$$

using the fact that $1 - \Phi(x'_i \beta) = \Phi(-x'_i \beta)$, where $\Phi(\cdot)$ is the cumulative standard normal distribution function. If we use the trick suggested by Greene (2012, 691, fn. 7), we can simplify the log-likelihood function, making the derivative calculation easier. Let $q_i = 2y_i - 1$. Then we can write the log-likelihood function as

$$
\ln \ell_i = \ln \Phi(q_i x'_i \beta)
$$

and the first derivative as

$$
\frac{\partial \ln \ell_i}{\partial \beta} = \frac{q_i \phi(q_i x'_i \beta)}{\Phi(q_i x'_i \beta)} x_i
$$

#### Example 4: Probit with one regressor

Say that we want to fit a probit model of `foreign` on `mpg` and a constant term. We have two parameters, so we will need to specify two derivatives; $x_i$ consists of the $i$th observation on `mpg` and a 1 as the constant term. Because the term $q_i x'_i \beta$ will appear several times in our command, we create a macro to store it. We type
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. generate q = 2*foreign - 1
. global qxb "q*({b1}*mpg + {b0})"
. mlexp (ln(normal($qxb))), derivative(/b1 = q*normalden($qxb)/normal($qxb)*mpg)
> deriv(/b0 = q*normalden($qxb)/normal($qxb))
initial: log likelihood = -51.292891
alternative: log likelihood = -2017.3105
rescale: log likelihood = -47.888213
rescale eq: log likelihood = -46.343247
Iteration 0: log likelihood = -46.343247
Iteration 1: log likelihood = -39.268764
Iteration 2: log likelihood = -39.258972
Iteration 3: log likelihood = -39.258972
Maximum likelihood estimation
Number of obs = 74
Log likelihood = -39.258972

|         | Coef.    | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|---------|----------|-----------|------|------|---------------------|
| /b1     | .0960601 | .0301523  | 3.19 | 0.001| .0369627            | .1551575 |
| /b0     | -2.635268| .6841462  | -3.85| 0.000| -3.97617            | -1.294366|

When you specify a linear combination of variables, you specify the derivative with respect to the linear combination. That way, if you change the variables that comprise the linear combination, you do not need to change the derivative at all. To see why this is the case, consider the function $f(x_i'\beta)$, where $x_i'\beta$ is a linear combination. Then, using the chain rule,

$$\frac{\partial f(x_i'\beta)}{\partial \beta_j} = \frac{\partial f(x_i'\beta)}{\partial x_i'\beta} \times \frac{\partial x_i'\beta}{\partial \beta_j} = \frac{\partial f(x_i'\beta)}{\partial x_i'\beta} \times x_{ij}$$

Once the derivative with respect to the linear combination is known, mlexp can then multiply it by each of the variables in the linear combination to get the full set of derivatives with respect to the parameters needed to maximize the likelihood function. Moreover, the derivative with respect to the linear combination does not depend on the variables within the linear combination, so even if you change the variables in it, you will not need to modify the specification of the corresponding derivative() option.

Example 5: Probit with a linear combination

Now let's fit a probit model of foreign on mpg and gear_ratio. We could specify the parameters and independent variables individually, but we will use a linear combination instead. First, note that

$$\frac{\partial \ln \ell_i}{\partial x_i'\beta} = \frac{q_i\phi(q_i x_i'\beta)}{\Phi(q_i x_i'\beta)}$$
We type

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. generate q = 2*foreign - 1
. global qxb "q*({xb:} + {b0})"
. mlexp (ln(normal(q*({xb:mpg gear_ratio}+{b0}))))
> deriv(/xb = q*normalden($qxb)/normal($qxb))
> deriv(/b0 = q*normalden($qxb)/normal($qxb))
```

Initial: log likelihood = -51.292891
Alternative: log likelihood = -2556.2172
Rescale: log likelihood = -47.865271
Rescale eq: log likelihood = -46.658776
Iteration 0: log likelihood = -46.658776
Iteration 1: log likelihood = -22.541058
Iteration 2: log likelihood = -21.467371
Iteration 3: log likelihood = -21.454446
Iteration 4: log likelihood = -21.454436
Iteration 5: log likelihood = -21.454436

Maximum likelihood estimation

Log likelihood = -21.454436 Number of obs = 74

| Coef. | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|-------|-----------|------|------|----------------------|
| /xb_mpg | -.0282433 | .0464514 | -0.61 | 0.543 | -.1192864 -.0627998 |
| /xb_gear_ratio | 3.699635 | .8368276 | 4.42 | 0.000 | 2.059483 5.339787 |
| /b0 | -11.57588 | 2.337239 | -4.95 | 0.000 | -16.15678 -6.994972 |

We first redefined our global macro $qxb$ to contain the linear combination $xb$ and a constant term $b0$. More importantly, we did not specify the variables in the linear combination just yet. Instead, we will use $qxb$ after we explicitly declare the variables in $xb$ when we specify our model. To avoid making mistakes, you can declare the variables in a linear combination only once when you set up your model. If we had declared the variables when we defined $qxb$, we would have received an error because, upon substituting for $qxb$, we would have declared the variables multiple times in our call to mlexp.
mlexp stores the following in \( \mathbf{e}() \):

### Scalars
- \( e(N) \): number of observations
- \( e(k) \): number of parameters
- \( e(k_{\text{aux}}) \): number of ancillary parameters
- \( e(k_{\text{eq}}) \): number of equations in \( e(b) \)

Syntax for predict

```
predict [ type ] { stub* | newvar₁ ... newvarₖ } [ if ] [ in ] [, scores]```

This statistic is only available for observations within the estimation sample. $k$ represents the number of parameters in the model.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Option for predict

scores, the default, calculates the equation-level score variables. The $j$th new variable will contain the scores for the $j$th parameter of the model. Linear combinations are expanded prior to computing scores, so each variable’s parameter will have its own score variable.

mlogit — Multinomial (polytomous) logistic regression

Menu
Statistics > Categorical outcomes > Multinomial logistic regression

Description

mlogit fits maximum-likelihood multinomial logit models, also known as polytomous logistic regression. You can define constraints to perform constrained estimation. Some people refer to conditional logistic regression as multinomial logit. If you are one of them, see [R] clogit.

See [R] logistic for a list of related estimation commands.

Options

**Model**

- noconstant; see [R] estimation options.
- baseoutcome(#) specifies the value of depvar to be treated as the base outcome. The default is to choose the most frequent outcome.
- constraints(clist), collinear; see [R] estimation options.

**SE/Robust**

- vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

If specifying vce(bootstrap) or vce(jackknife), you must also specify baseoutcome().

**Reporting**

- level(#); see [R] estimation options.
- rrr reports the estimated coefficients transformed to relative-risk ratios, that is, \( e^b \) rather than \( b \); see Description of the model below for an explanation of this concept. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. rrr may be specified at estimation or when replaying previously estimated results.
- nocnsreport; see [R] estimation options.

**Maximization**

- display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofemptylabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

- maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

The following option is available with mlogit but is not shown in the dialog box:
- coeflegend; see [R] estimation options.
Remarks and examples

Remarks are presented under the following headings:

- Description of the model
- Fitting unconstrained models
- Fitting constrained models

\texttt{mlogit} fits maximum likelihood models with discrete dependent (left-hand-side) variables when the dependent variable takes on more than two outcomes and the outcomes have no natural ordering. If the dependent variable takes on only two outcomes, estimates are identical to those produced by \texttt{logistic} or \texttt{logit}; see \texttt{R} \texttt{logistic} or \texttt{R} \texttt{logit}. If the outcomes are ordered, see \texttt{R} \texttt{ologit}.

Description of the model

Consider the outcomes 1, 2, 3, \ldots, \textit{m} recorded in \textit{y}, and the explanatory variables \textit{X}. Assume that there are \textit{m} = 3 outcomes: “buy an American car”, “buy a Japanese car”, and “buy a European car”. The values of \textit{y} are then said to be “unordered”. Even though the outcomes are coded 1, 2, and 3, the numerical values are arbitrary because \(1 < 2 < 3\) does not imply that outcome 1 (buy American) is less than outcome 2 (buy Japanese) is less than outcome 3 (buy European). This unordered categorical property of \textit{y} distinguishes the use of \texttt{mlogit} from \texttt{regress} (which is appropriate for a continuous dependent variable), from \texttt{ologit} (which is appropriate for ordered categorical data), and from \texttt{logit} (which is appropriate for two outcomes, which can be thought of as ordered).

In the multinomial logit model, you estimate a set of coefficients, \(\beta^{(1)}\), \(\beta^{(2)}\), and \(\beta^{(3)}\), corresponding to each outcome:

\[
\Pr(y = 1) = \frac{e^{X\beta^{(1)}}}{e^{X\beta^{(1)}} + e^{X\beta^{(2)}} + e^{X\beta^{(3)}}}
\]
\[
\Pr(y = 2) = \frac{e^{X\beta^{(2)}}}{e^{X\beta^{(1)}} + e^{X\beta^{(2)}} + e^{X\beta^{(3)}}}
\]
\[
\Pr(y = 3) = \frac{e^{X\beta^{(3)}}}{e^{X\beta^{(1)}} + e^{X\beta^{(2)}} + e^{X\beta^{(3)}}}
\]

The model, however, is unidentified in the sense that there is more than one solution to \(\beta^{(1)}\), \(\beta^{(2)}\), and \(\beta^{(3)}\) that leads to the same probabilities for \(y = 1\), \(y = 2\), and \(y = 3\). To identify the model, you arbitrarily set one of \(\beta^{(1)}\), \(\beta^{(2)}\), or \(\beta^{(3)}\) to 0—it does not matter which. That is, if you arbitrarily set \(\beta^{(1)} = 0\), the remaining coefficients \(\beta^{(2)}\) and \(\beta^{(3)}\) will measure the change relative to the \(y = 1\) group. If you instead set \(\beta^{(2)} = 0\), the remaining coefficients \(\beta^{(1)}\) and \(\beta^{(3)}\) will measure the change relative to the \(y = 2\) group. The coefficients will differ because they have different interpretations, but the predicted probabilities for \(y = 1\), \(2\), and 3 will still be the same. Thus either parameterization will be a solution to the same underlying model.
Setting $\beta^{(1)} = 0$, the equations become

$$
\Pr(y = 1) = \frac{1}{1 + e^{X\beta^{(2)}} + e^{X\beta^{(3)}}}
$$

$$
\Pr(y = 2) = \frac{e^{X\beta^{(2)}}}{1 + e^{X\beta^{(2)}} + e^{X\beta^{(3)}}}
$$

$$
\Pr(y = 3) = \frac{e^{X\beta^{(3)}}}{1 + e^{X\beta^{(2)}} + e^{X\beta^{(3)}}}
$$

The relative probability of $y = 2$ to the base outcome is

$$
\frac{\Pr(y = 2)}{\Pr(y = 1)} = e^{X\beta^{(2)}}
$$

Let’s call this ratio the relative risk, and let’s further assume that $X$ and $\beta^{(2)}_k$ are vectors equal to $(x_1, x_2, \ldots, x_k)$ and $(\beta^{(2)}_1, \beta^{(2)}_2, \ldots, \beta^{(2)}_k)'$, respectively. The ratio of the relative risk for a one-unit change in $x_i$ is then

$$
\frac{e^{\beta^{(2)}_i x_1 + \cdots + \beta^{(2)}_i (x_i + 1) + \cdots + \beta^{(2)}_k x_k}}{e^{\beta^{(2)}_1 x_1 + \cdots + \beta^{(2)}_i x_i + \cdots + \beta^{(2)}_k x_k}} = e^{\beta^{(2)}_i}
$$

Thus the exponentiated value of a coefficient is the relative-risk ratio for a one-unit change in the corresponding variable (risk is measured as the risk of the outcome relative to the base outcome).

**Fitting unconstrained models**

- **Example 1: A first example**

  We have data on the type of health insurance available to 616 psychologically depressed subjects in the United States (Tarlov et al. 1989; Wells et al. 1989). The insurance is categorized as either an indemnity plan (that is, regular fee-for-service insurance, which may have a deductible or coinsurance rate) or a prepaid plan (a fixed up-front payment allowing subsequent unlimited use as provided, for instance, by an HMO). The third possibility is that the subject has no insurance whatsoever. We wish to explore the demographic factors associated with each subject’s insurance choice. One of the demographic factors in our data is the race of the participant, coded as white or nonwhite:
. use http://www.stata-press.com/data/r13/sysdsn1
(Health insurance data)
. tabulate insure nonwhite, chi2 col

Pearson chi2(2) = 9.5599  Pr = 0.008

Although `insure` appears to take on the values `Indemnity`, `Prepaid`, and `Uninsure`, it actually takes on the values 1, 2, and 3. The words appear because we have associated a value label with the numeric variable `insure`; see [U] 12.6.3 Value labels.

When we fit a multinomial logit model, we can tell `mlogit` which outcome to use as the base outcome, or we can let `mlogit` choose. To fit a model of `insure` on `nonwhite`, letting `mlogit` choose the base outcome, we type

```
. mlogit insure nonwhite
```

```
Iteration 0:  log likelihood =  -556.59502
Iteration 1:  log likelihood =  -551.78935
Iteration 2:  log likelihood =  -551.78348
Iteration 3:  log likelihood =  -551.78348

Multinomial logistic regression                   Number of obs  =        616
LR chi2(2)    =    9.6200
Prob > chi2    =    0.0081
Log likelihood =  -551.78348                     Pseudo R2       =    0.0086

```

```
insure | Coef.     Std. Err.     z     P>|z|     [95% Conf. Interval]
-------|-----------|-----------------|------|--------|------------------|
Indemnity | (base outcome) |
Prepaid | nonwhite _cons | .6608212  .2157321  3.06  0.002   .2379942   1.083648 |
          | cons         | -.1879149  .0937644  2.00  0.045   -.3716896   -.0041401 |
Uninsure | nonwhite _cons | .3779586  .407589   0.93  0.354   -.4209011   1.176818 |
          | cons         | -1.941934  .1782185 -10.90 0.000   -2.291236  -1.592632 |
```

`mlogit` chose the indemnity outcome as the base outcome and presented coefficients for the outcomes prepaid and uninsured. According to the model, the probability of prepaid for whites (`nonwhite = 0`) is
Pr(\text{insure} = \text{Prepaid}) = \frac{e^{-1.88}}{1 + e^{-1.88} + e^{-1.942}} = 0.420

Similarly, for nonwhites, the probability of prepaid is

Pr(\text{insure} = \text{Prepaid}) = \frac{e^{-1.88 + 0.661}}{1 + e^{-1.88 + 0.661} + e^{-1.942 + 0.378}} = 0.570

These results agree with the column percentages presented by \texttt{tabulate} because the \texttt{mlogit} model is fully saturated. That is, there are enough terms in the model to fully explain the column percentage in each cell. The model chi-squared and the \texttt{tabulate} chi-squared are in almost perfect agreement; both test that the column percentages of \texttt{insure} are the same for both values of \texttt{nonwhite}.

\textbf{Example 2: Specifying the base outcome}

By specifying the \texttt{baseoutcome()} option, we can control which outcome of the dependent variable is treated as the base. Left to its own, \texttt{mlogit} chose to make outcome 1, indemnity, the base outcome. To make outcome 2, prepaid, the base, we would type

```
   . mlogit insure nonwhite, base(2)
```

```
Iteration 0: log likelihood = -556.59502
Iteration 1: log likelihood = -551.78935
Iteration 2: log likelihood = -551.78348
Iteration 3: log likelihood = -551.78348

Multinomial logistic regression
Log likelihood = -551.78348

Number of obs = 616
LR chi2(2) = 9.62
Prob > chi2 = 0.0081
Pseudo R2 = 0.0086
```

```
| insure | Coef.     | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|--------|-----------|-----------|-------|------|----------------------|
|        | Indemnity |           |       |      |                      |
|        | nonwhite  |          |       |      |                      |
| _cons  | -.660821  | .2157321  | -3.06 | 0.002| -1.083648 -.2379942  |
|        | .1879149  | .0937644  | 2.00  | 0.045| .0041401 .3716896    |
|        | Prepaid (base outcome) | | | | |
|        | Uninsure  |           |       |      |                      |
|        | nonwhite  |          |       |      |                      |
| _cons  | -.2828627 | .3977302  | -0.71 | 0.477| -1.0624 .4966742    |
|        | -1.754019 | .1805145  | -9.72 | 0.000| -2.107821 -1.400217  |
```

The \texttt{baseoutcome()} option requires that we specify the numeric value of the outcome, so we could not type \texttt{base(Prepaid)}.

Although the coefficients now appear to be different, the summary statistics reported at the top are identical. With this parameterization, the probability of prepaid insurance for whites is

Pr(\text{insure} = \text{Prepaid}) = \frac{1}{1 + e^{1.88} + e^{-1.754}} = 0.420

This is the same answer we obtained previously.
Example 3: Displaying relative-risk ratios

By specifying `rrr`, which we can do at estimation time or when we redisplay results, we see the model in terms of relative-risk ratios:

```
.mlogit, rrr
Multinomial logistic regression
Number of obs  =  616
LR chi2(2)     =  9.62
Prob > chi2    =  0.0081
Log likelihood = -551.78348 Pseudo R2 =  0.0086

RRR  Std. Err.     z     P>|z|      [95% Conf. Interval]
Indemnity
   nonwhite     .516427    .1114099  -3.06   0.002     .3383588    .7882073
   _cons       1.206731    .1131483   2.00   0.045     1.004149    1.450183
Prepaid (base outcome)
Uninsure
   nonwhite     .7536233   .2997387   -0.71   0.477     .3456255    1.643247
   _cons       1.1730769   .0312429   -9.72   0.000     1.1215024    1.2465434
```

Looked at this way, the relative risk of choosing an indemnity over a prepaid plan is 0.516 for nonwhites relative to whites.

To illustrate, from the output and discussions of examples 1 and 2 we find that

\[
\Pr(\text{insure} = \text{Indemnity} | \text{white}) = \frac{1}{1 + e^{-0.188} + e^{-1.942}} = 0.507
\]

and thus the relative risk of choosing indemnity over prepaid (for whites) is

\[
\frac{\Pr(\text{insure} = \text{Indemnity} | \text{white})}{\Pr(\text{insure} = \text{Prepaid} | \text{white})} = \frac{0.507}{0.420} = 1.207
\]

For nonwhites,

\[
\Pr(\text{insure} = \text{Indemnity} | \text{not white}) = \frac{1}{1 + e^{-0.188+0.661} + e^{-1.942+0.378}} = 0.355
\]

and thus the relative risk of choosing indemnity over prepaid (for nonwhites) is

\[
\frac{\Pr(\text{insure} = \text{Indemnity} | \text{not white})}{\Pr(\text{insure} = \text{Prepaid} | \text{not white})} = \frac{0.355}{0.570} = 0.623
\]

The ratio of these two relative risks, hence the name “relative-risk ratio”, is 0.623/1.207 = 0.516, as given in the output under the heading “RRR”.
Technical note

In models where only two categories are considered, the mlogit model reduces to standard logit. Consequently the exponentiated regression coefficients, labeled as RRR within mlogit, are equal to the odds ratios as given when the or option is specified under logit; see [R] logit.

As such, always referring to mlogit’s exponentiated coefficients as odds ratios may be tempting. However, the discussion in example 3 demonstrates that doing so would be incorrect. In general mlogit models, the exponentiated coefficients are ratios of relative risks, not ratios of odds.

Example 4: Model with continuous and multiple categorical variables

One of the advantages of mlogit over tabulate is that we can include continuous variables and multiple categorical variables in the model. In examining the data on insurance choice, we decide that we want to control for age, gender, and site of study (the study was conducted in three sites):

```
.mlogit insure age male nonwhite i.site
Iteration 0:  log likelihood = -555.85446
Iteration 1:  log likelihood = -534.67443
Iteration 2:  log likelihood = -534.36284
Iteration 3:  log likelihood = -534.36165
Iteration 4:  log likelihood = -534.36165
Multinomial logistic regression Number of obs = 615
LR chi2(10) = 42.99
Prob > chi2 = 0.0000
Log likelihood = -534.36165 Pseudo R2 = 0.0387

        |                   | Uninsured
---------|-------------------+------------------+
        |                   | age               -0.0077961   0.0114418  -0.68  0.496   -0.0302217   0.0146294
        |                   | male               0.4518496   0.3674867   1.23  0.219   -0.268411   1.17211
        |                   | nonwhite           0.2170589   0.4256361   0.51  0.610   -0.6171725   1.05129
        |                   | site=2             -1.211563   0.4705127  -2.57  0.010   -2.133751   -0.2893747
        |                   | site=3             -0.2078123   0.3662926  -0.57  0.570   -0.9257327   0.510108
        |                   | _cons              -1.286943   0.5923219  -2.17  0.030   -2.447872   -1.1260134
```

These results suggest that the inclination of nonwhites to choose prepaid care is even stronger than it was without controlling. We also see that subjects in site 2 are less likely to be uninsured.
Fitting constrained models

`mlogit` can fit models with subsets of coefficients constrained to be zero, with subsets of coefficients constrained to be equal both within and across equations, and with subsets of coefficients arbitrarily constrained to equal linear combinations of other estimated coefficients.

Before fitting a constrained model, you define the constraints with the `constraint` command; see [R] constraint. Once the constraints are defined, you estimate using `mlogit`, specifying the `constraint()` option. Typing `constraint(4)` would use the constraint you previously saved as 4. Typing `constraint(1,4,6)` would use the previously stored constraints 1, 4, and 6. Typing `constraint(1-4,6)` would use the previously stored constraints 1, 2, 3, 4, and 6.

Sometimes you will not be able to specify the constraints without knowing the omitted outcome. In such cases, assume that the omitted outcome is whatever outcome is convenient for you, and include the `baseoutcome()` option when you specify the `mlogit` command.

Example 5: Specifying constraints to test hypotheses

We can use constraints to test hypotheses, among other things. In our insurance-choice model, let's test the hypothesis that there is no distinction between having indemnity insurance and being uninsured. Indemnity-style insurance was the omitted outcome, so we type

```
  . test [Uninsured]
    ( 1) [Uninsured]age = 0
    ( 2) [Uninsured]male = 0
    ( 3) [Uninsured]nonwhite = 0
    ( 4) [Uninsured]1b.site = 0
    ( 5) [Uninsured]2b.site = 0
    ( 6) [Uninsured]3b.site = 0
    Constraint 4 dropped
    chi2( 5) = 9.31
    Prob > chi2 = 0.0973
```

If indemnity had not been the omitted outcome, we would have typed `test [Uninsured=Indemnity]`.

The results produced by `test` are an approximation based on the estimated covariance matrix of the coefficients. Because the probability of being uninsured is low, the log likelihood may be nonlinear for the uninsured. Conventional statistical wisdom is not to trust the asymptotic answer under these circumstances but to perform a likelihood-ratio test instead.

To use Stata's `lrtest` (likelihood-ratio test) command, we must fit both the unconstrained and constrained models. The unconstrained model is the one we have previously fit. Following the instruction in [R] `lrtest`, we first store the unconstrained model results:

```
  . estimates store unconstrained
```

To fit the constrained model, we must refit our model with all the coefficients except the constant set to 0 in the `Uninsured` equation. We define the constraint and then refit:
. constraint 1 [Uninsure]
. mlogit insure age male nonwhite i.site, constraints(1)

Iteration 0:  log likelihood = -555.85446
Iteration 1:  log likelihood = -539.80523
Iteration 2:  log likelihood = -539.75644
Iteration 3:  log likelihood = -539.75643

Multinomial logistic regression Number of obs = 615
Log likelihood = -539.75643 Wald chi2(5) = 29.70
Prob > chi2 = 0.0000
( 1) [Uninsure]o.age = 0
( 2) [Uninsure]o.male = 0
( 3) [Uninsure]o.nonwhite = 0
( 4) [Uninsure]2o.site = 0
( 5) [Uninsure]3o.site = 0

Coef. Std. Err. z P>|z| [95% Conf. Interval]

</tbody>
</table>

We can now perform the likelihood-ratio test:

. lrtest unconstrained

Likelihood-ratio test LR chi2(5) = 10.79
(Assumption: . nested in unconstrained) Prob > chi2 = 0.0557

The likelihood-ratio chi-squared is 10.79 with 5 degrees of freedom—just slightly greater than the magic \( p = 0.05 \) level—so we should not call this difference significant.

Technical note

In certain circumstances, you should fit a multinomial logit model with conditional logit; see [R] clogit. With substantial data manipulation, clogit can handle the same class of models with some interesting additions. For example, if we had available the price and deductible of the most competitive insurance plan of each type, mlogit could not use this information, but clogit could.
mlogit stores the following in e():

Scalars

- `e(N)`: number of observations
- `e(N_cd)`: number of completely determined observations
- `e(k_out)`: number of outcomes
- `e(k)`: number of parameters
- `e(k_eq)`: number of equations in e(b)
- `e(k_eq_model)`: number of equations in overall model test
- `e(k_dv)`: number of dependent variables
- `e(df_m)`: model degrees of freedom
- `e(r2_p)`: pseudo-$R^2$-squared
- `e(ll)`: log likelihood
- `e(ll0)`: log likelihood, constant-only model
- `e(N_clust)`: number of clusters
- `e(chi2)`: $\chi^2$
- `e(p)`: significance
- `e(k_eq_base)`: equation number of the base outcome
- `e(baseout)`: the value of depvar to be treated as the base outcome
- `e(ibaseout)`: index of the base outcome
- `e(rank)`: rank of e(V)
- `e(ic)`: number of iterations
- `e(rc)`: return code
- `e(converged)`: 1 if converged, 0 otherwise

Macros

- `e(cmd)`: mlogit
- `e(cmdline)`: command as typed
- `e(depvar)`: name of dependent variable
- `e(wtype)`: weight type
- `e(wexp)`: weight expression
- `e(title)`: title in estimation output
- `e(clustvar)`: name of cluster variable
- `e(chi2type)`: Wald or LR; type of model $\chi^2$ test
- `e(vce)`: vcetype specified in vce()
- `e(vcetype)`: title used to label Std. Err.
- `e(eqnames)`: names of equations
- `e(baselab)`: value label corresponding to base outcome
- `e(opt)`: type of optimization
- `e(which)`: max or min; whether optimizer is to perform maximization or minimization
- `e(ml_method)`: type of ml method
- `e(user)`: name of likelihood-evaluator program
- `e(technique)`: maximization technique
- `e(properties)`: b V
- `e(predict)`: program used to implement predict
- `e(marginsnotok)`: predictions disallowed by margins
- `e(asbalanced)`: factor variables fvset as asbalanced
- `e(asobserved)`: factor variables fvset as asobserved
### Matrices

- `e(b)` coefficient vector
- `e(out)` outcome values
- `e(Cns)` constraints matrix
- `e(ilog)` iteration log (up to 20 iterations)
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

### Functions

- `e(sample)` marks estimation sample

### Methods and Formulas

The multinomial logit model is described in Greene (2012, 763–766).

Suppose that there are $k$ categorical outcomes and—without loss of generality—let the base outcome be 1. The probability that the response for the $j$th observation is equal to the $i$th outcome is

$$\begin{align*}
    p_{ij} &= \Pr(y_j = i) = \begin{cases} 
        1, & \text{if } i = 1 \\
        \frac{1}{1 + \sum_{m=2}^{k} \exp(x_j \beta_m)}, & \text{if } i > 1
    \end{cases}
\end{align*}$$

where $x_j$ is the row vector of observed values of the independent variables for the $j$th observation and $\beta_m$ is the coefficient vector for outcome $m$. The log pseudolikelihood is

$$\ln L = \sum_j w_j \sum_{i=1}^{k} I_i(y_j) \ln p_{ik}$$

where $w_j$ is an optional weight and

$$I_i(y_j) = \begin{cases} 
    1, & \text{if } y_j = i \\
    0, & \text{otherwise}
\end{cases}$$

Newton–Raphson maximum likelihood is used; see [R] `maximize`.

For constrained equations, the set of constraints is orthogonalized, and a subset of maximizable parameters is selected. For example, a parameter that is constrained to zero is not a maximizable parameter. If two parameters are constrained to be equal to each other, only one is a maximizable parameter.

Let $\mathbf{r}$ be the vector of maximizable parameters. $\mathbf{r}$ is physically a subset of the solution parameters, $\mathbf{b}$. A matrix, $\mathbf{T}$, and a vector, $\mathbf{m}$, are defined as

$$\mathbf{b} = \mathbf{Tr} + \mathbf{m}$$
so that
\[
\frac{\partial f}{\partial b} = \frac{\partial f}{\partial r} T'
\]
\[
\frac{\partial^2 f}{\partial b^2} = T \frac{\partial^2 f}{\partial r^2} T'
\]

\(T\) consists of a block form in which one part is a permutation of the identity matrix and the other part describes how to calculate the constrained parameters from the maximizable parameters.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \texttt{[P] _robust}, particularly \texttt{Maximum likelihood estimators} and \texttt{Methods and formulas}.

\texttt{mlogit} also supports estimation with survey data. For details on VCEs with survey data, see \texttt{[SVY]} \texttt{variance estimation}.

Syntax for predict

\[
\text{predict} \ [\text{type}] \ \{ \text{stub}\* | \text{newvar} | \text{newvarlist} \} \ [\text{if}] \ [\text{in}] \ [, \ \text{statistic} \ \text{outcome}(\text{outcome})] \\
\text{predict} \ [\text{type}] \ \{ \text{stub}\* | \text{newvarlist} \} \ [\text{if}] \ [\text{in}], \ \text{scores}
\]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>probability of a positive outcome; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td>stddp</td>
<td>standard error of the difference in two linear predictions</td>
</tr>
</tbody>
</table>

If you do not specify \text{outcome()}, \text{pr} (with one new variable specified), \text{xb}, and \text{stdp} assume \text{outcome(#1)}. You must specify \text{outcome()} with the \text{stddp} option.

You specify one or \(k\) new variables with \text{pr}, where \(k\) is the number of outcomes.

You specify one new variable with \text{xb}, \text{stdp}, and \text{stddp}.

These statistics are available both in and out of sample; type \text{predict} ... if \text{e(sample)} ... if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

\text{pr}, the default, calculates the probability of each of the categories of the dependent variable or the probability of the level specified in \text{outcome}(\text{outcome}). If you specify the \text{outcome}(\text{outcome}) option, you need to specify only one new variable; otherwise, you must specify a new variable for each category of the dependent variable.

\text{xb} calculates the linear prediction. You must also specify the \text{outcome}(\text{outcome}) option.

\text{stdp} calculates the standard error of the linear prediction. You must also specify the \text{outcome}(\text{outcome}) option.

\text{stddp} calculates the standard error of the difference in two linear predictions. You must specify the \text{outcome}(\text{outcome}) option, and here you specify the two particular outcomes of interest inside the parentheses, for example, \text{predict sed, stddp outcome(1,3)}.

\text{outcome}(\text{outcome}) specifies the outcome for which the statistic is to be calculated. \text{equation()} is a synonym for \text{outcome}(): it does not matter which you use. \text{outcome()} or \text{equation()} can be specified using

\[
#1, #2, \ldots, \text{where } #1 \text{ means the first category of the dependent variable, } #2 \text{ means the second category, etc.;}
\]

the values of the dependent variable; or

the value labels of the dependent variable if they exist.
scores calculates equation-level score variables. The number of score variables created will be one less than the number of outcomes in the model. If the number of outcomes in the model were \( k \), then

- the first new variable will contain \( \partial \ln L / \partial (x_j \beta_1) \);
- the second new variable will contain \( \partial \ln L / \partial (x_j \beta_2) \);
- \( \ldots \)
- the \( (k - 1) \)th new variable will contain \( \partial \ln L / \partial (x_j \beta_{k-1}) \).

Remarks and examples

Remarks are presented under the following headings:

- Obtaining predicted values
- Calculating marginal effects
- Testing hypotheses about coefficients

Obtaining predicted values

Example 1: Obtaining predicted probabilities

After estimation, we can use predict to obtain predicted probabilities, index values, and standard errors of the index, or differences in the index. For instance, in example 4 of [R] mlogit, we fit a model of insurance choice on various characteristics. We can obtain the predicted probabilities for outcome 1 by typing

```stata
use http://www.stata-press.com/data/r13/sysdsn1
(Health insurance data)
mlogit insure age i.male i.nonwhite i.site
(predict omitted)
predict p1 if e(sample), outcome(1)
(option pr assumed; predicted probability)
(29 missing values generated)
summarize p1
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>p1</td>
<td>615</td>
<td>.4764228</td>
<td>.1032279</td>
<td>.1698142</td>
<td>.71939</td>
</tr>
</tbody>
</table>

We added the i. prefix to the male, nonwhite, and site variables to explicitly identify them as factor variables. That makes no difference in the estimated results, but we will take advantage of it in later examples. We also included if e(sample) to restrict the calculation to the estimation sample. In example 4 of [R] mlogit, the multinomial logit model was fit on 615 observations, so there must be missing values in our dataset.

Although we typed outcome(1), specifying 1 for the indemnity outcome, we could have typed outcome(Indemnity). For instance, to obtain the probabilities for prepaid, we could type

```stata
predict p2 if e(sample), outcome(Prepaid)
(option pr assumed; predicted probability)
(29 missing values generated)
summarize p2
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>p2</td>
<td>615</td>
<td>.4504065</td>
<td>.1125962</td>
<td>.1964103</td>
<td>.7885724</td>
</tr>
</tbody>
</table>
We must specify the label exactly as it appears in the underlying value label (or how it appears in the `mlogit` output), including capitalization.

Here we have used `predict` to obtain probabilities for the same sample on which we estimated. That is not necessary. We could use another dataset that had the independent variables defined (in our example, `age`, `male`, `nonwhite`, and `site`) and use `predict` to obtain predicted probabilities; here, we would not specify `if e(sample)`.

Example 2: Obtaining index values

`predict` can also be used to obtain the index values—the $\sum x_i\hat{\beta}_i^{(k)}$—as well as the probabilities:

```
. predict idx1, outcome(Indemnity) xb
(1 missing value generated)
. summarize idx1
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>idx1</td>
<td>643</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

The indemnity outcome was our base outcome—the outcome for which all the coefficients were set to 0—so the index is always 0. For the prepaid and uninsured outcomes, we type

```
. predict idx2, outcome(Prepaid) xb
(1 missing value generated)
. predict idx3, outcome(Uninsure) xb
(1 missing value generated)
. summarize idx2 idx3
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>idx2</td>
<td>643</td>
<td>-.0566113</td>
<td>.4962973</td>
<td>-1.298198</td>
<td>1.700719</td>
</tr>
<tr>
<td>idx3</td>
<td>643</td>
<td>-1.980747</td>
<td>.6018139</td>
<td>-3.112741</td>
<td>-.8258458</td>
</tr>
</tbody>
</table>

We can obtain the standard error of the index by specifying the `stdp` option:

```
. predict se2, outcome(Prepaid) stdp
(1 missing value generated)
. list p2 idx2 se2 in 1/5
```

<table>
<thead>
<tr>
<th>p2</th>
<th>idx2</th>
<th>se2</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>.3709022</td>
<td>-.4831167</td>
</tr>
<tr>
<td>2.</td>
<td>.4977667</td>
<td>.055111</td>
</tr>
<tr>
<td>3.</td>
<td>.4113073</td>
<td>-.1712106</td>
</tr>
<tr>
<td>4.</td>
<td>.5424927</td>
<td>.3788345</td>
</tr>
<tr>
<td>5.</td>
<td>.</td>
<td>-.0925817</td>
</tr>
</tbody>
</table>

We obtained the probability, `p2`, in the previous example.
Finally, `predict` can calculate the standard error of the difference in the index values between two outcomes with the `stddp` option:

```
. predict se_2_3, outcome(Prepaid,Uninsure) stddp
(1 missing value generated)
```

```
. list idx2 idx3 se_2_3 in 1/5
```

<table>
<thead>
<tr>
<th>idx2</th>
<th>idx3</th>
<th>se_2_3</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>-0.483</td>
<td>0.547</td>
</tr>
<tr>
<td>2.</td>
<td>0.055</td>
<td>0.433</td>
</tr>
<tr>
<td>3.</td>
<td>-0.171</td>
<td>0.305</td>
</tr>
<tr>
<td>4.</td>
<td>0.378</td>
<td>0.449</td>
</tr>
<tr>
<td>5.</td>
<td>-0.093</td>
<td>0.403</td>
</tr>
</tbody>
</table>

In the first observation, the difference in the indexes is $-0.483 - (-3.073) = 2.59$. The standard error of that difference is 0.547.

Example 3: Interpreting results using predictive margins

It is more difficult to interpret the results from `mlogit` than those from `clogit` or `logit` because there are multiple equations. For example, suppose that one of the independent variables in our model takes on the values 0 and 1, and we are attempting to understand the effect of this variable. Assume that the coefficient on this variable for the second outcome, $\beta^{(2)}$, is positive. We might then be tempted to reason that the probability of the second outcome is higher if the variable is 1 rather than 0. Most of the time, that will be true, but occasionally we will be surprised. The probability of some other outcome could increase even more (say, $\beta^{(3)} > \beta^{(2)}$), and thus the probability of outcome 2 would actually fall relative to that outcome. We can use `predict` to help interpret such results.

Continuing with our previously fit insurance-choice model, we wish to describe the model’s predictions by race. For this purpose, we can use the method of predictive margins (also known as recycled predictions), in which we vary characteristics of interest across the whole dataset and average the predictions. That is, we have data on both whites and nonwhites, and our individuals have other characteristics as well. We will first pretend that all the people in our data are white but hold their other characteristics constant. We then calculate the probabilities of each outcome. Next we will pretend that all the people in our data are nonwhite, still holding their other characteristics constant. Again we calculate the probabilities of each outcome. The difference in those two sets of calculated probabilities, then, is the difference due to race, holding other characteristics constant.

```
. gen byte nonwhold=nonwhite // save real race
. replace nonwhite=0 // make everyone white
(126 real changes made)
. predict wpind, outcome(Indemnity) // predict probabilities
(option pr assumed; predicted probability)
(1 missing value generated)
. predict wpp, outcome(Prepaid)
(option pr assumed; predicted probability)
(1 missing value generated)
. predict wpnoi, outcome(Uninsure)
(option pr assumed; predicted probability)
(1 missing value generated)
. replace nonwhite=1 // make everyone nonwhite
(644 real changes made)
```
In example 1 of [R] mlogit, we presented a cross-tabulation of insurance type and race. Those values were unadjusted. The means reported above are the values adjusted for age, sex, and site. Combining the results gives

<table>
<thead>
<tr>
<th></th>
<th>Unadjusted</th>
<th>Adjusted</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>white</td>
<td>nonwhite</td>
</tr>
<tr>
<td>Indemnity</td>
<td>0.51</td>
<td>0.36</td>
</tr>
<tr>
<td>Prepaid</td>
<td>0.42</td>
<td>0.57</td>
</tr>
<tr>
<td>Uninsured</td>
<td>0.07</td>
<td>0.07</td>
</tr>
</tbody>
</table>

We find, for instance, after adjusting for age, sex, and site, that although 57% of nonwhites in our data had prepaid plans, 63% of nonwhites chose prepaid plans.

Computing predictive margins by hand was instructive, but we can compute these values more easily using the margins command (see [R] margins). The two margins for the indemnity outcome can be estimated by typing

```
margins nonwhite, predict(outcome(Indemnity)) noesample
```

<table>
<thead>
<tr>
<th></th>
<th>Delta-method</th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>

```
margins also estimates the standard errors and confidence intervals of the margins. By default, margins uses only the estimation sample. We added the noesample option so that margins would use the entire sample and produce results comparable to our earlier analysis.
We can use `marginsplot` to graph the results from margins:

```stata
.marginsplot
Variables that uniquely identify margins: nonwhite
```

![Predictive Margins of nonwhite with 95% CIs](image)

The margins for the other two outcomes can be computed by typing

```stata
.margins nonwhite, predict(outcome(Prepaid)) noesample (output omitted)
margins nonwhite, predict(outcome(Uninsure)) noesample (output omitted)
```

**Technical note**

You can use `predict` to classify predicted values and compare them with the observed outcomes to interpret a multinomial logit model. This is a variation on the notions of sensitivity and specificity for logistic regression. Here we will classify indemnity and prepaid as definitely predicting indemnity, definitely predicting prepaid, and ambiguous.

```stata
.predict indem, outcome(Indemnity) index // obtain indexes
.predict prepaid, outcome(Prepaid) index // obtain indexes
.gen diff = prepaid-indem // obtain difference
.predict sediff, outcome(Indemnity,Prepaid) stddp // & its standard error
.gen type = 1 if diff/sediff < -1.96 // definitely indemnity
.replace type = 3 if diff/sediff > 1.96 // definitely prepaid
.replace type = 2 if type>=. & diff/sediff < . // ambiguous
.label def type 1 "Def Ind" 2 "Ambiguous" 3 "Def Prep"
.label values type type // label results
```
We can see that the predictive power of this model is modest. There are many misclassifications in both directions, though there are more correctly classified observations than misclassified observations.

Also the uninsured look overwhelmingly as though they might have come from the indemnity system rather than from the prepaid system.

Calculating marginal effects

Example 4

We have already noted that the coefficients from multinomial logit can be difficult to interpret because they are relative to the base outcome. Another way to evaluate the effect of covariates is to examine the marginal effect of changing their values on the probability of observing an outcome.

The margins command can be used for this too. We can estimate the marginal effect of each covariate on the probability of observing the first outcome—indemnity insurance—by typing

```
. margins, dydx(*) predict(outcome(Indemnity))
```

By default, margins estimates the average marginal effect over the estimation sample, and that is what we see above. Being male decreases the average probability of having indemnity insurance by 0.130. We also see, from the note at the bottom of the table, that the marginal effect was computed as a discrete change in the probability of being male rather than female. That is why we made male a factor variable when fitting the model.

The dydx(*) option requested that margins estimate the marginal effect for each regressor, dydx(age) would have produced estimates only for the effect of age. margins has many options for controlling how the marginal effect is computed, including the ability to average over subgroups or to compute estimates for specified values of the regressors; see [R] margins.
We could evaluate the marginal effects on the other two outcomes by typing

```
. margins, dydx(*) predict(outcome(Prepaid))
(output omitted)
. margins, dydx(*) predict(outcome(Uninsure))
(output omitted)
```

### Testing hypotheses about coefficients

#### Example 5

test tests hypotheses about the coefficients just as after any estimation command; see [R] test. Note, however, test’s syntax for dealing with multiple-equation models. Because test bases its results on the estimated covariance matrix, we might prefer a likelihood-ratio test; see example 5 in [R] mlogit for an example of lrtest.

If we simply list variables after the test command, we are testing that the corresponding coefficients are zero across all equations:

```
. test 2.site 3.site
   ( 1) [Indemnity]2o.site = 0
   ( 2) [Prepaid]2.site = 0
   ( 3) [Uninsure]2.site = 0
   ( 4) [Indemnity]3o.site = 0
   ( 5) [Prepaid]3.site = 0
   ( 6) [Uninsure]3.site = 0
   Constraint 1 dropped
   Constraint 4 dropped
   chi2( 4) = 19.74
   Prob > chi2 = 0.0006
```

We can test that all the coefficients (except the constant) in an equation are zero by simply typing the outcome in square brackets:

```
. test [Uninsure]
   ( 1) [Uninsure]age = 0
   ( 2) [Uninsure]0b.male = 0
   ( 3) [Uninsure]1.male = 0
   ( 4) [Uninsure]0b.nonwhite = 0
   ( 5) [Uninsure]1.nonwhite = 0
   ( 6) [Uninsure]1b.site = 0
   ( 7) [Uninsure]2.site = 0
   ( 8) [Uninsure]3.site = 0
   Constraint 2 dropped
   Constraint 4 dropped
   Constraint 6 dropped
   chi2( 5) =  9.31
   Prob > chi2 =  0.0973
```

We specify the outcome just as we do with predict; we can specify the label if the outcome variable is labeled, or we can specify the numeric value of the outcome. We would have obtained the same test as above if we had typed test [3] because 3 is the value of insure for the outcome uninsured.

We can combine the two syntaxes. To test that the coefficients on the site variables are 0 in the equation corresponding to the outcome prepaid, we can type
We specified the outcome and then followed that with a colon and the variables we wanted to test.

We can also test that coefficients are equal across equations. To test that all coefficients except the constant are equal for the prepaid and uninsured outcomes, we can type

```
.test [Prepaid=Uninsure]
( 1) [Prepaid]age - [Uninsure]age = 0
( 2) [Prepaid]0b.male - [Uninsure]0b.male = 0
( 3) [Prepaid]1.male - [Uninsure]1.male = 0
( 4) [Prepaid]0b.nonwhite - [Uninsure]0b.nonwhite = 0
( 5) [Prepaid]1.nonwhite - [Uninsure]1.nonwhite = 0
( 6) [Prepaid]1b.site - [Uninsure]1b.site = 0
( 7) [Prepaid]2.site - [Uninsure]2.site = 0
( 8) [Prepaid]3.site - [Uninsure]3.site = 0
Constraint 2 dropped
Constraint 4 dropped
Constraint 6 dropped
```

```
chi2( 5) = 13.80
Prob > chi2 = 0.0169
```

To test that only the site variables are equal, we can type

```
.test [Prepaid=Uninsure]: 2.site 3.site
( 1) [Prepaid]2.site - [Uninsure]2.site = 0
( 2) [Prepaid]3.site - [Uninsure]3.site = 0
```

```
chi2( 2) = 12.68
Prob > chi2 = 0.0018
```

Finally, we can test any arbitrary constraint by simply entering the equation and specifying the coefficients as described in [U] 13.5 Accessing coefficients and standard errors. The following hypothesis is senseless but illustrates the point:

```
.test ([Prepaid]age+[Uninsure]2.site)/2 = 2-[Uninsure]1.nonwhite
( 1) .5*[Prepaid]age + [Uninsure]1.nonwhite + .5*[Uninsure]2.site = 2
```

```
chi2( 1) = 22.45
Prob > chi2 = 0.0000
```

See [R] test for more information about test. The information there about combining hypotheses across test commands (the accumulate option) also applies after mlogit.

[U] 20 Estimation and postestimation commands
more — The —more— message

Syntax

Tell Stata to pause or not pause for —more— messages

set more { on|off } [, permanently ]

Set number of lines between —more— messages

set pagesize #

Description

set more on, which is the default, tells Stata to wait until you press a key before continuing when a —more— message is displayed.

set more off tells Stata not to pause or display the —more— message.

set pagesize # sets the number of lines between —more— messages. The permanently option is not allowed with set pagesize.

Option

permanently specifies that, in addition to making the change right now, the more setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

When you see —more— at the bottom of the screen,

<table>
<thead>
<tr>
<th>Press</th>
<th>and Stata</th>
</tr>
</thead>
<tbody>
<tr>
<td>letter l or</td>
<td>displays the next line</td>
</tr>
<tr>
<td>Enter</td>
<td></td>
</tr>
<tr>
<td>letter q</td>
<td>acts as if you pressed Break</td>
</tr>
<tr>
<td>Spacebar or</td>
<td>displays the next screen</td>
</tr>
<tr>
<td>any other key</td>
<td></td>
</tr>
</tbody>
</table>

You can also click on the More button or click on —more— to display the next screen.

—more— is Stata’s way of telling you that it has something more to show you but that showing it to you will cause the information on the screen to scroll off.

If you type set more off, —more— conditions will never arise, and Stata’s output will scroll by at full speed.

If you type set more on, —more— conditions will be restored at the appropriate places.

Programmers should see [P] more for information on the more programming command.

indepvars may contain factor variables; see [U] 11.4.3 Factor variables.

bootstrap, by, fp, jackknife, mi estimate, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.

vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

vce() and weights are not allowed with the svy prefix; see [SVY] svy.

fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.

coeflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
Menu

Statistics > Categorical outcomes > Independent multinomial probit

Description

`mprobit` fits multinomial probit (MNP) models via maximum likelihood. `depvar` contains the outcome for each observation, and `indepvars` are the associated covariates. The error terms are assumed to be independent, standard normal, random variables. See [R] `asmprob` for the case where the latent-variable errors are correlated or heteroskedastic and you have alternative-specific variables.

Options

- **Model**
  - `noconstant` suppresses the $J - 1$ constant terms.
  - `baseoutcome(# | lbl)` specifies the outcome used to normalize the location of the latent variable. The base outcome may be specified as a number or a label. The default is to use the most frequent outcome. The coefficients associated with the base outcome are zero.
  - `probitparam` specifies to use the probit variance parameterization by fixing the variance of the differenced latent errors between the scale and the base alternatives to be one. The default is to make the variance of the base and scale latent errors one, thereby making the variance of the difference to be two.

- **SE/Robust**
  - `vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim, opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap, jackknife`); see [R] `vce_option`.
    - If specifying `vce(bootstrap)` or `vce(jackknife)`, you must also specify `baseoutcome()`.

- **Reporting**
  - `level(#)`; see [R] `estimation options`.
  - `nocnsreport`; see [R] `estimation options`.
  - `display_options`: `nomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch`; see [R] `estimation options`.

- **Integration**
  - `intpoints(#)` specifies the number of Gaussian quadrature points to use in approximating the likelihood. The default is 15.
**Remarks and examples**

The MNP model is used with discrete dependent variables that take on more than two outcomes that do not have a natural ordering. The stochastic error terms for this implementation of the model are assumed to have independent, standard normal distributions. To use `mprobit`, you must have one observation for each decision maker in the sample. See `[R] asmprobit` for another implementation of the MNP model that permits correlated and heteroskedastic errors and is suitable when you have data for each alternative that a decision maker faced.

The MNP model is frequently motivated using a latent-variable framework. The latent variable for the $j$th alternative, $j = 1, \ldots, J$, is

$$
\eta_{ij} = z_i \alpha_j + \xi_{ij}
$$

where the $1 \times q$ row vector $z_i$ contains the observed independent variables for the $i$th decision maker. Associated with $z_i$ are the $J$ vectors of regression coefficients $\alpha_j$. The $\xi_{i1}, \ldots, \xi_{iJ}$ are distributed independently and identically standard normal. The decision maker chooses the alternative $k$ such that $\eta_{ik} \geq \eta_{im}$ for $m \neq k$.

Suppose that case $i$ chooses alternative $k$, and take the difference between latent variable $\eta_{ik}$ and the $J-1$ others:

$$
v_{ijk} = \eta_{ij} - \eta_{ik} = z_i (\alpha_j - \alpha_k) + \xi_{ij} - \xi_{ik} = z_i \gamma_{j'} + \epsilon_{ij'}
$$

where $j' = j$ if $j < k$ and $j' = j-1$ if $j > k$ so that $j' = 1, \ldots, J-1$. $\text{Var}(\epsilon_{ij'}) = \text{Var}(\xi_{ij} - \xi_{ik}) = 2$ and $\text{Cov}(\epsilon_{ij'}, \epsilon_{il'}) = 1$ for $j' \neq l'$. The probability that alternative $k$ is chosen is

$$
\Pr(i \text{ chooses } k) = \Pr(v_{i1k} \leq 0, \ldots, v_{i,J-1,k} \leq 0) = \Pr(\epsilon_{i1} \leq -z_i \gamma_1, \ldots, \epsilon_{i,J-1} \leq -z_i \gamma_{J-1})
$$

Hence, evaluating the likelihood function involves computing probabilities from the multivariate normal distribution. That all the covariances are equal simplifies the problem somewhat; see *Methods and formulas* for details.

In (1), not all $J$ of the $\alpha_j$ are identifiable. To remove the indeterminacy, $\alpha_l$ is set to the zero vector, where $l$ is the base outcome as specified in the `baseoutcome()` option. That fixes the $l$th latent variable to zero so that the remaining variables measure the attractiveness of the other alternatives relative to the base.
Example 1

As discussed in example 1 of [R] mlogit, we have data on the type of health insurance available to 616 psychologically depressed subjects in the United States (Tarlov et al. 1989; Wells et al. 1989). Patients may have either an indemnity (fee-for-service) plan or a prepaid plan such as an HMO, or the patient may be uninsured. Demographic variables include age, gender, race, and site. Indemnity insurance is the most popular alternative, so mprobit will choose it as the base outcome by default.

```
. use http://www.stata-press.com/data/r13/sysdsn1  \n   (Health insurance data)
. mprobit insure age male nonwhite i.site
```

```

```

The likelihood function for mprobit is derived under the assumption that all decision-making units face the same choice set, which is the union of all outcomes observed in the dataset. If that is not true for your model, then an alternative is to use the asmprobit command, which does not require this assumption. To do that, you will need to expand the dataset so that each decision maker has \( k_i \) observations, where \( k_i \) is the number of alternatives in the choice set faced by decision maker \( i \). You will also need to create a binary variable to indicate the choice made by each decision maker. Moreover, you will need to use the correlation(independent) and stddev(homoskedastic) options with asmprobit unless you have alternative-specific variables.
Stored results

`mprobit` stores the following in `e()`:

Scalars

- `e(N)` number of observations
- `e(k_out)` number of outcomes
- `e(k_points)` number of quadrature points
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_indvars)` number of independent variables
- `e(k_dv)` number of dependent variables
- `e(df_m)` log simulated-likelihood
- `e(ll)` number of clusters
- `e(chi2)` log simulated-likelihood
- `e(chi2)` number of clusters
- `e(chi2)` significance
- `e(i_base)` base outcome index
- `e(const)` 0 if `noconstant` is specified, 1 otherwise
- `e(probitparam)` 1 if `probitparam` is specified, 0 otherwise
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

Macros

- `e(cmd)` `mprobit`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(indvars)` independent variables
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(chi2type)` Wald, type of model `\chi^2` test
- `e(vce)` vcetype specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(outeqs)` outcome equations
- `e(out#)` outcome labels, `#` = 1, ..., `e(k_out)`
- `e(opt)` type of optimization
- `e(which)` `max` or `min`; whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of ml method
- `e(user)` name of likelihood-evaluator program
- `e(technique)` maximization technique
- `e(properties)` `b V`
- `e(predict)` program used to implement predict
- `e(marginsnotok)` predictions disallowed by `margins`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`
Methods and formulas

See Cameron and Trivedi (2005, chap. 15) for a discussion of multinomial models, including multinomial probit. Long and Freese (2014, chap. 8) discuss the multinomial logistic, multinomial probit, and stereotype logistic regression models, with examples using Stata.

As discussed in Remarks and examples, the latent variables for a \( J \)-alternative model are \( \eta_{ij} = z_i \alpha_j + \xi_{ij}, \) for \( j = 1, \ldots, J, \ i = 1, \ldots, n, \) and \( \{\xi_{i,1}, \ldots, \xi_{i,J}\} \sim \text{i.i.d.} N(0, 1). \) The experimenter observes alternative \( k \) for the \( i \)th observation if \( \eta_{ik} > \eta_{il} \) for \( l \neq k. \) For \( j \neq k, \) let

\[
v_{ij'} = \eta_{ij} - \eta_{ik} = z_i (\alpha_j - \alpha_k) + \xi_{ij} - \xi_{ik} = z_i \gamma_{j'} + \epsilon_{ij'},
\]

where \( j' = j \) if \( j < k \) and \( j' = j - 1 \) if \( j > k \) so that \( j' = 1, \ldots, J - 1. \) \( \epsilon_i = (\epsilon_{i,1}, \ldots, \epsilon_{i,J-1}) \sim MVN(0, \Sigma), \) where

\[
\Sigma = \begin{pmatrix}
2 & 1 & 1 & \ldots & 1 \\
1 & 2 & 1 & \ldots & 1 \\
1 & 1 & 2 & \ldots & 1 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
1 & 1 & 1 & \ldots & 2
\end{pmatrix}
\]

Denote the deterministic part of the model as \( \lambda_{ij'} = z_i \gamma_{j'}, \) the probability that subject \( i \) chooses outcome \( k \) is

\[
\Pr(y_i = k) = \Pr(v_{i1} \leq 0, \ldots, v_{i,J-1} \leq 0) = \Pr(\epsilon_{i1} \leq -\lambda_{i1}, \ldots, \epsilon_{i,J-1} \leq -\lambda_{i,J-1}) = \frac{1}{(2\pi)^{(J-1)/2} |\Sigma|^{1/2}} \int_{-\infty}^{-\lambda_{i1}} \cdots \int_{-\infty}^{-\lambda_{i,J-1}} \exp \left( -\frac{1}{2} z' \Sigma^{-1} z \right) dz
\]

Because of the exchangeable correlation structure of \( \Sigma (\rho_{ij} = 1/2 \text{ for all } i \neq j), \) we can use Dunnett’s (1989) result to reduce the multidimensional integral to one dimension:

\[
\Pr(y_i = k) = \frac{1}{\sqrt{\pi}} \int_{0}^{\infty} \left\{ \prod_{j=1}^{J-1} \Phi \left( -z\sqrt{2} - \lambda_{ij} \right) + \prod_{j=1}^{J-1} \Phi \left( z\sqrt{2} - \lambda_{ij} \right) \right\} e^{-z^2} dz
\]
Gaussian quadrature is used to approximate this integral, resulting in the $K$-point quadrature formula

$$\Pr(y_i = k) \approx \frac{1}{2} \sum_{k=1}^{K} w_k \left\{ \prod_{j=1}^{J-1} \Phi \left( -\sqrt{2}x_k - \lambda_{ij} \right) + \prod_{j=1}^{J-1} \Phi \left( \sqrt{2}x_k - \lambda_{ij} \right) \right\}$$

where $w_k$ and $x_k$ are the weights and roots of the Laguerre polynomial of order $K$. In mprobit, $K$ is specified by the `intpoints()` option.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

mprobit also supports estimation with survey data. For details on VCEs with survey data, see [SVY] variance estimation.

**mprobit postestimation — Postestimation tools for mprobit**

**Description**

The following postestimation commands are available after `mprobit`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>contrast</strong></td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td><strong>estat ic</strong></td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td><strong>estat summarize</strong></td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td><strong>estat vce</strong></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><strong>estat (svy)</strong></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><strong>estimates</strong></td>
<td>cataloging estimation results</td>
</tr>
<tr>

</tr>
<tr>
<td><strong>testnl</strong></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

1 **forecast** is not appropriate with `mi` or `svy` estimation results.

2 **lrtest** is not appropriate with `svy` estimation results.
Syntax for predict

```
predict [type] { stub* | newvar | newvarlist } [if] [in] [, statistic outcome(outcome)]
predict [type] { stub* | newvarlist } [if] [in], scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>probability of a positive outcome; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

If you do not specify outcome(), pr (with one new variable specified), xb, and stdp assume outcome(#1). You specify one or k new variables with pr, where k is the number of outcomes. You specify one new variable with xb and stdp. These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

**Main**

pr, the default, calculates the probability of each of the categories of the dependent variable or the probability of the level specified in outcome(outcome). If you specify the outcome(outcome) option, you need to specify only one new variable; otherwise, you must specify a new variable for each category of the dependent variable.

xb calculates the linear prediction, \( x_i \alpha_j \), for alternative \( j \) and individual \( i \). The index, \( j \), corresponds to the outcome specified in outcome().

stdp calculates the standard error of the linear prediction.

outcome(outcome) specifies the outcome for which the statistic is to be calculated. equation() is a synonym for outcome(): it does not matter which you use. outcome() or equation() can be specified using

```
#1, #2, ..., where #1 means the first category of the dependent variable, #2 means the second category, etc.;
the values of the dependent variable; or
the value labels of the dependent variable if they exist.
```

scores calculates the equation-level score variables. The \( j \)th new variable will contain the scores for the \( j \)th fitted equation.
Remarks and examples

Once you have fit a multinomial probit model, you can use `predict` to obtain probabilities that an individual will choose each of the alternatives for the estimation sample, as well as other samples; see [U] 20 Estimation and postestimation commands and [R] `predict`.

Example 1

In example 1 of [R] `mprobit`, we fit the multinomial probit model to a dataset containing the type of health insurance available to 616 psychologically depressed subjects in the United States (Tarlov et al. 1989; Wells et al. 1989). We can obtain the predicted probabilities by typing

```
. use http://www.stata-press.com/data/r13/sysdsn1
(Health insurance data)
. mprobit insure age male nonwhite i.site
(output omitted)
. predict p1-p3
(option pr assumed; predicted probabilities)
. list p1-p3 insure in 1/10

p1  p2  p3   insure
1.  .5961306   .3741824   .029687   Indemnity
2.  .4719296   .4972289   .0308415   Prepaid
3.  .4896086   .4121961   .0981953   Indemnity
4.  .3730529   .5416623   .0852848   Prepaid
5.  .5063069   .4629773   .0307158
6.  .4768125   .4923548   .0308327   Prepaid
7.  .5036572   .4657016   .0307312   Prepaid
8.  .3326361   .5580404   .1093235
9.  .4758165   .4384811   .0857024   Uninsured
10.  .5734057   .3316601   .0949342   Prepaid
```

`insure` contains a missing value for observations 5 and 8. Because of that, those two observations were not used in the estimation. However, because none of the independent variables is missing, `predict` can still calculate the probabilities. Had we typed

```
. predict p1-p3 if e(sample)
```

`predict` would have filled in missing values for `p1`, `p2`, and `p3` for those observations because they were not used in the estimation.

Title

nbreg — Negative binomial regression

Syntax

Negative binomial regression model

```
nbreg depvar [ indepvars ] [ if ] [ in ] [ weight ] [ , nbreg_options ]
```

Generalized negative binomial model

```
gnbreg depvar [ indepvars ] [ if ] [ in ] [ weight ] [ , gnbreg_options ]
```

**nbreg_options**

**Model**
- **noconstant** suppress constant term
- **dispersion(mean)** parameterization of dispersion; the default
- **dispersion(constant)** constant dispersion for all observations
- **exposure(varname)** include ln(varname) in model with coefficient constrained to 1
- **offset(varname)** include varname in model with coefficient constrained to 1
- **constraints(constraints)** apply specified linear constraints
- **collinear** keep collinear variables

**SE/Robust**
- **vce(vcetype)** vcetype may be oim, robust, cluster clustvar, opg, bootstrap, or jackknife

**Reporting**
- **level(#)** set confidence level; default is level(95)
- **nolrtest** suppress likelihood-ratio test
- **irr** report incidence-rate ratios
- **nocnsreport** do not display constraints
- **display_options** control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

**Maximization**
- **maximize_options** control the maximization process; seldom used
- **coeflegend** display legend instead of statistics

**nbreg**

Statistics > Count outcomes > Negative binomial regression

**gnbreg**

Statistics > Count outcomes > Generalized negative binomial regression

### Description

**nbreg** fits a negative binomial regression model of *depvar* on *indepvars*, where *depvar* is a nonnegative count variable. In this model, the count variable is believed to be generated by a Poisson-like process, except that the variation is greater than that of a true Poisson. This extra variation is referred to as overdispersion. See [R] poisson before reading this entry.

---

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

---

indepvars and varlist may contain factor variables; see [U] 11.4.3 Factor variables.

depvar, indepvars, varname_e, and varname_o may contain time-series operators (nbreg only); see [U] 11.4.4 Time-series varlists.

bootstrap, by (nbreg only), fp (nbreg only), jackknife, mfp (nbreg only), mi estimate, nestreg (nbreg only), rolling, statsby, stepwise, and svy are allowed; see [U] 11.1.10 Prefix commands.

vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

vce() and weights are not allowed with the svy prefix; see [SVY] svy.

fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.

coefflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
gnbreg fits a generalization of the negative binomial mean-dispersion model; the shape parameter $\alpha$ may also be parameterized.

If you have panel data, see [XT] xtnbreg and [ME] menbreg.

Options for nbreg

- **Model**
  - `noconstant`; see [R] estimation options.
  - `dispersion(mean | constant)` specifies the parameterization of the model. dispersion(mean), the default, yields a model with dispersion equal to $1 + \alpha \exp(x_j \beta + \text{offset}_j)$; that is, the dispersion is a function of the expected mean: $\exp(x_j \beta + \text{offset}_j)$. dispersion(constant) has dispersion equal to $1 + \delta$; that is, it is a constant for all observations.

- **SE/Robust**
  - `vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

- **Reporting**
  - `level(#)`; see [R] estimation options.
  - `nolrtest` suppresses fitting the Poisson model. Without this option, a comparison Poisson model is fit, and the likelihood is used in a likelihood-ratio test of the null hypothesis that the dispersion parameter is zero.
  - `irr` reports estimated coefficients transformed to incidence-rate ratios, that is, $e^{\beta_i}$ rather than $\beta_i$. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. `irr` may be specified at estimation or when replaying previously estimated results.

- **display_options**: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

- **Maximization**
  - `maximize_options`: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

  Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following option is available with nbreg but is not shown in the dialog box: coeflegend; see [R] estimation options.
Options for gnbreg

```
noconstant; see [R] estimation options.
```

`lnalpha(varlist)` allows you to specify a linear equation for lnα. Specifying `lnalpha(male old)` means that lnα = γ₀ + γ₁\text{male} + γ₂\text{old}, where γ₀, γ₁, and γ₂ are parameters to be estimated along with the other model coefficients. If this option is not specified, gnbreg and nbreg will produce the same results because the shape parameter will be parameterized as a constant.

```
exposure(varname), offset(varname), constraints(constraints), collinear; see [R] estimation options.
```

```
SE/Robust
vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.
```

```
Reporting
level(#) ; see [R] estimation options.
```

`irr` reports estimated coefficients transformed to incidence-rate ratios, that is, e\beta, rather than \beta. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. `irr` may be specified at estimation or when replaying previously estimated results.

```
ocnsreport ; see [R] estimation options.
```

`display_options`: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrappar(style), cformat(%)fmt), pformat(%)fmt), sformat(%)fmt), and nolstretch; see [R] estimation options.

```
Maximization
maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.
```

Setting the optimization type to `technique(bhhh)` resets the default `vcetype` to `vce(opg)`.

The following option is available with gnbreg but is not shown in the dialog box:

```
coeflegend; see [R] estimation options.
```

Remarks and examples

Remarks are presented under the following headings:

- Introduction to negative binomial regression
- nbreg
- gnbreg

The following option is available with gnbreg but is not shown in the dialog box:

```
coeflegend; see [R] estimation options.
```
Introduction to negative binomial regression

Negative binomial regression models the number of occurrences (counts) of an event when the event has extra-Poisson variation, that is, when it has overdispersion. The Poisson regression model is

\[ y_j \sim \text{Poisson}(\mu_j) \]

where

\[ \mu_j = \exp(x_j \beta + \text{offset}_j) \]

for observed counts \( y_j \) with covariates \( x_j \) for the \( j \)th observation. One derivation of the negative binomial mean-dispersion model is that individual units follow a Poisson regression model, but there is an omitted variable \( \nu_j \), such that \( e^{\nu_j} \) follows a gamma distribution with mean 1 and variance \( \alpha \):

\[ y_j \sim \text{Poisson}(\mu^*_j) \]

where

\[ \mu^*_j = \exp(x_j \beta + \text{offset}_j + \nu_j) \]

and

\[ e^{\nu_j} \sim \text{Gamma}(1/\alpha, \alpha) \]

With this parameterization, a Gamma\((a,b)\) distribution will have expectation \( ab \) and variance \( ab^2 \).

We refer to \( \alpha \) as the overdispersion parameter. The larger \( \alpha \) is, the greater the overdispersion. The Poisson model corresponds to \( \alpha = 0 \). \texttt{nbreg} parameterizes \( \alpha \) as \( \ln \alpha \). \texttt{gnbreg} allows \( \ln \alpha \) to be modeled as \( \ln \alpha_j = z_j \gamma \), a linear combination of covariates \( z_j \).

\texttt{nbreg} will fit two different parameterizations of the negative binomial model. The default, described above and also given by the \texttt{dispersion(mean)} option, has dispersion for the \( j \)th observation equal to \( 1 + \alpha \exp(x_j \beta + \text{offset}_j) \). This is seen by noting that the above implies that

\[ \mu^*_j \sim \text{Gamma}(1/\alpha, \alpha \mu_j) \]

and thus

\[ \text{Var}(y_j) = E \{ \text{Var}(y_j | \mu^*_j) \} + \text{Var} \{ E(y_j | \mu^*_j) \} \\
= E(\mu^*_j) + \text{Var}(\mu^*_j) \\
= \mu_j (1 + \alpha \mu_j) \]

The alternative parameterization, given by the \texttt{dispersion(constant)} option, has dispersion equal to \( 1 + \delta \); that is, it is constant for all observations. This is so because the constant-dispersion model assumes instead that

\[ \mu^*_j \sim \text{Gamma}(\mu_j / \delta, \delta) \]

and thus \( \text{Var}(y_j) = \mu_j (1 + \delta) \). The Poisson model corresponds to \( \delta = 0 \).

For detailed derivations of both models, see Cameron and Trivedi (2013, 80–89). In particular, note that the mean-dispersion model is known as the NB2 model in their terminology, whereas the constant-dispersion model is referred to as the NB1 model.

See Long and Freese (2014) and Cameron and Trivedi (2010, chap. 17) for a discussion of the negative binomial regression model with Stata examples and for a discussion of other regression models for count data.

Hilbe (2011) provides an extensive review of the negative binomial model and its variations, using Stata examples.
It is not uncommon to posit a Poisson regression model and observe a lack of model fit. The following data appeared in Rodríguez (1993):

```stata
use http://www.stata-press.com/data/r13/rod93
list, sepby(cohort)
```

The extreme significance of the goodness-of-fit χ² indicates that the Poisson regression model is inappropriate, suggesting to us that we should try a negative binomial model:

```
. estat gof
Deviance goodness-of-fit =  4190.689
Prob > chi2(18) =    0.0000
Pearson goodness-of-fit = 15387.67
Prob > chi2(18) =    0.0000
```

Our original Poisson model is a special case of the negative binomial—it corresponds to α = 0. `nbreg`, however, estimates α indirectly, estimating instead lnα. In our model, lnα = 0.594, meaning that α = 1.81 (`nbreg` undoes the transformation for us at the bottom of the output).

To test α = 0 (equivalent to lnα = −∞), `nbreg` performs a likelihood-ratio test. The staggering χ² value of 4,056 asserts that the probability that we would observe these data conditional on α = 0 is virtually zero, that is, conditional on the process being Poisson. The data are not Poisson. It is not accidental that this χ² value is close to the goodness-of-fit statistic from the Poisson regression itself.

**Technical note**

The usual Gaussian test of α = 0 is omitted because this test occurs on the boundary, invalidating the usual theory associated with such tests. However, the likelihood-ratio test of α = 0 has been modified to be valid on the boundary. In particular, the null distribution of the likelihood-ratio test statistic is not the usual χ², but rather a 50:50 mixture of a χ²₀ (point mass at zero) and a χ²₁, denoted as χ²₀₁. See Gutierrez, Carter, and Drukker (2001) for more details.

**Technical note**

The negative binomial model deals with cases in which there is more variation than would be expected if the process were Poisson. The negative binomial model is not helpful if there is less than Poisson variation—if the variance of the count variable is less than its mean. However, underdispersion is uncommon. Poisson models arise because of independently generated events. Overdispersion comes about if some of the parameters (causes) of the Poisson processes are unknown. To obtain underdispersion, the sequence of events somehow would have to be regulated; that is, events would not be independent but controlled based on past occurrences.
gnbreg

gnbreg is a generalization of nbreg, dispersion(mean). Whereas in nbreg, one \( \ln \alpha \) is estimated, gnbreg allows \( \ln \alpha \) to vary, observation by observation, as a linear combination of another set of covariates: \( \ln \alpha_j = z_j \gamma \).

We will assume that the number of deaths is a function of age, whereas the \( \ln \alpha \) parameter is a function of cohort. To fit the model, we type

```
.gnbreg deaths age_mos, lalpha(i.cohort) offset(logexp)
```

|--------|-------|-----------|-----|-----|---------------------|
| deaths | age_mos | -0.0516657 | 0.0051747 | -9.98 | 0.000 | -0.061808 - 0.0415233 |
|        | _cons  | -1.867225 | 0.2227944 | -8.38 | 0.000 | -2.303894 -1.430556 |
|        | logexp | 1         |         | (offset) | |

lnalpha

| cohort | Coef. | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|--------|-------|-----------|-----|-----|---------------------|
| 1960-1967 | 0.0939546 | 0.7187747 | 0.13 | 0.896 | -1.314818 1.502727 |
| 1968-1976 | 0.0815279 | 0.7365476 | 0.11 | 0.912 | -1.362079 1.525135 |
| _cons   | -0.4759581 | 0.5156502 | -0.92 | 0.356 | -1.486614 0.5346978 |

We find that age is a significant determinant of the number of deaths. The standard errors for the variables in the \( \ln \alpha \) equation suggest that the overdispersion parameter does not vary across cohorts. We can test this assertion by typing

```
.test 2.cohort 3.cohort
```

( 1) [lnalpha]2.cohort = 0
( 2) [lnalpha]3.cohort = 0

\[ \text{ch2( 2)} = 0.02 \]
\[ \text{Prob > ch2} = 0.9904 \]

There is no evidence of variation by cohort in these data.
Technical note

Note the intentional absence of a likelihood-ratio test for $\alpha = 0$ in \texttt{gnbreg}. The test is affected by the same boundary condition that affects the comparison test in \texttt{nbreg}; however, when $\alpha$ is parameterized by more than a constant term, the null distribution becomes intractable. For this reason, we recommend using \texttt{nbreg} to test for overdispersion and, if you have reason to believe that overdispersion exists, only then modeling the overdispersion using \texttt{gnbreg}.

Stored results

\texttt{nbreg} and \texttt{gnbreg} store the following in \texttt{e()}: 

Scalars

- \texttt{e(N)}: number of observations
- \texttt{e(k)}: number of parameters
- \texttt{e(k_aux)}: number of auxiliary parameters
- \texttt{e(k_eq)}: number of equations in \texttt{e(b)}
- \texttt{e(k_eq_model)}: number of equations in overall model test
- \texttt{e(k_dv)}: number of dependent variables
- \texttt{e(df_m)}: model degrees of freedom
- \texttt{e(ll)}: log likelihood
- \texttt{e(ll_0)}: log likelihood, constant-only mode
- \texttt{e(ll_c)}: log likelihood, comparison model
- \texttt{e(alpha)}: value of alpha
- \texttt{e(delta)}: value of delta
- \texttt{e(N_clust)}: number of clusters
- \texttt{e(chi2)}: $\chi^2$
- \texttt{e(chi2_c)}: $\chi^2$ for comparison test
- \texttt{e(p)}: significance
- \texttt{e(rank)}: rank of \texttt{e(V)}
- \texttt{e(rank0)}: rank of \texttt{e(V)} for constant-only model
- \texttt{e(ic)}: number of iterations
- \texttt{e(rc)}: return code
- \texttt{e(converged)}: 1 if converged, 0 otherwise

Macros

- \texttt{e(cmd)}: \texttt{nbreg} or \texttt{gnbreg}
- \texttt{e(cmdline)}: command as typed
- \texttt{e(depvar)}: name of dependent variable
- \texttt{e(vtype)}: weight type
- \texttt{e(wexp)}: weight expression
- \texttt{e(title)}: title in estimation output
- \texttt{e(clustvar)}: name of cluster variable
- \texttt{e(offset)}: linear offset variable (\texttt{nbreg})
- \texttt{e(offset1)}: linear offset variable (\texttt{gnbreg})
- \texttt{e(chi2type)}: Wald or LR: type of model $\chi^2$ test
- \texttt{e(chi2_ct)}: Wald or LR: type of model $\chi^2$ test corresponding to \texttt{e(chi2_c)}
- \texttt{e(disper)}: mean or constant
- \texttt{e(vc)}: \texttt{vcetype} specified in \texttt{vce()} 
- \texttt{e(vcetype)}: title used to label Std. Err.
- \texttt{e(opt)}: type of optimization
- \texttt{e(which)}: \texttt{max} or \texttt{min}; whether optimizer is to perform maximization or minimization
- \texttt{e(ml_method)}: type of \texttt{ml} method
- \texttt{e(user)}: name of likelihood-evaluator program
- \texttt{e(technique)}: maximization technique
- \texttt{e(properties)}: \texttt{b V}
- \texttt{e(predict)}: program used to implement \texttt{predict}
- \texttt{e(asbalanced)}: factor variables \texttt{fvset} as \texttt{asbalanced}
- \texttt{e(asobserved)}: factor variables \texttt{fvset} as \texttt{asobserved}
Matrices
- \(e(b)\)  
  coefficient vector
- \(e(Cns)\)  
  constraints matrix
- \(e(ilog)\)  
  iteration log (up to 20 iterations)
- \(e(gradient)\)  
  gradient vector
- \(e(V)\)  
  variance–covariance matrix of the estimators
- \(e(V_{\text{modelbased}})\)  
  model-based variance

Functions
- \(e(sample)\)  
  marks estimation sample

Methods and formulas

See \([R]\) \texttt{poisson} and Johnson, Kemp, and Kotz (2005, chap. 4) for an introduction to the Poisson distribution.

Methods and formulas are presented under the following headings:

\begin{itemize}
  \item Mean-dispersion model
  \item Constant-dispersion model
\end{itemize}

Mean-dispersion model

A negative binomial distribution can be regarded as a gamma mixture of Poisson random variables. The number of times something occurs, \(y_j\), is distributed as Poisson(\(\nu_j\mu_j\)). That is, its conditional likelihood is

\[
f(y_j \mid \nu_j) = \frac{(\nu_j\mu_j)^{y_j}e^{-\nu_j\mu_j}}{\Gamma(y_j + 1)}
\]

where \(\mu_j = \exp(x_j\beta + \text{offset}_j)\) and \(\nu_j\) is an unobserved parameter with a Gamma(1/\(\alpha\), \(\alpha\)) density:

\[
g(\nu) = \frac{n(1-\alpha)/\alpha e^{-\nu/\alpha}}{\alpha^{1/\alpha} \Gamma(1/\alpha)}
\]

This gamma distribution has mean 1 and variance \(\alpha\), where \(\alpha\) is our ancillary parameter. The unconditional likelihood for the \(j\)th observation \(\alpha\), where \(\alpha\) is our ancillary parameter. The unconditional likelihood for the \(j\)th observation is therefore

\[
f(y_j) = \int_0^\infty f(y_j \mid \nu)g(\nu) d\nu = \frac{\Gamma(m + y_j)}{\Gamma(y_j + 1)\Gamma(m)} p_j^m (1 - p_j)^{y_j}
\]

where \(p_j = 1/(1 + \alpha\mu_j)\) and \(m = 1/\alpha\). Solutions for \(\alpha\) are handled by searching for \(\ln\alpha\) because \(\alpha\) must be greater than zero.

The log likelihood (with weights \(w_j\) and offsets) is given by

\[
\ln L = \sum_{j=1}^{n} w_j \left[ \ln\{\Gamma(m + y_j)\} - \ln\{\Gamma(y_j + 1)\} \\
- \ln\{\Gamma(m)\} + m \ln(p_j) + y_j \ln(1 - p_j) \right]
\]

For \texttt{gnbreg}, \(\alpha\) can vary across the observations according to the parameterization \(\ln\alpha_j = z_j\gamma\).
Constant-dispersion model

The constant-dispersion model assumes that \( y_j \) is conditionally distributed as Poisson(\( \mu_j^* \)), where \( \mu_j^* \sim \text{Gamma}(\mu_j/\delta, \delta) \) for some dispersion parameter \( \delta \) (by contrast, the mean-dispersion model assumes that \( \mu_j^* \sim \text{Gamma}(1/\alpha, \alpha \mu_j) \)). The log likelihood is given by

\[
m_j = \mu_j/\delta \quad p = 1/(1 + \delta) \\
\ln L = \sum_{j=1}^{n} w_j \left[ \ln \left\{ \Gamma(m_j + y_j) \right\} - \ln \left\{ \Gamma(y_j + 1) \right\} - \ln \left\{ \Gamma(m_j) \right\} + m_j \ln(p) + y_j \ln(1 - p) \right]
\]

with everything else defined as before in the calculations for the mean-dispersion model.

\texttt{nbreg} and \texttt{gnbreg} support the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \cite{robust}, particularly \textit{Maximum likelihood estimators} and \textit{Methods and formulas}.

These commands also support estimation with survey data. For details on VCEs with survey data, see \cite{SVY} \textit{variance estimation}.

### Description

The following postestimation commands are available after `nbreg` and `gnbreg`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>contrast</code></td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td><code>estat ic</code></td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td><code>estat summarize</code></td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>forecast</code></td>
<td>dynamic forecasts and simulations</td>
</tr>
<tr>
<td><code>lincom</code></td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td><code>linktest</code></td>
<td>link test for model specification</td>
</tr>
<tr>
<td><code>lrtest</code></td>
<td>likelihood-ratio test</td>
</tr>
<tr>
<td><code>margins</code></td>
<td>marginal means, predictive margins, marginal effects, and average marginal effects</td>
</tr>
<tr>
<td><code>marginsplot</code></td>
<td>graph the results from margins (profile plots, interaction plots, etc.)</td>
</tr>
<tr>
<td><code>nlcom</code></td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td><code>predict</code></td>
<td>predictions, residuals, influence statistics, and other diagnostic measures</td>
</tr>
<tr>
<td><code>predictnl</code></td>
<td>point estimates, standard errors, testing, and inference for generalized predictions</td>
</tr>
<tr>
<td><code>pwcompare</code></td>
<td>pairwise comparisons of estimates</td>
</tr>
<tr>
<td><code>suest</code></td>
<td>seemingly unrelated estimation</td>
</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

1 `forecast` is not appropriate with `mi` or `svy` estimation results.
2 `lrtest` is not appropriate with `svy` estimation results.
Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
predict [type] {stub* | newvar_reg newvar Disp} [if] [in], scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>n</td>
<td>number of events; the default</td>
</tr>
<tr>
<td>ir</td>
<td>incidence rate (equivalent to predict ... , n nooffset)</td>
</tr>
<tr>
<td>pr(n)</td>
<td>probability $\Pr(y_j = n)$</td>
</tr>
<tr>
<td>pr(a,b)</td>
<td>probability $\Pr(a \leq y_j \leq b)$</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

In addition, relevant only after `gnbreg` are the following:

```
<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>alpha</td>
<td>predicted values of $\alpha_j$</td>
</tr>
<tr>
<td>lnalpha</td>
<td>predicted values of $\ln\alpha_j$</td>
</tr>
<tr>
<td>stdplna</td>
<td>standard error of predicted $\ln\alpha_j$</td>
</tr>
</tbody>
</table>
```

These statistics are available both in and out of sample; type `predict ... if e(sample) ... if wanted` only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

```
n, the default, calculates the predicted number of events, which is $\exp(x_j\beta)$ if neither `offset(varname_o)` nor `exposure(varname_e)` was specified when the model was fit; $\exp(x_j\beta + offset_j)$ if `offset()` was specified; or $\exp(x_j\beta) \times \text{exposure}_j$ if `exposure()` was specified.

ir calculates the incidence rate $\exp(x_j\beta)$, which is the predicted number of events when exposure is 1. This is equivalent to specifying both the n and the nooffset options.

pr(n) calculates the probability $\Pr(y_j = n)$, where n is a nonnegative integer that may be specified as a number or a variable.

pr(a,b) calculates the probability $\Pr(a \leq y_j \leq b)$, where a and b are nonnegative integers that may be specified as numbers or variables;

b missing (b ≥ .) means $+\infty$;

pr(20,..) calculates $Pr(y_j \geq 20)$;
pr(20,b) calculates $Pr(y_j \geq 20)$ in observations for which $b \geq .$ and calculates $Pr(20 \leq y_j \leq b)$ elsewhere.
```
\texttt{pr(.,b)} produces a syntax error. A missing value in an observation of the variable \textit{a} causes a missing value in that observation for \texttt{pr(a,b)}.

\texttt{xb} calculates the linear prediction, which is \(x_j\beta\) if neither \texttt{offset()} nor \texttt{exposure()} was specified; \(x_j\beta + \text{offset}_j\) if \texttt{offset()} was specified; or \(x_j\beta + \ln(\text{exposure}_j)\) if \texttt{exposure()} was specified; see \texttt{nooffset} below.

\texttt{stdp} calculates the standard error of the linear prediction.

\texttt{alpha}, \texttt{lnalpha}, and \texttt{stdplna} are relevant after \texttt{gnbreg} estimation only; they produce the predicted values of \(\alpha_j\), \(\ln\alpha_j\), and the standard error of the predicted \(\ln\alpha_j\), respectively.

\texttt{nooffset} is relevant only if you specified \texttt{offset()} or \texttt{exposure()} when you fit the model. It modifies the calculations made by \texttt{predict} so that they ignore the offset or exposure variable; the linear prediction is treated as \(x_j\beta\) rather than as \(x_j\beta + \text{offset}_j\) or \(x_j\beta + \ln(\text{exposure}_j)\). Specifying \texttt{predict ...}, \texttt{nooffset} is equivalent to specifying \texttt{predict ...}, \texttt{ir}.

\texttt{scores} calculates equation-level score variables.

The first new variable will contain \(\frac{\partial \ln L}{\partial (x_j\beta)}\).

The second new variable will contain \(\frac{\partial \ln L}{\partial (\ln\alpha_j)}\) for \texttt{dispersion(mean)} and \texttt{gnbreg}.

The second new variable will contain \(\frac{\partial \ln L}{\partial (\ln\delta)}\) for \texttt{dispersion(constant)}.

### Remarks and examples

After \texttt{nbreg} and \texttt{gnbreg}, \texttt{predict} returns the expected number of deaths per cohort and the probability of observing the number of deaths recorded or fewer.

```stata
. use http://www.stata-press.com/data/r13/rod93
. nbreg deaths i.cohort, nolog
```

<table>
<thead>
<tr>
<th></th>
<th>Number of obs</th>
<th>LR chi2(2)</th>
<th>Dispersion</th>
<th>Log likelihood</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td>mean</td>
<td>-108.48841</td>
</tr>
</tbody>
</table>

|          | Coef. Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|----------|------------------|-----|------|----------------------|
| cohort   |                  |     |      |                      |
| 1960-1967| .0591305         | .2978419 | 0.20 | 0.843 | -.5246289 | .64289 |
| 1968-1976| -.0538792        | .2981621 | -0.18| 0.857 | -.6382662 | .5305077 |
| _cons    | 4.435906         | .2107213 | 21.05| 0.000 | 4.0229    | 4.848912 |
| /lnalpha | -1.207379        | .3108622 |      | -1.816657 | -.5980999 |
| alpha    | .29898           | .0929416 |      | .1625683   | .5498555 |

Likelihood-ratio test of alpha=0: \(\text{chibar2(01)} = 434.62\) \(\text{Prob}>=\text{chibar2} = 0.000\)

```stata
. predict count (option n assumed; predicted number of events)
. predict p, pr(0, deaths)
. summarize deaths count p
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>deaths</td>
<td>21</td>
<td>84.66667</td>
<td>48.84192</td>
<td>10</td>
<td>197</td>
</tr>
<tr>
<td>count</td>
<td>21</td>
<td>84.66667</td>
<td>4.00773</td>
<td>80</td>
<td>89.57143</td>
</tr>
<tr>
<td>p</td>
<td>21</td>
<td>.4991542</td>
<td>.2743702</td>
<td>.0070255</td>
<td>.9801285</td>
</tr>
</tbody>
</table>
The expected number of deaths ranges from 80 to 90. The probability \( \Pr(y_i \leq \text{deaths}) \) ranges from 0.007 to 0.98.

**Methods and formulas**

In the following, we use the same notation as in [R] `nbreg`. Methods and formulas are presented under the following headings:

- **Mean-dispersion model**
- **Constant-dispersion model**

**Mean-dispersion model**

The equation-level scores are given by
\[
\begin{align*}
\text{score}(x \beta)_j &= p_j(y_j - \mu_j) \\
\text{score}(\tau)_j &= -m \left\{ \frac{\alpha_j(\mu_j - y_j)}{1 + \alpha_j \mu_j} - \ln(1 + \alpha_j \mu_j) + \psi(y_j + m) - \psi(m) \right\}
\end{align*}
\]

where \( \tau_j = \ln\alpha_j \) and \( \psi(z) \) is the digamma function.

**Constant-dispersion model**

The equation-level scores are given by
\[
\begin{align*}
\text{score}(x \beta)_j &= m_j \left\{ \psi(y_j + m_j) - \psi(m_j) + \ln(p) \right\} \\
\text{score}(\tau)_j &= y_j - (y_j + m_j)(1 - p) - \text{score}(x \beta)_j
\end{align*}
\]

where \( \tau_j = \ln\delta_j \).

[U] 20 Estimation and postestimation commands
Syntax

Standard estimation command syntax

```
nestreg [, options]: command_name depvar (varlist) [(varlist) ...] 
       [if] [in] [weight] [command_options]
```

Survey estimation command syntax

```
nestreg [, options]: svy [vcetype], [svy_options]: command_name depvar 
       (varlist) [(varlist) ...] [if] [in], [command_options]
```

### options Description

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>waldtable</td>
<td>report Wald test results; the default</td>
</tr>
<tr>
<td>lrtable</td>
<td>report likelihood-ratio test results</td>
</tr>
<tr>
<td>quietly</td>
<td>suppress any output from command_name</td>
</tr>
<tr>
<td>store(stub)</td>
<td>store nested estimation results in _est_stub#</td>
</tr>
</tbody>
</table>

Weights are allowed if `command_name` allows them; see [U] 11.1.6 weight.

A `varlist` in parentheses indicates that this list of variables is to be considered as a block. Each variable in a `varlist` not bound in parentheses will be treated as its own block.

All postestimation commands behave as they would after `command_name` without the `nestreg` prefix; see the postestimation manual entry for `command_name`.

Menu

Statistics > Other > Nested model statistics

Description

`nestreg` fits nested models by sequentially adding blocks of variables and then reports comparison tests between the nested models.
Options

Options

waldtable specifies that the table of Wald test results be reported. waldtable is the default.

lrtable specifies that the table of likelihood-ratio tests be reported. This option is not allowed if
pwights, the vce(robust) option, or the vce(cluster clustvar) option is specified. lrtable
is also not allowed with the svy prefix.

quietly suppresses the display of any output from command_name.

store(stub) specifies that each model fit by nestreg be stored under the name _est_stub#, where
# is the nesting order from first to last.

Remarks and examples

Remarks are presented under the following headings:

Estimation commands
Wald tests
Likelihood-ratio tests
Programming for nestreg

Estimation commands

nestreg removes collinear predictors and observations with missing values from the estimation
sample before calling command_name.

The following Stata commands are supported by nestreg:

clogit nbreg regress
cloglog ologit scobit
glm oprobit stcox
intreg poisson stcrreg
logistic probit streg
logit qreg tobit

You do not supply a depvar for stcox, stcrreg, or streg; otherwise, depvar is required. You
must supply two depvars for intreg.

Wald tests

Use nestreg to test the significance of blocks of predictors, building the regression model one
block at a time. Using the data from example 1 of [R] test, we wish to test the significance of the
following predictors of birth rate: medage, medagesq, and region (already partitioned into four
indicator variables: reg1, reg2, reg3, and reg4).
. use http://www.stata-press.com/data/r13/census4
(birth rate, median age)
. nestreg: regress brate (medage) (medagesq) (reg2-reg4)

Block 1: medage

`nestreg` collected the $F$ statistic for the corresponding block of predictors and the model $R^2$ statistic from each model fit.

The $F$ statistic for the first block, 164.72, is for a test of the joint significance of the first block of variables; it is simply the $F$ statistic from the regression of `brate` on `medage`. The $F$ statistic for the second block, 35.25, is for a test of the joint significance of the second block of variables in a regression of both the first and second blocks of variables. In our example, it is an $F$ test of `medagesq` in the regression of `brate` on `medage` and `medagesq`. Similarly, the third block’s $F$ statistic of 8.85 corresponds to a joint test of `reg2`, `reg3`, and `reg4` in the final regression.
Likelihood-ratio tests

The `nestreg` command provides a simple syntax for performing likelihood-ratio tests for nested model specifications; also see `lrtest`. Using the data from example 1 of [R] `lrtest`, we wish to jointly test the significance of the following predictors of low birthweight: `age`, `lwt`, `ptl`, and `ht`.

```stata
use http://www.stata-press.com/data/r13/lbw
(xi: nestreg, lr: logistic low (i.race smoke ui) (age lwt ptl ht)
i.race _Irace_1-3 (naturally coded; _Irace_1 omitted)

```

The estimation results from the full model are left in `e()`, so we can later use `estat` and other postestimation commands.

```
estat gof
Logistic model for low, goodness-of-fit test
number of observations = 189
number of covariate patterns = 182
Pearson chi2(173) = 179.24
Prob > chi2 = 0.3567
```

The estimation results from the full model are left in `e()`, so we can later use `estat` and other postestimation commands.
Programming for nestreg

If you want your user-written command (*command_name*) to work with *nestreg*, it must follow standard Stata syntax and allow the *if* qualifier. Furthermore, *command_name* must have *sw* or *swml* as a program property; see [*P* program properties]. If *command_name* has *swml* as a property, *command_name* must store the log-likelihood value in *e(ll)* and the model degrees of freedom in *e(df_m)*.

Stored results

*nestreg* stores the following in *r()*:

Matrices

- *r(wald)*: matrix corresponding to the Wald table
- *r(lr)*: matrix corresponding to the likelihood-ratio table

Acknowledgment

We thank Paul H. Bern of Syracuse University for developing the hierarchical regression command that inspired *nestreg*.

### Syntax

**Set current location for net**

```bash
net from directory_or_url
```

**Change to a different net directory**

```bash
net cd path_or_url
```

**Change to a different net site**

```bash
net link linkname
```

**Search for installed packages**

```bash
net search (see [R] net search)
```

**Report current net location**

```bash
net
```

**Describe a package**

```bash
net describe pkgname [, from(directory_or_url)]
```

**Set location where packages will be installed**

```bash
net set ado dirname
```

**Set location where ancillary files will be installed**

```bash
net set other dirname
```

**Report net ‘from’, ‘ado’, and ‘other’ settings**

```bash
net query
```

**Install ado-files and help files from a package**

```bash
net install pkgname [, all replace force from(directory_or_url)]
```
Install ancillary files from a package

```
net get pkgname [, all replace force from(directory_or_url)]
```

Shortcut to access Stata Journal (SJ) net site

```
net sj vol-issue [ insert]
```

Shortcut to access Stata Technical Bulletin (STB) net site

```
net stb issue [ insert]
```

List installed packages

```
ado [ , find(string) from(dirname)]
ado dir [pkgid] [ , find(string) from(dirname)]
```

Describe installed packages

```
ado describe [pkgid] [ , find(string) from(dirname)]
```

Uninstall an installed package

```
ado uninstall pkgid [ , from(dirname)]
```

where

- `pkgname` is name of a package
- `pkgid` is name of a package
- or a number in square brackets: [#]
- `dirname` is a directory name
- or PLUS (default)
- or PERSONAL
- or SITE

**Description**

`net` downloads and installs additions to Stata. The additions can be obtained from the Internet or from physical media. The additions can be ado-files (new commands), help files, or even datasets. Collections of files are bound together into packages. For instance, the package named zz49 might add the `xyz` command to Stata. At a minimum, such a package would contain `xyz.ado`, the code to implement the new command, and `xyz.sthlp`, the system help to describe it. That the package contains two files is a detail: you use `net` to download the package zz49, regardless of the number of files.

`ado` manages the packages you have installed by using `net`. The `ado` command lets you list and uninstall previously installed packages. You can also access the `net` and `ado` features by selecting Help > SJ and User-written Programs; this is the recommended method to find and install additions to Stata.
Options

all is used with net install and net get. Typing it with either one makes the command equivalent to typing net install followed by net get.

replace is for use with net install and net get. It specifies that the downloaded files replace existing files if any of the files already exists.

force specifies that the downloaded files replace existing files if any of the files already exists, even if Stata thinks all the files are the same. force implies replace.

find(string) is for use with ado, ado dir, and ado describe. It specifies that the descriptions of the packages installed on your computer be searched, and that the package descriptions containing string be listed.

from(dirname), when used with ado, specifies where the packages are installed. The default is from(PLUS). PLUS is a code word that Stata understands to correspond to a particular directory on your computer that was set at installation time. On Windows computers, PLUS probably means the directory c:\ado\plus, but it might mean something else. You can find out what it means by typing sysdir, but doing so is irrelevant if you use the defaults.

from(directory_or_url), when used with net, specifies the directory or URL where installable packages may be found. The directory or URL is the same as the one that would have been specified with net from.

Remarks and examples

For an introduction to using net and ado, see [U] 28 Using the Internet to keep up to date. The purpose of this documentation is

- to briefly, but accurately, describe net and ado and all their features and
- to provide documentation to those who wish to set up their own sites to distribute additions to Stata.

Remarks are presented under the following headings:

- Definition of a package
- The purpose of the net and ado commands
- Content pages
- Package-description pages
- Where packages are installed
- A summary of the net command
- A summary of the ado command
- Relationship of net and ado to the point-and-click interface
- Creating your own site
- Format of content and package-description files
- Example 1
- Example 2
- Additional package directives
- SMCL in content and package-description files
- Error-free file delivery
Definition of a package

A package is a collection of files—typically, .ado and .sthlp files—that together provide a new feature in Stata. Packages contain additions that you wish had been part of Stata at the outset. We write such additions, and so do other users.

One source of these additions is the Stata Journal, a printed and electronic journal with corresponding software. If you want the journal, you must subscribe, but the software is available for free from our website.

The purpose of the net and ado commands

The net command makes it easy to distribute and install packages. The goal is to get you quickly to a package-description page that summarizes the addition, for example,

```
. net describe rte_stat, from(http://www.wemakeitupaswego.edu/faculty/sgazer/)
```

<table>
<thead>
<tr>
<th>TITLE</th>
</tr>
</thead>
<tbody>
<tr>
<td>rte_stat. The robust-to-everything statistic; update.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>DESCRIPTION/AUTHOR(S)</th>
</tr>
</thead>
<tbody>
<tr>
<td>S. Gazer, Dept. of Applied Theoretical Mathematics, WMIUAWG Univ.</td>
</tr>
<tr>
<td>Aleph-0 100% confidence intervals proved too conservative for some applications; Aleph-1 confidence intervals have been substituted.</td>
</tr>
<tr>
<td>The new robust-to-everything supplants the previous robust-to-everything-conceivable statistic. See &quot;Inference in the absence of data&quot; (forthcoming). After installation, see help rte.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>INSTALLATION FILES</th>
</tr>
</thead>
<tbody>
<tr>
<td>(type net install rte_stat)</td>
</tr>
<tr>
<td>rte.ado</td>
</tr>
<tr>
<td>rte.sthlp</td>
</tr>
<tr>
<td>nullset.ado</td>
</tr>
<tr>
<td>random.ado</td>
</tr>
</tbody>
</table>

If you decide that the addition might prove useful, net makes the installation easy:

```
. net install rte_stat
checking rte_stat consistency and verifying not already installed...
installing into c:\ado\plus\ ...
installation complete.
```

The ado command helps you manage packages installed with net. Perhaps you remember that you installed a package that calculates the robust-to-everything statistic, but you cannot remember the command’s name. You could use ado to search what you have previously installed for the rte command,

```
. ado
   STB-56 sg145. Scalar measures of fit for regression models.
   (output omitted)
   rte_stat. The robust-to-everything statistic; update.
   (output omitted)
   SJ7-1 st0119. Rasch analysis
```
or you might type

```
. ado, find("robust-to-everything")
    rte_stat. The robust-to-everything statistic; update.
```

Perhaps you decide that `rte`, despite the author’s claims, is not worth the disk space it occupies. You can use `ado` to erase it:

```
. ado uninstall rte_stat
    package rte_stat from http://www.wemakeitupaswego.edu/faculty/sgazer
    rte_stat. The robust-to-everything statistic; update.
    (package uninstalled)
```

`ado uninstall` is easier than erasing the files by hand because `ado uninstall` erases every file associated with the package, and, moreover, `ado` knows where on your computer `rte_stat` is installed; you would have to hunt for these files.

### Content pages

There are two types of pages displayed by `net`: content pages and package-description pages. When you type `net from`, `net cd`, `net link`, or `net` without arguments, Stata goes to the specified place and displays the content page:

```
. net from http://www.stata.com
```

```
http://www.stata.com/
StataCorp

Welcome to StataCorp.

Below we provide links to sites providing additions to Stata, including the Stata Journal, STB, and Statalist. These are NOT THE OFFICIAL UPDATES; you fetch and install the official updates by typing `-update-`.

**PLACES you could `-net link-` to:**
- `sj` The Stata Journal

**DIRECTORIES you could `-net cd-` to:**
- `stb` materials published in the Stata Technical Bulletin
- `users` materials written by various people, including StataCorp employees
- `meetings` software packages from Stata Users Group meetings
- `links` links to other locations providing additions to Stata

A content page tells you about other content pages and package-description pages. The example above lists other content pages only. Below we follow one of the links for the *Stata Journal*: 
. net link sj

http://www.stata-journal.com/
The Stata Journal

The Stata Journal is a refereed, quarterly journal containing articles of interest to Stata users. For more details and subscription information, visit the Stata Journal website at http://www.stata-journal.com.

PLACES you could -net link- to:
  stata       StataCorp website

DIRECTORIES you could -net cd- to:
  production Files for authors of the Stata Journal
  software   Software associated with Stata Journal articles

. net cd software

http://www.stata-journal.com/software/
The Stata Journal

PLACES you could -net link- to:
  stata       StataCorp website
  stb         Stata Technical Bulletin (STB) software archive

DIRECTORIES you could -net cd- to:
  (output omitted) sj7-1 volume 7, issue 1
  (output omitted) sj1-1 volume 1, issue 1

. net cd sj7-1

http://www.stata-journal.com/software/sj7-1/
Stata Journal volume 7, issue 1

DIRECTORIES you could -net cd- to:
  .. Other Stata Journals

PACKAGES you could -net describe-:
  dm0027 File filtering in Stata: handling complex data formats and navigating log files efficiently
  st0119 Rasch analysis
  st0120 Multivariable regression spline models
  st0121 mhbounds - Sensitivity Analysis for Average Treatment Effects

dm0027, st0119, ..., st0121 are links to package-description pages.

1. When you type net from, you follow that with a location to display the location’s content page.
   a. The location could be a URL, such as http://www.stata.com. The content page at that location would then be listed.
   b. The location could be e: on a Windows computer or a mounted volume on a Mac computer. The content page on that source would be listed. That would work if you had special media obtained from StataCorp or special media prepared by another user.
   c. The location could even be a directory on your computer, but that would work only if that directory contained the right kind of files.
2. Once you have specified a location, typing `net cd` will take you into subdirectories of that location, if there are any. Typing

```
.net from http://www.stata-journal.com
.net cd software
```

is equivalent to typing

```
.net from http://www.stata-journal.com/software
```

Typing `net cd` displays the content page from that location.

3. Typing `net` without arguments redisplays the current content page, which is the content page last displayed.

4. `net link` is similar to `net cd` in that the result is to change the location, but rather than changing to subdirectories of the current location, `net link` jumps to another location:

```
.net from http://www.stata-journal.com
```

The Stata Journal is a refereed, quarterly journal containing articles of interest to Stata users. For more details and subscription information, visit the Stata Journal website at [http://www.stata-journal.com](http://www.stata-journal.com).

PLACES you could `-net link-` to:

- `stata` StataCorp website

DIRECTORIES you could `-net cd-` to:

- `production` Files for authors of the Stata Journal
- `software` Software associated with Stata Journal articles

Typing `net link stata` would jump to [http://www.stata.com](http://www.stata.com):

```
.net link stata
```

[http://www.stata.com](http://www.stata.com)

Welcome to StataCorp.

(output omitted)

### Package-description pages

Package-description pages describe what could be installed:
A package-description page describes the package and tells you how to install the component files. Package-description pages potentially describe two types of files:

1. Installation files: files that you type `net install` to install and that are required to make the addition work.

2. Ancillary files: additional files that you might want to install—you type `net get` to install them—but that you can ignore. Ancillary files are typically datasets that are useful for demonstration purposes. Ancillary files are not really installed in the sense of being copied to an official place for use by Stata itself. They are merely copied into the current directory so that you may use them if you wish.

You install the official files by typing `net install` followed by the package name. For example, to install `st0119`, you would type

```
. net install st0119
```

You get the ancillary files—if there are any and if you want them—by typing `net get` followed by the package name:
Most users ignore the ancillary files.

Once you have installed a package—by typing `net install`—use `ado` to redisplay the package-description page whenever you wish:

```
. ado describe st0119
```

The package-description page shown by `ado` includes the location from which we got the package and when we installed it. It does not mention the ancillary files that were originally part of this package because they are not tracked by `ado`.

**Where packages are installed**

Packages should be installed in PLUS or SITE, which are code words that Stata understands and that correspond to some real directories on your computer. Typing `sysdir` will tell you where these are, if you care.

```
. sysdir
```

<table>
<thead>
<tr>
<th>Directory</th>
<th>Path</th>
</tr>
</thead>
<tbody>
<tr>
<td>STATA</td>
<td>C:\Program Files\Stata13\</td>
</tr>
<tr>
<td>BASE</td>
<td>C:\Program Files\Stata13\ado\base\</td>
</tr>
<tr>
<td>SITE</td>
<td>C:\Program Files\Stata13\ado\site\</td>
</tr>
<tr>
<td>PLUS</td>
<td>c:\ado\plus\</td>
</tr>
<tr>
<td>PERSONAL</td>
<td>c:\ado\personal\</td>
</tr>
<tr>
<td>OLDPLACE</td>
<td>c:\ado\</td>
</tr>
</tbody>
</table>

If you type `sysdir`, you may obtain different results.
By default, net installs in the PLUS directory, and ado tells you about what is installed there. If you are on a multiple-user system, you may wish to install some packages in the SITE directory. This way, they will be available to other Stata users. To do that, before using net install, type

```
    . net set ado SITE
```

and when reviewing what is installed or removing packages, redirect ado to that directory:

```
    . ado ..., from(SITE)
```

In both cases, you type SITE because Stata will understand that SITE means the site ado-directory as defined by sysdir. To install into SITE, you must have write access to that directory.

If you reset where net installs and then, in the same session, wish to install into your private ado-directory, type

```
    . net set ado PLUS
```

That is how things were originally. If you are confused as to where you are, type net query.

A summary of the net command

The net command displays content pages and package-description pages. Such pages are provided over the Internet, and most users get them there. We recommend that you start at http://www.stata.com and work out from there. We also recommend using net search to find packages of interest to you; see [R] net search.

```
    net from
```

moves you to a location and displays the content page.

```
    net cd and net link
```

change from your current location to other locations. net cd enters subdirectories of the original location. net link jumps from one location to another, depending on the code on the content page.

```
    net describe
```

lists a package-description page. Packages are named, and you type net describe pkgname.

```
    net install
```

installs a package into your copy of Stata. net get copies any additional files (ancillary files) to your current directory.

```
    net sj and net stb
```

simplify loading files from the Stata Journal and its predecessor, the Stata Technical Bulletin.

```
    net sj vol-issue
```

is a synonym for typing

```
    net from http://www.stata-journal.com/software/sjvol-issue
```

whereas

```
    net sj vol-issue insert
```

is a synonym for typing

```
    net from http://www.stata-journal.com/software/sjvol-issue
    net describe insert
```

net set controls where net installs files. By default, net installs in the PLUS directory; see [P] sysdir. net set ado SITE would cause subsequent net commands to install in the SITE directory. net set other sets where ancillary files, such as .dta files, are installed. The default is the current directory.

```
    net query
```

displays the current net from, net set ado, and net set other settings.
A summary of the ado command

The ado command lists the package descriptions of previously installed packages.

Typing ado without arguments is the same as typing ado dir. Both list the names and titles of the packages you have installed.

ado describe lists full package-description pages.

ado uninstall removes packages from your computer.

Because you can install packages from a variety of sources, the package names may not always be unique. Thus the packages installed on your computer are numbered sequentially, and you may refer to them by name or by number. For instance, say that you wanted to get rid of the robust-to-everything statistic command you installed. Type

```
. ado, find("robust-to-everything")
    rte_stat. The robust-to-everything statistic; update.
```

You could then type

```
. ado uninstall rte_stat
```

or

```
. ado uninstall [15]
```

Typing ado uninstall rte_stat would work only if the name rte_stat were unique; otherwise, ado would refuse, and you would have to type the number.

The find() option is allowed with ado dir and ado describe. It searches the package description for the word or phrase you specify, ignoring case (alpha matches Alpha). The complete package description is searched, including the author’s name and the name of the files. Thus if rte was the name of a command that you wanted to eliminate, but you could not remember the name of the package, you could type

```
. ado, find(rte)
    rte_stat. The robust-to-everything statistic; update.
```

Relationship of net and ado to the point-and-click interface

Users may instead select Help > SJ and User-written Programs. There are advantages and disadvantages:

1. Flipping through content and package-description pages is easier; it is much like a browser. See [GS] 19 Updating and extending Stata—Internet functionality (GSM, GSU, or GSW).

2. When browsing a product-description page, note that the .sthlp files are highlighted. You may click on .sthlp files to review them before installing the package.

3. You may not redirect from where ado searches for files.
Creating your own site

The rest of this entry concerns how to create your own site to distribute additions to Stata. The idea is that you have written additions for use with Stata—say, xyz.ado and xyz.sthlp—and you wish to put them out so that coworkers or researchers at other institutions can easily install them. Or, perhaps you just have a dataset that you and others want to share.

In any case, all you need is a webpage. You place the files that you want to distribute on your webpage (or in a subdirectory), and you add two more files—a content file and a package-description file—and you are done.

Format of content and package-description files

The content file describes the content page. It must be named stata.toc:

```
begin stata.toc
OFF (to make site unavailable temporarily)
*
lines starting with * are comments; they are ignored
* blank lines are ignored, too
* v indicates version—specify v 3, which is the current version of .toc files
 v 3
* d lines display description text
* the first d line is the title, and the remaining ones are text
* blank d lines display a blank line
d title
d text
d... 
*
1 lines display links
1 word-to-show path-or-url [description]
1 word-to-show path-or-url [description]
...
*
 t lines display other directories within the site
 t path [description]
 t path [description]
...
*
p lines display packages
p pkgname [description]
p pkgname [description]
p... 
end stata.toc
```

Package files describe packages and are named pkgname.pkg:
Note the Distribution-Date description line. This line is optional but recommended. Stata can look for updates to user-written programs with the `adoupdate` command if the package files from which those programs were installed contain a Distribution-Date description line.

**Example 1**

Say that we want the user to see the following:

```
.net from http://www.university.edu/~me
```

```
http://www.university.edu/~me
Chris Farrar, Uni University
PACKAGES you could `-net describe-`
```

```
xyz interval-truncated survival
```

```
.package `xyz' from http://www.university.edu/~me
```

```
TITLE
`xyz'. interval-truncated survival.
```

```
DESCRIPTION/AUTHOR(S)
C. Farrar, Uni University.
```

```
INSTALLATION FILES
`xyz'.ado
`xyz'.sthlp
```

```
ANCILLARY FILES
sample.dta
```

The files needed to do this would be

```
begin stata.toc

v 3
d Chris Farrar, Uni University
p `xyz' interval-truncated survival

end stata.toc
```
On his homepage, Chris would place the following files:

<table>
<thead>
<tr>
<th>File</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>stata.toc</td>
<td>(shown above)</td>
</tr>
<tr>
<td>xyz.pkg</td>
<td>(shown above)</td>
</tr>
<tr>
<td>xyz.ado</td>
<td>file to be delivered (for use by net install)</td>
</tr>
<tr>
<td>xyz.sthlp</td>
<td>file to be delivered (for use by net install)</td>
</tr>
<tr>
<td>sample.dta</td>
<td>file to be delivered (for use by net get)</td>
</tr>
</tbody>
</table>

Chris does nothing to distinguish ancillary files from installation files.

Example 2

S. Gazer wants to create a more complex site:

```bash
. net from http://www.wemakeitupaswego.edu/faculty/sgazer
```

http://www.wemakeitupaswego.edu/faculty/sgazer

**Data-free inference materials**

S. Gazer, Department of Applied Theoretical Mathematics

Also see my homepage for the preprint of "Irrefutable inference".

PLACES you could `net link` to:
- stata: StataCorp website

DIRECTORIES you could `net cd` to:
- ir: irrefutable inference programs (work in progress)

PACKAGES you could `net describe`-
- rtec: Robust-to-everything-conceivable statistic
- rte: Robust-to-everything statistic
. net describe rte

package rte from http://www.wemakeitupaswego.edu/faculty/sgazer/

TITLE
rte. The robust-to-everything statistic; update.

DESCRIPTION/AUTHOR(S)
S. Gazer, Dept. of Applied Theoretical Mathematics, WMIUAWG Univ.
Aleph-0 100% confidence intervals proved too conservative for some
applications; Aleph-1 confidence intervals have been substituted.
The new robust-to-everything supplants the previous robust-to-
everything-conceivable statistic. See "Inference in the absence
of data" (forthcoming). After installation, see help rte.

Distribution-Date: 20130420
Support: email sgazer@wemakeitupaswego.edu

INSTALLATION FILES
(type net install rte_stat)
rte.ado
rte.sthlp
nullset.ado
random.ado

ANCILLARY FILES
(type net get rte_stat)
empty.dta

The files needed to do this would be

f rte.ado
f rte.sthlp
f nullset.ado
f random.ado
f empty.dta
---end rte.pkg---
On his homepage, Mr. Gazer would place the following files:

- `stata.toc` (shown above)
- `rte.pkg` (shown above)
- `rte.ado` (file to be delivered)
- `rte.sthlp` (file to be delivered)
- `nullset.ado` (file to be delivered)
- `random.ado` (file to be delivered)
- `empty.dta` (file to be delivered)
- `rtec.pkg` (the other package referred to in `stata.toc`)
- `rtec.ado` (the corresponding files to be delivered)
- `rtec.sthlp` (files to be delivered)
- `ir/stata.toc` (the contents file for when the user types `net cd ir`)
- `ir/*` (whatever other `.pkg` files are referred to)
- `ir/*` (whatever other files are to be delivered)

If Mr. Gazer later updated the `rte` package, he could change the Distribution-Date description line in his package. Then, if someone who had previously installed the `rte` packaged wanted to obtain the latest version, that person could use the `adoupdate` command; see [R] adoupdate.

For complex sites, a different structure may prove more convenient:

- `stata.toc` (shown above)
- `rte.pkg` (shown above)
- `rtec.pkg` (the other package referred to in `stata.toc`)
- `rte/` directory containing `rte` files to be delivered:
  - `rte/rte.ado` (file to be delivered)
  - `rte/rte.sthlp` (file to be delivered)
  - `rte/nullset.ado` (file to be delivered)
  - `rte/random.ado` (file to be delivered)
  - `rte/empty.dta` (file to be delivered)
- `rtec/` directory containing `rtec` files to be delivered:
  - `rtec/*` (files to be delivered)
- `ir/stata.toc` (the contents file for when the user types `net cd ir`)
- `ir/*` (whatever other package files are referred to)
- `ir/*` (whatever other files are to be delivered)

If you prefer this structure, it is simply a matter of changing the bottom of the `rte.pkg` from

```
  f rte.ado
  f rte.sthlp
  f nullset.ado
  f random.ado
  f empty.dta
```

to

```
  f rte/rte.ado
  f rte/rte.sthlp
  f rte/nullset.ado
  f rte/random.ado
  f rte/empty.dta
```

In writing paths and files, the directory separator forward slash (`/`) is used, regardless of operating system, because this is what the Internet uses.

It does not matter whether the files you put out are in Windows, Mac, or Unix format (how lines end is recorded differently). When Stata reads the files over the Internet, it will figure out the file format on its own and will automatically translate the files to what is appropriate for the receiver.
Additional package directives

**F filename** is similar to **f filename**, except that, when the file is installed, it will always be copied to the system directories (and not the current directory).

With **f filename**, the file is installed into a directory according to the file’s suffix. For instance, `xyz.ado` would be installed in the system directories, whereas `xyz.dta` would be installed in the current directory.

Coding **F xyz.ado** would have the same result as coding **f xyz.ado**.

Coding **F xyz.dta**, however, would state that `xyz.dta` is to be installed in the system directories.

**g platformname filename** is also a variation on **f filename**. It specifies that the file be installed only if the user’s operating system is of type **platformname**; otherwise, the file is ignored. The platform names are `WIN64A` (64-bit x86-64) and `WIN` (32-bit x86) for Windows; `MACINTEL64` (64-bit Intel, GUI), `OSX.X8664` (64-bit Intel, console), `MACINTEL` (32-bit Intel, GUI), and `OSX.X86` (32-bit Intel, console) for Mac; and `LINUX64` (64-bit x86-64), `LINUX` (32-bit x86), `SOLX8664` (64-bit x86-64), and `SOL64` for Unix.

**G platformname filename** is a variation on **F filename**. The file, if not ignored, is to be installed in the system directories.

**g platformname filename1 filename2** is a more detailed version of **g platformname filename**. In this case, `filename1` is the name of the file on the server (the file to be copied), and `filename2` is to be the name of the file on the user’s system; for example, you might code

```
g WIN mydll.forwin mydll.plugin
```

When you specify one `filename`, the result is the same as specifying two identical `filenames`.

**G platformname filename1 filename2** is the install-in-system-directories version of **g platformname filename1 filename2**.

**h filename** asserts that `filename` must be loaded, or this package is not to be installed; for example, you might code

```
g WIN mydll.forwin mydll.plugin
```

if you were offering the plugin `mydll.plugin` for Windows and Linux only.

SMCL in content and package-description files

The text listed on the second and subsequent **d** lines in both `stata.toc` and `pkgname.pkg` may contain SMCL as long as you include `v 3`; see [P] smcl.

Thus, in `rte.pkg`, S. Gazer coded the third line as

```
d {bf:S. Gazer, Dept. of Applied Theoretical Mathematics, WMIUAWG Univ.}
```
Error-free file delivery

Most people transport files over the Internet and never worry about the file being corrupted in the process because corruption rarely occurs. If, however, the files must be delivered perfectly or not at all, you can include checksum files in the directory.

For instance, say that \texttt{big.dta} is included in your package and that it must be sent perfectly. First, use Stata to make the checksum file for \texttt{big.dta}

\begin{verbatim}
    . checksum big.dta, save
\end{verbatim}

That command creates a small file called \texttt{big.sum}; see \cite{D:checksum}. Then copy both \texttt{big.dta} and \texttt{big.sum} to your homepage. If \texttt{set checksum} is on (the default is off), whenever Stata reads \texttt{filename.whatever} over the net, it also looks for \texttt{filename.sum}. If it finds such a file, it uses the information recorded in it to verify that what was copied was error free.

If you do this, be cautious. If you put \texttt{big.dta} and \texttt{big.sum} on your homepage and then later change \texttt{big.dta} without changing \texttt{big.sum}, people will think that there are transmission errors when they try to download \texttt{big.dta}.

</tr>
</tbody>
</table>

### Description

`net search` searches the Internet for user-written additions to Stata, including, but not limited to, user-written additions published in the *Stata Journal* (*SJ*) and in the *Stata Technical Bulletin* (*STB*). `net search` lists the available additions that contain the specified keywords.

The user-written materials found are available for immediate download by using the `net` command or by clicking on the link.

In addition to typing `net search`, you may select Help > Search... and choose Search net resources. This is the recommended way to search for user-written additions to Stata.

### Options

`or` is relevant only when multiple keywords are specified. By default, `net search` lists only packages that include all the keywords. `or` changes the command to list packages that contain any of the keywords.

`nosj` specifies that `net search` not list matches that were published in the SJ or in the STB.

`tocpkg`, `toc`, and `pkg` determine what is searched. `tocpkg` is the default, meaning that both tables of contents (tocs) and packages (pkgs) are searched. `toc` restricts the search to tables of contents. `pkg` restricts the search to packages.

`everywhere` and `filenames` determine where in packages `net search` looks for keywords. The default is `everywhere`. `filenames` restricts `net search` to search for matches only in the filenames associated with a package. Specifying `everywhere` implies `pkg`.

`errnone` is a programmer’s option that causes the return code to be 111 instead of 0 when no matches are found.
Remarks and examples

net search searches the Internet for user-written additions to Stata. If you want to search the Stata documentation for a particular topic, command, or author, see [R] search. net search word [word ...] (without options) is equivalent to typing search word [word ...], net.

Remarks are presented under the following headings:

- Topic searches
- Author searches
- Command searches
- Where does net search look?
- How does net search work?

Topic searches

Example: Find what is available about random effects

```
.net search random effect
```

Comments:

- It is best to search using the singular form of a word. net search random effect will find both “random effect” and “random effects”.
- net search random effect will also find “random-effect” because net search performs a string search and not a word search.
- net search random effect lists all packages containing the words “random” and “effect”, not necessarily used together.
- If you wanted all packages containing the word “random” or the word “effect”, you would type net search random effect, or.

Author searches

Example: Find what is available by author Jeroen Weesie

```
.net search weesie
```

Comments:

- You could type net search jeroen weesie, but that might list fewer results because sometimes the last name is used without the first.
- You could type net search Weesie, but it would not matter. Capitalization is ignored in the search.

Example: Find what is available by Jeroen Weesie, excluding SJ and STB materials

```
.net search weesie, nosj
```

- The SJ and the STB tend to dominate search results because so much has been published in them. If you know that what you are looking for is not in the SJ or in the STB, specifying the nosj option will narrow the search.
- net search weesie lists everything that net search weesie, nosj lists, and more. If you just type net search weesie, look down the list. SJ and STB materials are listed first, and non-SJ and non-STB materials are listed last.
Command searches

Example: Find the user-written command kursus

```
.net search kursus, file
```

- You could just type `net search kursus`, and that will list everything `net search kursus`, `file` lists, and more. Because you know `kursus` is a command, however, there must be a `kursus.ado` file associated with the package. Typing `net search kursus, file` narrows the search.

- You could also type `net search kursus.ado, file` to narrow the search even more.

Where does net search look?

`net search` begins by looking at `http://www.stata.com`, but then follows every link, which takes it to other places, and then follows every link again, which takes it to even more places, and so on.

Authors: Please let us know if you have a site that we should include in our search by sending an email to webmaster@stata.com. We will then link to your site from ours to ensure that `net search` finds your materials. That is not strictly necessary, however, as long as your site is directly or indirectly linked from some site that is linked to ours.

How does net search work?

![Diagram showing how `net search` works](image-url)
Our website maintains a database of Stata resources. When you use \texttt{net search}, it contacts \url{http://www.stata.com} with your request, \url{http://www.stata.com} searches its database, and Stata returns the results to you.

Another part of the system is called the crawler, which searches the web for new Stata resources to add to the \texttt{net search} database and verifies that the resources already found are still available. When a new resource becomes available, the crawler takes about 2 days to add it to the database, and, similarly, if a resource disappears, the crawler takes roughly 2 days to remove it from the database.

Turn on or off the use of a proxy server

```bash
set httpproxy {on | off} [, init]
```

Set proxy host name

```bash
set httpproxyhost "name"
```

Set the proxy port number

```bash
set httpproxyport#
```

Turn on or off proxy authorization

```bash
set httpproxyauth {on | off}
```

Set proxy authorization user ID

```bash
set httpproxyuser "name"
```

Set proxy authorization password

```bash
set httpproxypw "password"
```

Set time limit for establishing initial connection

```bash
set timeout1 #seconds [, permanently]
```

Set time limit for data transfer

```bash
set timeout2 #seconds [, permanently]
```

Description

Several commands (for example, `net`, `news`, and `update`) are designed specifically for use over the Internet. Many other Stata commands that read a file (for example, `copy`, `type`, and `use`) can also read directly from a URL. All of these commands will usually work without your ever needing to concern yourself with the `set` commands discussed here. These `set` commands provide control over network system parameters.

If you experience problems when using Stata’s network features, ask your system administrator if your site uses a proxy. A proxy is a server between your computer and the rest of the Internet, and your computer may need to communicate with other computers on the Internet through this proxy. If your site uses a proxy, your system administrator can provide you with its host name and the port your computer can use to communicate with it. If your site’s proxy requires you to log in to it before it will respond, your system administrator will provide you with a user ID and password.
set httpproxyhost sets the name of the host to be used as a proxy server. set httpproxyport sets the port number. set httpproxy turns on or off the use of a proxy server, leaving the proxy host name and port intact, even when not in use.

Under the Mac and Windows operating systems, when you set httpproxy on, Stata will attempt to obtain the values of httpproxyhost and httpproxyport from the operating system if they have not been previously set. set httpproxy on, init attempts to obtain these values from the operating system, even if they have been previously set.

If the proxy requires authorization (user ID and password), set authorization on via set http-proxyauth on. The proxy user and proxy password must also be set to the appropriate user ID and password by using set httpproxyuser and set httpproxypw.

Stata remembers the various proxy settings between sessions and does not need a permanently option.

set timeout1 changes the time limit in seconds that Stata imposes for establishing the initial connection with a remote host. The default value is 30. set timeout2 changes the time limit in seconds that Stata imposes for subsequent data transfer with the host. The default value is 180. If these time limits are exceeded, a “connection timed out” message and error code 2 are produced. You should seldom need to change these settings.

Options

init specifies that set httpproxy on attempts to initialize httpproxyhost and httpproxyport from the operating system (Mac and Windows only).

permanently specifies that, in addition to making the change right now, the timeout1 and timeout2 settings be remembered and become the default setting when you invoke Stata.

The various httpproxy settings do not have a permanently option because permanently is implied.

Remarks and examples

If you receive an error message, see http://www.stata.com/support/faqs/web/ for the latest information.

1. remote connection failed r(677);

If you see

remote connection failed
r(677);

then you asked for something to be done over the web, and Stata tried but could not contact the specified host. Stata was able to talk over the network and look up the host but was not able to establish a connection to that host. Perhaps the host is down; try again later.

If all your web accesses result in this message, then perhaps your network connection is through a proxy server. If it is, then you must tell Stata.
Contact your system administrator. Ask for the name and port of the “HTTP proxy server”. Say that you are told

HTTP proxy server: jupiter.myuni.edu
port number: 8080

In Stata, type

```
.set httpproxyhost jupiter.myuni.edu
.set httpproxyport 8080
.set httpproxy on
```

Your web accesses should then work.

2. connection timed out r(2);

If you see

```
connection timed out
r(2);
```

then an Internet connection has timed out. This can happen when
a. the connection between you and the host is slow, or
b. the connection between you and the host has disappeared, and so it eventually “timed out”.

For (b), wait a while (say, 5 minutes) and try again (sometimes pieces of the Internet can break for up to a day, but that is rare). For (a), you can reset the limits for what constitutes “timed out”. There are two numbers to set.

The time to establish the initial connection is `timeout1`. By default, Stata waits 30 seconds before declaring a timeout. You can change the limit:

```
.set timeout1 #seconds
```

You might try doubling the usual limit and specify 60; `#seconds` must be between 1 and 32,000.

The time to retrieve data from an open connection is `timeout2`. By default, Stata waits 180 seconds (3 minutes) before declaring a timeout. To change the limit, type

```
.set timeout2 #seconds
```

You might try doubling the usual limit and specify 360; `#seconds` must be between 1 and 32,000.

## Syntax

### Interactive version

```stata
nl (depvar = <sexp>) [if] [in] [weight] [, options]
```

### Programmed substitutable expression version

```stata
nl sexp_prog : depvar [varlist] [if] [in] [weight] [, options]
```

### Function evaluator program version

```stata
nl func_prog @ depvar [varlist] [if] [in] [weight] ,
   { parameters(namelist) | nparameters(#)} [options]
```

where

- `depvar` is the dependent variable;
- `<sexp>` is a substitutable expression;
- `sexp_prog` is a substitutable expression program; and
- `func_prog` is a function evaluator program.
### Model

### Notes

- For function evaluator program version, you must specify **parameters(namelist)** or **nparameters(#)**, or both.
- bootstrap, by, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.
- Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
- aweights are not allowed with the jackknife prefix; see [R] jackknife.
- vce(), leave, and weights are not allowed with the svy prefix; see [SVY] svy.
- aweights, fweights, and iweights are allowed; see [U] 11.1.6 weight.
- coeflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

### Menu

Statistics > Linear models and related > Nonlinear least squares
Description

nl fits an arbitrary nonlinear regression function by least squares. With the interactive version of the command, you enter the function directly on the command line or in the dialog box by using a substitutable expression. If you have a function that you use regularly, you can write a substitutable expression program and use the second syntax to avoid having to reenter the function every time. The function evaluator program version gives you the most flexibility in exchange for increased complexity; with this version, your program is given a vector of parameters and a variable list, and your program computes the regression function.

When you write a substitutable expression program or function evaluator program, the first two letters of the name must be nl. sexp_prog and func_prog refer to the name of the program without the first two letters. For example, if you wrote a function evaluator program named nlregss, you would type nl regss @ ... to estimate the parameters.

Options

Model

variables(varlist) specifies the variables in the model. nl ignores observations for which any of these variables have missing values. If you do not specify variables(), then nl issues an error message with return code 480 if the estimation sample contains any missing values.

initial(initial_values) specifies the initial values to begin the estimation. You can specify a $1 \times k$ matrix, where $k$ is the number of parameters in the model, or you can specify a parameter name, its initial value, another parameter name, its initial value, and so on. For example, to initialize alpha to 1.23 and delta to 4.57, you would type

\[ \text{nl ... , initial(alpha 1.23 delta 4.57) ...} \]

Initial values declared using this option override any that are declared within substitutable expressions. If you specify a parameter that does not appear in your model, nl exits with error code 480. If you specify a matrix, the values must be in the same order that the parameters are declared in your model. nl ignores the row and column names of the matrix.

parameters(namelist) specifies the names of the parameters in the model. The names of the parameters must adhere to the naming conventions of Stata’s variables; see \[U\] 11.3 Naming conventions. If you specify both parameters() and nparameters(), the number of names in the former must match the number specified in the latter; if not, nl issues an error message with return code 198.

nparameters(#) specifies the number of parameters in the model. If you do not specify names with the parameters() option, nl names them $b_1, b_2, \ldots, b_\#$. If you specify both parameters() and nparameters(), the number of names in the former must match the number specified in the latter; if not, nl issues an error message with return code 198.

sexp_options refer to any options allowed by your sexp_prog.

func_options refer to any options allowed by your func_prog.

Model 2

lnlsq(#) fits the model by using log least-squares, which we define as least squares with shifted lognormal errors. In other words, $\ln(\text{depvar} - \#) \text{ is assumed to be normally distributed. Sums of squares and deviance are adjusted to the same scale as depvar.}$
**noconstant** indicates that the function does not include a constant term. This option is generally not needed, even if there is no constant term in the model, unless the coefficient of variation (over observations) of the partial derivative of the function with respect to a parameter is less than **eps()** and that parameter is not a constant term.

**hasconstant(name)** indicates that parameter name be treated as the constant term in the model and that nl should not use its default algorithm to find a constant term. As with noconstant, this option is seldom used.

**vce(vcetype)** specifies the type of standard error reported, which includes types that are derived from asymptotic theory (**gnr**), that are robust to some kinds of misspecification (**robust**), that allow for intragroup correlation (**cluster clustvar**), and that use bootstrap or jackknife methods (**bootstrap, jackknife**); see [R] vce_option.

**vce(gnr)**, the default, uses the conventionally derived variance estimator for nonlinear models fit using Gauss–Newton regression.

**vce(hac kernel [#])** specifies that a heteroskedasticity- and autocorrelation-consistent (HAC) variance estimate be used. HAC refers to the general form for combining weighted matrices to form the variance estimate. There are three kernels available for nl:

- **nwest**
- **gallant**
- **anderson**

# specifies the number of lags. If # is not specified, N – 2 is assumed.

**vce(hac kernel [#])** is not allowed if weights are specified.

**vce(hc2)** and **vce(hc3)** specify alternative bias corrections for the robust variance calculation. **vce(hc2)** and **vce(hc3)** may not be specified with the svy prefix. By default, **vce(robust)** uses \( \hat{\sigma}_j^2 = \{n/(n-k)\}u_j^2 \) as an estimate of the variance of the jth observation, where \( u_j \) is the calculated residual and \( n/(n-k) \) is included to improve the overall estimate’s small-sample properties.

**vce(hc2)** instead uses \( u_j^2/(1 - h_{jj}) \) as the observation’s variance estimate, where \( h_{jj} \) is the jth diagonal element of the hat (projection) matrix. This produces an unbiased estimate of the covariance matrix if the model is homoskedastic. **vce(hc2)** tends to produce slightly more conservative confidence intervals than **vce(robust)**.

**vce(hc3)** uses \( u_j^2/(1 - h_{jj})^2 \) as suggested by Davidson and MacKinnon (1993 and 2004), who report that this often produces better results when the model is heteroskedastic. **vce(hc3)** produces confidence intervals that tend to be even more conservative.

See, in particular, Davidson and MacKinnon (2004, 239), who advocate the use of **vce(hc2)** or **vce(hc3)** instead of the plain robust estimator for nonlinear least squares.

**level(#);** see [R] estimation options.

**leave** leaves behind after estimation a set of new variables with the same names as the estimated parameters containing the derivatives of \( E(y) \) with respect to the parameters. If the dataset contains an existing variable with the same name as a parameter, then using **leave** causes nl to issue an error message with return code 110.

**leave** may not be specified with **vce(cluster clustvar)** or the svy prefix.
title(string) specifies an optional title that will be displayed just above the table of parameter estimates.

title2(string) specifies an optional subtitle that will be displayed between the title specified in title() and the table of parameter estimates. If title2() is specified but title() is not, title2() has the same effect as title().

display_options: cformat('%fmt'), pformat('%fmt'), sformat('%fmt'), and nolstretch; see [R] estimation options.

Optimization

optimization_options: iterate(#), [no] log, trace. iterate() specifies the maximum number of iterations, log/nolog specifies whether to show the iteration log, and trace specifies that the iteration log should include the current parameter vector. These options are seldom used.

eps(#) specifies the convergence criterion for successive parameter estimates and for the residual sum of squares. The default is eps(1e-5).

delta(#) specifies the relative change in a parameter to be used in computing the numeric derivatives. The derivative for parameter $\beta_i$ is computed as $\{f(X, \beta_1, \beta_2, \ldots, \beta_i + d, \beta_{i+1}, \ldots) - f(X, \beta_1, \beta_2, \ldots, \beta_i, \beta_{i+1}, \ldots)\}/d$, where $d$ is $\delta(\beta_i + \delta)$. The default is delta(4e-7).

The following options are available with nl but are not shown in the dialog box: coeflegend; see [R] estimation options.

General comments on fitting nonlinear models
Function evaluator programs

nl fits an arbitrary nonlinear function by least squares. The interactive version allows you to enter the function directly on the command line or dialog box using substitutable expressions. You can write a substitutable expression program for functions that you fit frequently to save yourself time. Finally, function evaluator programs give you the most flexibility in defining your nonlinear function, though they are more complicated to use.

The next section explains the substitutable expressions that are used to define the regression function, and the section thereafter explains how to write substitutable expression program files so that you do not need to type in commonly used functions over and over. Later sections highlight other features of nl.

The final section discusses function evaluator programs. If you find substitutable expressions adequate to define your nonlinear function, then you can skip that section entirely. Function evaluator programs are generally needed only for complicated problems, such as multistep estimators. The program receives a vector of parameters at which it is to compute the function and a variable into which the results are to be placed.
Substitutable expressions

You define the nonlinear function to be fit by nl by using a substitutable expression. Substitutable expressions are just like any other mathematical expressions involving scalars and variables, such as those you would use with Stata’s generate command, except that the parameters to be estimated are bound in braces. See [U] 13.2 Operators and [U] 13.3 Functions for more information on expressions.

For example, suppose that you wish to fit the function

\[ y_i = \beta_0(1 - e^{-\beta_1 x_i}) + \epsilon_i \]

where \( \beta_0 \) and \( \beta_1 \) are the parameters to be estimated and \( \epsilon_i \) is an error term. You would simply type

```
.nl (y = {b0}*(1 - exp(-1*{b1}*x)))
```

You must enclose the entire equation in parentheses. Because \( b_0 \) and \( b_1 \) are enclosed in braces, nl knows that they are parameters in the model. nl will initialize \( b_0 \) and \( b_1 \) to zero by default. To request that nl initialize \( b_0 \) to 1 and \( b_1 \) to 0.25, you would type

```
.nl (y = {b0=1}*(1 - exp(-1*{b1=0.25}*x)))
```

That is, inside the braces denoting a parameter, you put the parameter name followed by an equal sign and the initial value. If a parameter appears in your function multiple times, you need only specify an initial value only once (or never, if you wish to set the initial value to zero). If you do specify more than one initial value for the same parameter, nl will use the last value given. Parameter names must follow the same conventions as variable names. See [U] 11.3 Naming conventions.

Frequently, even nonlinear functions contain linear combinations of variables. As an example, suppose that you wish to fit the function

\[ y_i = \beta_0 \left( 1 - e^{-(\beta_1 x_{1i} + \beta_2 x_{2i} + \beta_3 x_{3i})} \right) + \epsilon_i \]

nl allows you to declare a linear combination of variables by using the shorthand notation

```
.nl (y = {b0=1}*(1 - exp(-1*{xb: x1 x2 x3})))
```

In the syntax {xb: x1 x2 x3}, you are telling nl that you are declaring a linear combination named \( xb \) that is a function of three variables, \( x1 \), \( x2 \), and \( x3 \). nl will create three parameters, named \( xb\_x1 \), \( xb\_x2 \), and \( xb\_x3 \), and initialize them to zero. Instead of typing the previous command, you could have typed

```
.nl (y = {b0=1}*(1 - exp(-1*({xb\_x1}*x1 + {xb\_x2}*x2 + {xb\_x3}*x3))))
```

and yielded the same result. You can refer to the parameters created by nl in the linear combination later in the function, though you must declare the linear combination first if you intend to do that. When creating linear combinations, nl ensures that the parameter names it chooses are unique and have not yet been used in the function.

In general, there are three rules to follow when defining substitutable expressions:

1. Parameters of the model are bound in braces: {b0}, {param}, etc.
2. Initial values for parameters are given by including an equal sign and the initial value inside the braces: {b0=1}, {param=3.571}, etc.
3. Linear combinations of variables can be included using the notation {eqname:varlist}, for example, {xb: mpg price weight}, {score: w x z}, etc. Parameters of linear combinations are initialized to zero.
If you specify initial values by using the `initial()` option, they override whatever initial values are given within the substitutable expression. Substitutable expressions are so named because, once values are assigned to the parameters, the resulting expression can be handled by `generate` and `replace`.

**Example 1**

We wish to fit the CES production function

\[
\ln Q_i = \beta_0 - \frac{1}{\rho} \ln \left\{ \delta K_i^{-\rho} + (1 - \delta) L_i^{-\rho} \right\} + \epsilon_i
\]

where \( \ln Q_i \) is the log of output for firm \( i \); \( K_i \) and \( L_i \) are firm \( i \)'s capital and labor usage, respectively; and \( \epsilon_i \) is a regression error term. Because \( \rho \) appears in the denominator of a fraction, zero is not a feasible initial value; for a CES production function, \( \rho = 1 \) is a reasonable choice. Setting \( \delta = 0.5 \) implies that labor and capital have equal impacts on output, which is also a reasonable choice for an initial value. We type

```
. nl (lnoutput = {b0} - 1/{rho=1}*ln({delta=0.5}*capital^(-1*{rho}) +
> (1 - {delta})*labor^(-1*{rho})))
```

```
Iteration 0: residual SS = 29.38631
Iteration 1: residual SS = 29.36637
Iteration 2: residual SS = 29.36583
Iteration 3: residual SS = 29.36581
Iteration 4: residual SS = 29.36581
Iteration 5: residual SS = 29.36581
Iteration 6: residual SS = 29.36581
Iteration 7: residual SS = 29.36581

Source | SS   df  MS

Parameter \( b0 \) taken as constant term in model & ANOVA table
```

\( \rho \) and \( \delta \) are parameters in the function. The elasticity of substitution for the CES production function is \( \sigma = \frac{1}{1 + \rho} \); and, having fit the model, we can use `nlcom` to estimate it:

```
. nlcom (1/(1 + _b[/rho]))
```

```
_nl_1: 1/(1 + _b[/rho])

\( \ln \)output  | Coef. | Std. Err. | z   | P>|z| | [95% Conf. Interval]
----------------|-------|-----------|-----|------|-----------------------
\( _nl_1 \)     | .4189| .0829| 5.05 | 0.000 | .2563| .5815
```

\( \rho \) and \( \delta \) are parameters in the function. The elasticity of substitution for the CES production function is \( \sigma = \frac{1}{1 + \rho} \); and, having fit the model, we can use `nlcom` to estimate it:
See [R] nlcom and [U] 13.5 Accessing coefficients and standard errors for more information.

n1’s output closely mimics that of regress; see [R] regress for more information. The $R^2$, sums of squares, and similar statistics are calculated in the same way that regress calculates them. If no “constant” term is specified, the usual caveats apply to the interpretation of the $R^2$ statistic; see the comments and references in Goldstein (1992). Unlike regress, n1 does not report a model $F$ statistic, because a test of the joint significance of all the parameters except the constant term may not be relevant in a nonlinear model.

Substitutable expression programs

If you fit the same model often or if you want to write an estimator that will operate on whatever variables you specify, then you will want to write a substitutable expression program. That program will return a macro containing a substitutable expression that n1 can then evaluate, and it may optionally calculate initial values as well. The name of the program must begin with the letters n1.

To illustrate, suppose that you use the CES production function often in your work. Instead of typing in the formula each time, you can write a program like this:

```stata
program nlces, rclass
version 13
syntax varlist(min=3 max=3) [if] local logout : word 1 of 'varlist'
local capital : word 2 of 'varlist'
local labor : word 3 of 'varlist'
// Initial value for b0 given delta=0.5 and rho=1
tempvar y
generate double 'y' = 'logout' + ln(0.5*'capital'^-1 + 0.5*'labor'^-1)
summarize 'y' 'if', meanonly
local b0val = r(mean)
// Terms for substitutable expression
local capterm "{delta=0.5}*'capital'^(-1*{rho})"
local labterm "(1-{delta})*'labor'^(-1*{rho})"
local term2 "1/{rho=1}*ln('capterm' + 'labterm')"
// Return substitutable expression and title
return local eq "'logout' = {b0='b0val'} - 'term2'"
return local title "CES ftn., ln Q='logout', K='capital', L='labor'"
end
```

The program accepts three variables for log output, capital, and labor, and it accepts an if exp qualifier to restrict the estimation sample. All programs that you write to use with n1 must accept an if exp qualifier because, when n1 calls the program, it passes a binary variable that marks the estimation sample (the variable equals one if the observation is in the sample and zero otherwise). When calculating initial values, you will want to restrict your computations to the estimation sample, and you can do so by using if with any commands that accept if exp qualifiers. Even if your program does not calculate initial values or otherwise use the if qualifier, the syntax statement must still allow it. See [P] syntax for more information on the syntax command and the use of if.

As in the previous example, reasonable initial values for $\delta$ and $\rho$ are 0.5 and 1, respectively. Conditional on those values, (1) can be rewritten as

$$
\beta_0 = \ln Q_i + \ln(0.5K_i^{-1} + 0.5L_i^{-1}) - \epsilon_i
$$

(2)

so a good initial value for $\beta_0$ is the mean of the right-hand side of (2) ignoring $\epsilon_i$. Lines 7–10 of the function evaluator program calculate that mean and store it in a local macro. Notice the use of if in the summarize statement so that the mean is calculated only for the estimation sample.
The final part of the program returns two macros. The macro title is optional and defines a short description of the model that will be displayed in the output immediately above the table of parameter estimates. The macro eq is required and defines the substitutable expression that nl will use. If the expression is short, you can define it all at once. However, because the expression used here is somewhat lengthy, defining local macros and then building up the final expression from them is easier.

To verify that there are no errors in your program, you can call it directly and then use return list:

```
use http://www.stata-press.com/data/r13/production
.nlces lnoutput capital labor
(output omitted)
.return list
macros:
   r(title) : "CES ftn., ln Q=lnoutput, K=capital, L=labor"
   r(eq) : "lnoutput = {b0=3.711606264663641} - 1/{rho=1}*ln({delta> a=0.5}*capital^(-1*{rho}) + (1-{delta})*labor^(-1*{rho}))"
```

The macro r(eq) contains the same substitutable expression that we specified at the command line in the preceding example, except for the initial value for b0. In short, an nl substitutable expression program should return in r(eq) the same substitutable expression you would type at the command line. The only difference is that when writing a substitutable expression program, you do not bind the entire expression inside parentheses.

Having written the program, you can use it by typing

```
.nl ces: lnoutput capital labor
```

(There is a space between nl and ces.) The output is identical to that shown in example 1, save for the title defined in the function evaluator program that appears immediately above the table of parameter estimates.

**Technical note**

You will want to store nlces as an ado-file called nlces.ado. The alternative is to type the code into Stata interactively or to place the code in a do-file. While those alternatives are adequate for occasional use, if you save the program as an ado-file, you can use the function anytime you use Stata without having to redefine the program. When nl attempts to execute nlces, if the program is not in Stata’s memory, Stata will search the disk(s) for an ado-file of the same name and, if found, automatically load it. All you have to do is name the file with the .ado suffix and then place it in a directory where Stata will find it. You should put the file in the directory Stata reserves for user-written ado-files, which, depending on your operating system, is c:\ado\personal (Windows), ~/ado/personal (Unix), or ~:ado:personal (Mac). See [U] 17 Ado-files.

Sometimes you may want to pass additional options to the substitutable expression program. You can modify the syntax statement of your program to accept whatever options you wish. Then when you call nl with the syntax

```
.nl func_prog: varlist, options
```

any options that are not recognized by nl (see the table of options at the beginning of this entry) are passed on to your function evaluator program. The only other restriction is that your program cannot accept an option named at because nl uses that option with function evaluator programs.

Built-in functions

Some functions are used so often that \texttt{n1} has them built in so that you do not need to write them yourself. \texttt{n1} automatically chooses initial values for the parameters, though you can use the \texttt{initial(...)} option to override them.

Three alternatives are provided for exponential regression with one asymptote:

\begin{align*}
\text{exp3} & \quad y_i = \beta_0 + \beta_1 x_i + \epsilon_i \\
\text{exp2} & \quad y_i = \beta_1 x_i + \epsilon_i \\
\text{exp2a} & \quad y_i = \beta_1 (1 - \beta_2 x_i) + \epsilon_i 
\end{align*}

For instance, typing \texttt{n1 exp3: ras dvl} with logistic regression):

\[ \beta \]

Finally, two alternatives are provided for the Gompertz function (asymmetric sigmoid shape):

\begin{align*}
\text{gom4} & \quad y_i = \beta_0 + \beta_1 \exp \left( - \exp \left( - \beta_2 (x_i - \beta_3) \right) \right) + \epsilon_i \\
\text{gom3} & \quad y_i = \beta_1 \exp \left( - \exp \left( - \beta_2 (x_i - \beta_3) \right) \right) + \epsilon_i 
\end{align*}

Lognormal errors

A nonlinear model with errors that are independent and identically distributed normal may be written as

\[ y_i = f(x_i, \beta) + u_i, \quad u_i \sim N(0, \sigma^2) \] (3)

for \( i = 1, \ldots, n \). If the \( y_i \) are thought to have a \( k \)-shifted lognormal instead of a normal distribution—that is, \( \ln(y_i - k) \sim N(\zeta_i, \tau^2) \), and the systematic part \( f(x_i, \beta) \) of the original model is still thought appropriate for \( y_i \)—the model becomes

\[ \ln(y_i - k) = \zeta_i + v_i = \ln\left\{ f(x_i, \beta) - k \right\} + v_i, \quad v_i \sim N(0, \tau^2) \] (4)

This model is fit if \texttt{lnlsq(k)} is specified.

If model (4) is correct, the variance of \( (y_i - k) \) is proportional to \( \left\{ f(x_i, \beta) - k \right\}^2 \). Probably the most common case is \( k = 0 \), sometimes called “proportional errors” because the standard error of \( y_i \) is proportional to its expectation, \( f(x_i, \beta) \). Assuming that the value of \( k \) is known, (4) is just another nonlinear model in \( \beta \), and it may be fit as usual. However, we may wish to compare the fit of (3) with that of (4) using the residual sum of squares (RSS) or the deviance \( D \), \( D = -2 \times \text{log-likelihood}, \) from each model. To do so, we must allow for the change in scale introduced by the log transformation.

Assuming, then, the \( y_i \) to be normally distributed, Atkinson (1985, 85–87, 184), by considering the Jacobian \[ \prod |\partial \ln(y_i - k)/\partial y_i| \], showed that multiplying both sides of (4) by the geometric mean of \( y_i - k \), \( \bar{y} \), gives residuals on the same scale as those of \( y_i \). The geometric mean is given by

\[ \bar{y} = e^{n^{-1} \sum \ln(y_i - k)} \]

which is a constant for a given dataset. The residual deviance for (3) and for (4) may be expressed as

\[ D(\beta) = \left\{ 1 + \ln(2\pi\sigma^2) \right\} n \] (5)
where $\hat{\beta}$ is the maximum likelihood estimate (MLE) of $\beta$ for each model and $n\hat{\sigma}^2$ is the RSS from (3), or that from (4) multiplied by $y^2$.

Because (3) and (4) are models with different error structures but the same functional form, the arithmetic difference in their RSS or deviances is not easily tested for statistical significance. However, if the deviance difference is large (>4, say), we would naturally prefer the model with the smaller deviance. Of course, the residuals for each model should be examined for departures from assumptions (nonconstant variance, nonnormality, serial correlations, etc.) in the usual way.

Alternatively, consider modeling

$$E(y_i) = 1/(C + Ae^{Bx_i})$$

(6)

$$E(1/y_i) = E(y'_i) = C + Ae^{Bx_i}$$

(7)

where $C$, $A$, and $B$ are parameters to be estimated. Using the data $(y, x) = (0.04, 5), (0.06, 12), (0.08, 25), (0.1, 35), (0.15, 42), (0.2, 48), (0.25, 60), (0.3, 75),$ and $(0.5, 120)$ (Danuso 1991), fitting the models yields

</tbody>
</table>

There is little to choose between the two versions of the logistic model (6), whereas for the exponential model (7), the fit using lnlsq(0) is much better (a deviance difference of 7.28). The reciprocal transformation has introduced heteroskedasticity into $y'_i$, which is countered by the proportional errors property of the lognormal distribution implicit in lnlsq(0). The deviances are not comparable between the logistic and exponential models because the change of scale has not been allowed for, although in principle it could be.

### Other uses

Even if you are fitting linear regression models, you may find that nl can save you some typing. Because you specify the parameters of your model explicitly, you can impose constraints on them directly.

#### Example 2

In example 2 of [R] cnsreg, we showed how to fit the model

$$mpg = \beta_0 + \beta_1 price + \beta_2 weight + \beta_3 displ + \beta_4 gear\_ratio + \beta_5 foreign + \beta_6 length + u$$

subject to the constraints

$$\beta_1 = \beta_2 = \beta_3 = \beta_6$$

$$\beta_4 = -\beta_5 = \beta_0/20$$
An alternative way is to use `nl`:

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. nl (mpg = {b0} + {b1}*price + {b1}*weight + {b1}*displ +
   > {b0}/20*gear_ratio - {b0}/20*foreign + {b1}*length)
(obs = 74)
Iteration 0: residual SS = 1578.522
Iteration 1: residual SS = 1578.522

Source | SS        df | MS
------|------------|---------
Model  | 34429.4777 | 2       | 17214.7389
Residual | 1578.5226 | 72      | 21.9239203
Total  | 36008      | 74      | 486.594595

Number of obs = 74
R-squared = 0.9562
Adj R-squared = 0.9549
Root MSE = 4.682299
Res. dev. = 436.4562

mpg | Coef.  Std. Err.  t  P>|t|  [95% Conf. Interval]
----|--------|--------|--------|--------|------------------
/b0 | 26.52229 1.375178 19.29  0.000  23.78092  29.26365
/b1 |  -0.000923 0.0001534  -6.02  0.000  -0.0012288 -0.0006172
```

The point estimates and standard errors for $\beta_0$ and $\beta_1$ are identical to those reported in example 2 of [R] cnsreg. To get the estimate for $\beta_4$, we can use `nlcom`:

```
. nlcom _b[/b0]/20
   _nl_1: _b[/b0]/20

mpg | Coef.  Std. Err.  z  P>|z|  [95% Conf. Interval]
----|--------|--------|--------|--------|------------------
  _nl_1 | 1.326114 0.0687589 19.29  0.000  1.191349  1.460879
```

The advantage to using `nl` is that we do not need to use the constraint command six times.

`nl` is also a useful tool when doing exploratory data analysis. For example, you may want to run a regression of $y$ on a function of $x$, though you have not decided whether to use $\sqrt{x}$ or $\ln(x)$. You can use `nl` to run both regressions without having first to generate two new variables:

```
. nl (y = {b0} + {b1}*ln(x))
. nl (y = {b0} + {b1}*sqrt(x))
```

Poi (2008) shows the advantages of using `nl` when marginal effects of transformed variables are desired as well.

### Weights

Weights are specified in the usual way—analytic and frequency weights as well as `iweights` are supported; see [U] 20.23 Weighted estimation. Use of analytic weights implies that the $y_i$ have different variances. Therefore, model (3) may be rewritten as

\[
y_i = f(x_i, \beta) + u_i, \quad u_i \sim N(0, \sigma^2/w_i)
\]  

(3a)

where $w_i$ are (positive) weights, assumed to be known and normalized such that their sum equals the number of observations. The residual deviance for (3a) is

\[
D(\hat{\beta}) = \left\{ 1 + \ln(2\pi\hat{\sigma}^2) \right\} n - \sum \ln(w_i)
\]

(5a)
[compare with (5)], where

\[ n\hat{\sigma}^2 = \text{RSS} = \sum w_i \left( y_i - f(x_i, \hat{\beta}) \right)^2 \]

Defining and fitting a model equivalent to (4) when weights have been specified as in (3a) is not straightforward and has not been attempted. Thus deviances using and not using the \texttt{lnlsq()} option may not be strictly comparable when analytic weights (other than 0 and 1) are used.

You do not need to modify your substitutable expression in any way to use weights. If, however, you write a substitutable expression program, then you should account for weights when obtaining initial values. When \texttt{nl} calls your program, it passes whatever weight expression (if any) was specified by the user. Here is an outline of a substitutable expression program that accepts weights:

```stata
program nl name, rclass
    version 13
    syntax varlist [aw fw iw] if ...
    // Obtain initial values allowing weights
    // Use the syntax ['weight''exp']. For example,
    summarize varname ['weight''exp'] 'if'
    regress depvar varlist ['weight''exp'] 'if'
    ...
    // Return substitutable expression
    return local eq "substitutable expression"
    return local title "description of estimator"
end
```

For details on how the \texttt{syntax} command processes weight expressions, see \cite{P_syntax}.

**Potential errors**

\texttt{nl} is reasonably robust to the inability of your nonlinear function to be evaluated at some parameter values. \texttt{nl} does assume that your function can be evaluated at the initial values of the parameters. If your function cannot be evaluated at the initial values, an error message is issued with return code 480. Recall that if you do not specify an initial value for a parameter, then \texttt{nl} initializes it to zero. Many nonlinear functions cannot be evaluated when some parameters are zero, so in those cases specifying alternative initial values is crucial.

Thereafter, as \texttt{nl} changes the parameter values, it monitors your function for unexpected missing values. If these are detected, \texttt{nl} backs up. That is, \texttt{nl} finds a point between the previous, known-to-be-good parameter vector and the new, known-to-be-bad vector at which the function can be evaluated and continues its iterations from that point.

\texttt{nl} requires that once a parameter vector is found where the predictions can be calculated, small changes to the parameter vector be made to calculate numeric derivatives. If a boundary is encountered at this point, an error message is issued with return code 481.

When specifying \texttt{lnlsq()}, an attempt to take logarithms of \( y_i - k \) when \( y_i \leq k \) results in an error message with return code 482.

If \texttt{iterate()} iterations are performed and estimates still have not converged, results are presented with a warning, and the return code is set to 430.

If you use the programmed substitutable expression version of \texttt{nl} with a function evaluator program, or vice versa, Stata issues an error message. Verify that you are using the syntax appropriate for the program you have.
General comments on fitting nonlinear models

Achieving convergence is often problematic. For example, a unique minimum of the sum-of-squares function may not exist. Much literature exists on different algorithms that have been used, on strategies for obtaining good initial parameter values, and on tricks for parameterizing the model to make its behavior as linear-like as possible. Selected references are Kennedy and Gentle (1980, chap. 10) for computational matters and Ross (1990) and Ratkowsky (1983) for all three aspects. Ratkowsky’s book is particularly clear and approachable, with useful discussion on the meaning and practical implications of intrinsic and parameter-effects nonlinearity. An excellent text on nonlinear estimation is Gallant (1987). Also see Davidson and MacKinnon (1993 and 2004).

To enhance the success of \texttt{nl}, pay attention to the form of the model fit, along the lines of Ratkowsky and Ross. For example, Ratkowsky (1983, 49–59) analyzes three possible three-parameter yield-density models for plant growth:

\[
E(y_i) = \begin{cases} 
  (\alpha + \beta x_i)^{-1/\theta} \\
  (\alpha + \beta x_i + \gamma x_i^2)^{-1} \\
  (\alpha + \beta x_i^\phi)^{-1}
\end{cases}
\]

All three models give similar fits. However, he shows that the second formulation is dramatically more linear-like than the other two and therefore has better convergence properties. In addition, the parameter estimates are virtually unbiased and normally distributed, and the asymptotic approximation to the standard errors, correlations, and confidence intervals is much more accurate than for the other models. Even within a given model, the way the parameters are expressed (for example, $\phi x_i$ or $e^{\theta x_i}$) affects the degree of linearity and convergence behavior.

Function evaluator programs

Occasionally, a nonlinear function may be so complex that writing a substitutable expression for it is impractical. For example, there could be many parameters in the model. Alternatively, if you are implementing a two-step estimator, writing a substitutable expression may be altogether impossible. Function evaluator programs can be used in these situations.

\texttt{nl} will pass to your function evaluator program a list of variables, a weight expression, a variable marking the estimation sample, and a vector of parameters. Your program is to replace the dependent variable, which is the first variable in the variables list, with the values of the nonlinear function evaluated at those parameters. As with substitutable expression programs, the first two letters of the name must be \texttt{nl}.

To focus on the mechanics of the function evaluator program, again let’s compare the CES production function to the previous examples. The function evaluator program is
program nlces2
version 13
syntax varlist(min=3 max=3) if, at(name)
local logout : word 1 of varlist
local capital : word 2 of varlist
local labor : word 3 of varlist
// Retrieve parameters out of at matrix
tempname b0 rho delta
scalar 'b0' = 'at'[1, 1]
scalar 'rho' = 'at'[1, 2]
scalar 'delta' = 'at'[1, 3]
tempvar kterm lterm
generate double 'kterm' = 'delta'*'capital'^(-1*'rho') 'if'
genrate double 'lterm' = (1-'delta')*'labor'^(-1*'rho') 'if'
// Fill in dependent variable
replace 'logout' = 'b0' - 1/'rho'*ln('kterm' + 'lterm') 'if'
end

Unlike the previous nlces program, this one is not declared to be r-class. The syntax statement again accepts three variables: one for log output, one for capital, and one for labor. An if exp is again required because nl will pass a binary variable marking the estimation sample. All function evaluator programs must accept an option named at() that takes a name as an argument—that is how nl passes the parameter vector to your program.

The next part of the program retrieves the output, labor, and capital variables from the variables list. It then breaks up the temporary matrix at and retrieves the parameters b0, rho, and delta. Pay careful attention to the order in which the parameters refer to the columns of the at matrix because that will affect the syntax you use with nl. The temporary names you use inside this program are immaterial, however.

The rest of the program computes the nonlinear function, using some temporary variables to hold intermediate results. The final line of the program then replaces the dependent variable with the values of the function. Notice the use of ‘if’ to restrict attention to the estimation sample. nl makes a copy of your dependent variable so that when the command is finished your data are left unchanged.

To use the program and fit your model, you type

```
use http://www.stata-press.com/data/r13/production, clear
.nl ces2 @ lnoutput capital labor, parameters(b0 rho delta)
  > initial(b0 0 rho 1 delta 0.5)
```

The output is again identical to that shown in example 1. The order in which the parameters were specified in the parameters() option is the same in which they are retrieved from the at matrix in the program. To initialize them, you simply list the parameter name, a space, the initial value, and so on.

If you use the nparameters() option instead of the parameters() option, the parameters are named b1, b2, ..., bk, where k is the number of parameters. Thus you could have typed

```
.nl ces2 @ lnoutput capital labor, nparameters(3) initial(b1 0 b2 1 b3 0.5)
```

With that syntax, the parameters called b0, rho, and delta in the program will be labeled b1, b2, and b3, respectively. In programming situations or if there are many parameters, instead of listing the parameter names and initial values in the initial() option, you may find it more convenient to pass a column vector. In those cases, you could type

```
matrix myvals = (0, 1, 0.5)
.nl ces2 @ lnoutput capital labor, nparameters(3) initial(myvals)
```
In summary, a function evaluator program receives a list of variables, the first of which is the dependent variable that you are to replace with the values of your nonlinear function. Additionally, it must accept an if exp, as well as an option named at that will contain the vector of parameters at which nl wants the function evaluated. You are then free to do whatever is necessary to evaluate your function and replace the dependent variable.

If you wish to use weights, your function evaluator program’s syntax statement must accept them. If your program consists only of, for example, generate statements, you need not do anything with the weights passed to your program. However, if in calculating the nonlinear function you use commands such as summarize or regress, then you will want to use the weights with those commands.

As with substitutable expression programs, nl will pass to it any options specified that nl does not accept, providing you with a way to pass more information to your function.

☐ Technical note

Before version 9 of Stata, the nl command used a different syntax, which required you to write an nlfcn program, and it did not have a syntax for interactive use other than the seven functions that were built-in. The old syntax of nl still works, and you can still use those nlfcn programs. If nl does not see a colon, an at sign, or a set of parentheses surrounding the equation in your command, it assumes that the old syntax is being used.

The current version of nl uses scalars and matrices to store intermediate calculations instead of local and global macros as the old version did, so the current version produces more accurate results. In practice, however, any discrepancies are likely to be small.
Stored results

nl stores the following in e():

Scalars
- e(N): number of observations
- e(k): number of parameters
- e(k_eq_model): number of equations in overall model test; always 0
- e(df_m): model degrees of freedom
- e(df_r): residual degrees of freedom
- e(df_t): total degrees of freedom
- e(mss): model sum of squares
- e(rss): residual sum of squares
- e(tss): total sum of squares
- e(mms): model mean square
- e(msr): residual mean square
- e(ll): log likelihood assuming i.i.d. normal errors
- e(r2): $R^2$
- e(r2_a): adjusted $R^2$
- e(rmse): root mean squared error
- e(dev): residual deviance
- e(N_clust): number of clusters
- e(lnlsq): value of lnlsq if specified
- e(log_t): 1 if lnlsq specified, 0 otherwise
- e(gm_2): square of geometric mean of $y - k$ if lnlsq; 1 otherwise
- e(cj): position of constant in e(b) or 0 if no constant
- e(delta): relative change used to compute derivatives
- e(rank): rank of e(V)
- e(ic): number of iterations
- e(converge): 1 if converged, 0 otherwise

Macros
- e(cmd): nl
- e(cmdline): command as typed
- e(depvar): name of dependent variable
- e(wtype): weight type
- e(wexp): weight expression
- e(title): title in estimation output
- e(title_2): secondary title in estimation output
- e(clustvar): name of cluster variable
- e(hac_kernel): HAC kernel
- e(hac_lag): HAC lag
- e(vcetype): vcetype specified in vce()
- e(vce()): title used to label Std. Err.
- e(type): 1 = interactively entered expression
- 2 = substitutable expression program
- 3 = function evaluator program
- e(sexp): substitutable expression
- e(params): names of parameters
- e(funcprog): function evaluator program
- e(rhs): contents of variables()
- e(properties): b V
- e(predict): program used to implement predict
- e(marginsnotok): predictions disallowed by margins

Matrices
- e(b): coefficient vector
- e(init): initial values vector
- e(V): variance-covariance matrix of the estimators

Functions
- e(sample): marks estimation sample
Methods and formulas

The derivation here is based on Davidson and MacKinnon (2004, chap. 6). Let \( \beta \) denote the \( k \times 1 \) vector of parameters, and write the regression function using matrix notation as \( y = f(x, \beta) + u \) so that the objective function can be written as

\[
SSR(\beta) = \{y - f(x, \beta)\}' D \{y - f(x, \beta)\}
\]

The \( D \) matrix contains the weights and is defined in \([R]\) \texttt{regress}; if no weights are specified, then \( D \) is the \( N \times N \) identity matrix. Taking a second-order Taylor series expansion centered at \( \beta_0 \) yields

\[
SSR(\beta) \approx SSR(\beta_0) + g'(\beta_0)(\beta - \beta_0) + \frac{1}{2}(\beta - \beta_0)' H(\beta_0)(\beta - \beta_0)
\]

(8)

where \( g(\beta_0) \) denotes the \( k \times 1 \) gradient of \( SSR(\beta) \) evaluated at \( \beta_0 \) and \( H(\beta_0) \) denotes the \( k \times k \) Hessian of \( SSR(\beta) \) evaluated at \( \beta_0 \). Letting \( X \) denote the \( N \times k \) matrix of derivatives of \( f(x, \beta) \) with respect to \( \beta \), the gradient \( g(\beta) \) is

\[
g(\beta) = -2X'Du
\]

(9)

\( X \) and \( u \) are obviously functions of \( \beta \), though for notational simplicity that dependence is not shown explicitly. The \( (m,n) \) element of the Hessian can be written as

\[
H_{mn}(\beta) = -2 \sum_{i=1}^{N} d_{ii} \left[ \frac{\partial^2 f_i}{\partial \beta_m \partial \beta_n} u_i - X_{im}X_{in} \right]
\]

(10)

where \( d_{ii} \) is the \( i \)th diagonal element of \( D \). As discussed in Davidson and MacKinnon (2004, chap. 6), the first term inside the brackets of (10) has expectation zero, so the Hessian can be approximated as

\[
H(\beta) = 2X'DX
\]

(11)

Differentiating the Taylor series expansion of \( SSR(\beta) \) shown in (8) yields the first-order condition for a minimum

\[
g(\beta_0) + H(\beta_0)(\beta - \beta_0) = 0
\]

which suggests the iterative procedure

\[
\beta_{j+1} = \beta_j - \alpha H^{-1}(\beta_j)g(\beta_j)
\]

(12)

where \( \alpha \) is a “step size” parameter chosen at each iteration to improve convergence. Using (9) and (11), we can write (12) as

\[
\beta_{j+1} = \beta_j + \alpha(X'DX)^{-1}X'Du
\]

(13)

where \( X \) and \( u \) are evaluated at \( \beta_j \). Apart from the scalar \( \alpha \), the second term on the right-hand side of (13) can be computed via a (weighted) regression of the columns of \( X \) on the errors. \texttt{nl} computes the derivatives numerically and then calls \texttt{regress}. At each iteration, \( \alpha \) is set to one, and a candidate value \( \beta_{j+1}^* \) is computed by (13). If \( SSR(\beta_{j+1}^*) < SSR(\beta_j) \), then \( \beta_{j+1} = \beta_{j+1}^* \) and the iteration is complete. Otherwise, \( \alpha \) is halved, a new \( \beta_{j+1}^* \) is calculated, and the process is repeated. Convergence is declared when \( \alpha |\beta_{j+1,m} - \beta_{j,m}| \leq \epsilon |\beta_{j,m}| + \tau \) for all \( m = 1, \ldots, k \). \texttt{nl} uses \( \tau = 10^{-3} \) and, by default, \( \epsilon = 10^{-5} \), though you can specify an alternative value of \( \epsilon \) with the \texttt{eps()} option.
As derived, for example, in Davidson and MacKinnon (2004, chap. 6), an expedient way to obtain the covariance matrix is to compute $u$ and the columns of $X$ at the final estimate $\hat{\beta}$ and then regress that $u$ on $X$. The covariance matrix of the estimated parameters of that regression serves as an estimate of $\text{Var}(\hat{\beta})$. If that regression employs a robust covariance matrix estimator, then the covariance matrix for the parameters of the nonlinear regression will also be robust.

All other statistics are calculated analogously to those in linear regression, except that the nonlinear function $f(x_i, \beta)$ plays the role of the linear function $x_i'\beta$. See [R] regress.

This command supports estimation with survey data. For details on VCEs with survey data, see [SVY] variance estimation.

Acknowledgments

The original version of nl was written by Patrick Royston (1992) of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model. Francesco Danuso’s menu-driven nonlinear regression program (1991) provided the inspiration.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

- **Main**
  - \( \hat{y} \), the default, calculates the fitted values.
  - residuals calculates the residuals.
  - \( pr(a, b) \) calculates \( \Pr(a < x_j b + u_j < b) \), the probability that \( y_j \mid x_j \) would be observed in the interval \((a, b)\).
    - \( a \) and \( b \) may be specified as numbers or variable names; \( lb \) and \( ub \) are variable names; \( pr(20,30) \) calculates \( \Pr(20 < x_j b + u_j < 30) \) and calculates \( \Pr(lb < x_j b + u_j < ub) \) elsewhere.
    - \( a \) missing (\( a \geq . \)) means \( -\infty \); \( pr(.,30) \) calculates \( \Pr(-\infty < x_j b + u_j < 30) \) and calculates \( \Pr(lb < x_j b + u_j < ub) \) elsewhere.
  - \( e(a, b) \) calculates \( E(x_j b + u_j \mid a < x_j b + u_j < b) \), the expected value of \( y_j \mid x_j \) conditional on \( y_j \mid x_j \) being in the interval \((a, b)\), meaning that \( y_j \mid x_j \) is truncated. \( a \) and \( b \) are specified as they are for \( pr() \).
  - \( ystar(a, b) \) calculates \( E(y_j^*) \), where \( y_j^* = a \) if \( x_j b + u_j \leq a \), \( y_j^* = b \) if \( x_j b + u_j \geq b \), and \( y_j^* = x_j b + u_j \) otherwise, meaning that \( y_j^* \) is censored. \( a \) and \( b \) are specified as they are for \( pr() \).
scores calculates the scores. The \( j \)th new variable created will contain the score for the \( j \)th parameter in \( \text{e(b)} \).

**Remarks and examples**

**Example 1**

Obtaining predictions after fitting a nonlinear regression model with `nl` is no more difficult than obtaining predictions after fitting a linear regression model with `regress`. Here we fit a model of `mpg` on `weight`, allowing for a nonlinear relationship:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. nl (mpg = {b0} + {b1}*weight^{gamma=-.5}), variables(weight) nolog
```

/gamma -.4460916 .6763643 -0.66 0.512 -1.794724 .9025405
```

Parameter \( b_0 \) taken as constant term in model & ANOVA table

Now we obtain the predicted values of `mpg` and plot them in a graph along with the observed values:

```
. predict mpghat
 (option yhat assumed; fitted values)
. scatter mpg weight || line mpghat weight, sort
```

![Graph of predicted vs observed mpg values](image-url)
Suppose we wanted to know how sensitive mpg is to changes in weight for cars that weigh 3,000 pounds. We can use margins to find out:

```
. margins, eyex(weight) at(weight = 3000)
Warning: cannot perform check for estimable functions.
```

Conditional marginal effects Number of obs = 74
Model VCE : GNR
Expression : Fitted values, predict()
ey/ex w.r.t. : weight
at : weight = 3000

<table>
<thead>
<tr>
<th></th>

</tr>
</thead>
<tbody>
<tr>
<td>ey/ex</td>
<td>Std. Err.</td>
</tr>
<tr>
<td>weight</td>
<td>-.8408119</td>
</tr>
</tbody>
</table>

With the `eyex()` option, margins reports elasticities. These results show that if we increase weight by 1%, then mpg decreases by about 0.84%.

💡 Technical note

Observant readers will notice that margins issued a warning message stating that it could not perform its usual check for estimable functions. In the case of nl, as long as you do not specify the `predict()` option of margins or specify the default `predict(yhat)`, you can safely ignore that message. The predicted values that nl produces are suitable for use with margins. However, if you specify any `predict()` options other than `yhat`, then the output from margins after using nl will not be correct.

</tr>
</tbody>
</table>

`noheader` and `df(#)` do not appear in the dialog box.

The second syntax means that if more than one expression is specified, each must be surrounded by parentheses. The optional `name` is any valid Stata name and labels the transformations.

`exp` is a possibly nonlinear expression containing

- `_b[coef]`
- `_b[eqno:coef]`
- `[eqno]coef`
- `[eqno]_b[coef]`

`eqno` is

- `##`
- `name`

`coef` identifies a coefficient in the model. `coef` is typically a variable name, a level indicator, an interaction indicator, or an interaction involving continuous variables. Level indicators identify one level of a factor variable and interaction indicators identify one combination of levels of an interaction; see [U] 11.4.3 Factor variables. `coef` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

Distinguish between [], which are to be typed, and [], which indicate optional arguments.
Description

nlcom computes point estimates, standard errors, test statistics, significance levels, and confidence intervals for (possibly) nonlinear combinations of parameter estimates after any Stata estimation command. Results are displayed in the usual table format used for displaying estimation results. Calculations are based on the “delta method”, an approximation appropriate in large samples.

nlcom can be used with svy estimation results; see [SVY] svy postestimation.

Options

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

iterate(#) specifies the maximum number of iterations used to find the optimal step size in calculating numerical derivatives of the transformation(s) with respect to the original parameters. By default, the maximum number of iterations is 100, but convergence is usually achieved after only a few iterations. You should rarely have to use this option.

post causes nlcom to behave like a Stata estimation (eclass) command. When post is specified, nlcom will post the vector of transformed estimators and its estimated variance–covariance matrix to e(). This option, in essence, makes the transformation permanent. Thus you could, after posting, treat the transformed estimation results in the same way as you would treat results from other Stata estimation commands. For example, after posting, you could redisplay the results by typing nlcom without any arguments, or use test to perform simultaneous tests of hypotheses on linear combinations of the transformed estimators; see [R] test.

Specifying post clears out the previous estimation results, which can be recovered only by refitting the original model or by storing the estimation results before running nlcom and then restoring them; see [R] estimates store.

display_options: cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

The following options are available with nlcom but are not shown in the dialog box:

noheader suppresses the output header.

df(#) specifies that the $t$ distribution with # degrees of freedom be used for computing $p$-values and confidence intervals.

Remarks and examples

Remarks are presented under the following headings:

Introduction
Basics
Using the post option
Reparameterizing ML estimators for univariate data
nlcom versus eform
**Introduction**

`nlcom` and `predictnl` both use the delta method. They take nonlinear transformations of the estimated parameter vector from some fitted model and apply the delta method to calculate the variance, standard error, Wald test statistic, etc., of the transformations. `nlcom` is designed for functions of the parameters, and `predictnl` is designed for functions of the parameters and of the data, that is, for predictions.

`nlcom` generalizes `lincom` (see [R] `lincom`) in two ways. First, `nlcom` allows the transformations to be nonlinear. Second, `nlcom` can be used to simultaneously estimate many transformations (whether linear or nonlinear) and to obtain the estimated variance–covariance matrix of these transformations.

**Basics**

In [R] `lincom`, the following regression was performed:

```
use http://www.stata-press.com/data/r13/regress
regress y x1 x2 x3
```

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 148</th>

<td>F( 3, 144) = 96.12</td>
</tr>
<tr>
<td>Residual</td>
<td>1627.56282</td>
<td>144</td>
<td>11.3025196</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Total</td>
<td>4886.9192</td>
<td>147</td>
<td>33.2443464</td>
<td>R-squared = 0.6670</td>
</tr>
</tbody>
</table>

| y     | Coef.         | Std. Err. | t     | P>|t|   | [95% Conf. Interval] |
|-------|---------------|-----------|-------|-------|----------------------|
| x1    | 1.457113      | 1.07461   | 1.36  | 0.177 | -0.666934 — 3.581161 |
| x2    | 2.221682      | .8610358  | 2.58  | 0.011 | .5197797 — 3.923583 |
| x3    | -.006139      | .0005543  | -11.08| 0.000 | -.0072345 — -.0050435|
| _cons | 36.10135      | 4.382693  | 8.24  | 0.000 | 27.43863 — 44.76407 |

Then `lincom` was used to estimate the difference between the coefficients of `x1` and `x2`:

```
lincom _b[x2] - _b[x1]
```

( 1 ) - x1 + x2 = 0

```
| y     | Coef.         | Std. Err. | t     | P>|t|   | [95% Conf. Interval] |
|-------|---------------|-----------|-------|-------|----------------------|
| (1)   | .7645682      | .9950282  | 0.77  | 0.444 | -1.20218 — 2.731316 |
```

It was noted, however, that nonlinear expressions are not allowed with `lincom`:

```
lincom _b[x2]/_b[x1]
```

*not possible with test*

r(131);

Nonlinear transformations are instead estimated using `nlcom`:

```
nlcom _b[x2]/_b[x1]
```

```
| y     | Coef.         | Std. Err. | z     | P>|z|   | [95% Conf. Interval] |
|-------|---------------|-----------|-------|-------|----------------------|
| _nl_1 | 1.524714      | .9812848  | 1.55  | 0.120 | -.3985686 — 3.447997 |
```
Technical note

The notation \(_b\{name\}\) is the standard way in Stata to refer to regression coefficients; see [U] 13.5 Accessing coefficients and standard errors. Some commands, such as lincom and test, allow you to drop the \(_b[]\) and just refer to the coefficients by \(name\). \texttt{nlcom}, however, requires the full specification \(_b\{name\}\).

Returning to our linear regression example, \texttt{nlcom} also allows simultaneous estimation of more than one combination:

\begin{verbatim}
    . nlcom (_b[x2]/_b[x1]) (_b[x3]/_b[x1]) (_b[x3]/_b[x2])
      _nl_1: _b[x2]/_b[x1]
      _nl_2: _b[x3]/_b[x1]
      _nl_3: _b[x3]/_b[x2]
\end{verbatim}

\begin{verbatim}

|       | Coef. | Std. Err. | z  | P>|z| | [95% Conf. Interval] |
|-------|-------|-----------|----|------|----------------------|
| _nl_1 | 1.524714 | .9812848 | 1.55 | 0.120 | -.3985686 3.447997 |
| _nl_2 | -.0042131 | .0033483 | -1.26 | 0.208 | -.0107756 .0023494 |
| _nl_3 | -.0027632 | .0010695 | -2.58 | 0.010 | -.0048594 -.000667 |
\end{verbatim}

We can also label the transformations to produce more informative names in the estimation table:

\begin{verbatim}
    . nlcom (ratio21:_b[x2]/_b[x1]) (ratio31:_b[x3]/_b[x1]) (ratio32:_b[x3]/_b[x2])
      ratio21: _b[x2]/_b[x1]
      ratio31: _b[x3]/_b[x1]
      ratio32: _b[x3]/_b[x2]
\end{verbatim}

\begin{verbatim}

|       | Coef. | Std. Err. | z  | P>|z| | [95% Conf. Interval] |
|-------|-------|-----------|----|------|----------------------|
| ratio21 | 1.524714 | .9812848 | 1.55 | 0.120 | -.3985686 3.447997 |
| ratio31 | -.0042131 | .0033483 | -1.26 | 0.208 | -.0107756 .0023494 |
| ratio32 | -.0027632 | .0010695 | -2.58 | 0.010 | -.0048594 -.000667 |
\end{verbatim}

\texttt{nlcom} stores the vector of estimated combinations and its estimated variance–covariance matrix in \texttt{r()}.

\begin{verbatim}
    . matrix list r(b)
    r(b)[1,3]
           ratio21  ratio31  ratio32
c1  1.5247143  -.00421315  -.00276324
    . matrix list r(V)
    symmetric r(V)[3,3]
           ratio21  ratio31  ratio32
    ratio21  .96291982   -.00287781   .00001121
    ratio31  -.00287781   .00001121
    ratio32  -.00014234   2.137e-06  1.144e-06
\end{verbatim}
Using the post option

When used with the post option, nlcom stores the estimation vector and variance–covariance matrix in e(), making the transformation permanent:

```stata
. quietly nlcom (ratio21:_b[x2]/_b[x1]) (ratio31:_b[x3]/_b[x1])
> (ratio32:_b[x3]/_b[x2]), post
. matrix list e(b)
   e(b)[1,3]
     ratio21   ratio31   ratio32
    y1      1.5247143   -.00421315   -.00276324
. matrix list e(V)
   symmetric e(V)[3,3]
    ratio21   ratio31   ratio32
   ratio21   .96291982
   ratio31   -.00287781   .00001121
   ratio32   -.00014234   2.137e-06   1.144e-06
```

After posting, we can proceed as if we had just run a Stata estimation (eclass) command. For instance, we can replay the results,

```stata
. nlcom

|        | Coef.    | Std. Err. | z      | P>|z|   | [95% Conf. Interval] |
|--------|----------|-----------|--------|-------|---------------------|
| y      |          |           |        |       |                     |
| ratio21| 1.5247143| .9812848  | 1.55   | 0.120 | -.3985686  3.447997 |
| ratio31| -.0042131| .0033483  | -1.26  | 0.208 | -.0107756  .0023494 |
| ratio32| -.0027632| .0010695  | -2.58  | 0.010 | -.0048594  -.000667 |
```

or perform other postestimation tasks in the transformed metric, this time making reference to the new “coefficients”:

```stata
. display _b[ratio31]
   -.00421315
. estat vce, correlation

Correlation matrix of coefficients of nlcom model

<table>
<thead>
<tr>
<th></th>
<th>ratio21</th>
<th>ratio31</th>
<th>ratio32</th>
</tr>
</thead>
<tbody>
<tr>
<td>ratio21</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>ratio31</td>
<td>-0.8759</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td>ratio32</td>
<td>-0.1356</td>
<td>0.5969</td>
<td>1.0000</td>
</tr>
</tbody>
</table>
```

We see that testing \(_b[ratio21]=1\) in the transformed metric is equivalent to testing using \(testnl \_b[x2]/\_b[x1]=1\) in the original metric:

```stata
. quietly regress y x1 x2 x3
. testnl \_b[x2]/\_b[x1] = 1
```

```
( 1)  _b[x2]/_b[x1] = 1
     ch2( 1) = 0.29
     Prob > chi2 = 0.5928
```

We needed to refit the regression model to recover the original parameter estimates.
Technical note

In a previous technical note, we mentioned that commands such as lincom and test permit reference to name instead of _b[name]. This is not the case when lincom and test are used after nlcom, post. In the above, we used

```
  . test _b[ratio21] = 1
```

rather than

```
  . test ratio21 = 1
```

which would have returned an error. Consider this a limitation of Stata. For the shorthand notation to work, you need a variable named name in the data. In nlcom, however, name is just a coefficient label that does not necessarily correspond to any variable in the data.

Reparameterizing ML estimators for univariate data

When run using only a response and no covariates, Stata’s maximum likelihood (ML) estimation commands will produce ML estimates of the parameters of some assumed univariate distribution for the response. The parameterization, however, is usually not one we are used to dealing with in a nonregression setting. In such cases, nlcom can be used to transform the estimation results from a regression model to those from a maximum likelihood estimation of the parameters of a univariate probability distribution in a more familiar metric.

Example 1

Consider the following univariate data on $Y =$ # of traffic accidents at a certain intersection in a given year:

```
  . use http://www.stata-press.com/data/r13/trafint
  . summarize accidents
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>accidents</td>
<td>12</td>
<td>13.83333</td>
<td>14.47778</td>
<td>0</td>
<td>41</td>
</tr>
</tbody>
</table>

A quick glance of the output from summarize leads us to quickly reject the assumption that $Y$ is distributed as Poisson because the estimated variance of $Y$ is much greater than the estimated mean of $Y$.

Instead, we choose to model the data as univariate negative binomial, of which a common parameterization is

$$
\Pr(Y = y) = \frac{\Gamma(r + y)}{\Gamma(r) \Gamma(y + 1)} p^r (1 - p)^y \quad 0 \leq p \leq 1, \quad r > 0, \quad y = 0, 1, \ldots
$$

with

$$
E(Y) = \frac{r(1 - p)}{p} \quad \text{Var}(Y) = \frac{r(1 - p)}{p^2}
$$

There exist no closed-form solutions for the maximum likelihood estimates of $p$ and $r$, yet they may be estimated by the iterative method of Newton–Raphson. One way to get these estimates would be to write our own Newton–Raphson program for the negative binomial. Another way would be to write our own ML evaluator; see [R] ml.
The easiest solution, however, would be to use Stata’s existing negative binomial ML regression command, `nbreg`. The only problem with this solution is that `nbreg` estimates a different parameterization of the negative binomial, but we can worry about that later.

```
    . nbreg accidents
    Fitting Poisson model:
    Iteration 0:  log likelihood = -105.05361
    Iteration 1:  log likelihood = -105.05361
    Fitting constant-only model:
    Iteration 0:  log likelihood = -43.948619
    Iteration 1:  log likelihood = -43.891483
    Iteration 2:  log likelihood = -43.89144
    Iteration 3:  log likelihood = -43.89144
    Fitting full model:

    alpha           1.150553  .4817534  .5064026  2.61407
    Likelihood-ratio test of alpha=0:  chibar2(01) = 122.32  Prob>=chibar2 = 0.000
    . nbreg, coeflegend
                  Negative binomial regression                       Number of obs = 12
                  LR chi2(0) = 0.00
                  Dispersion = mean
                  Log likelihood = -43.89144
                  Pseudo R2 = 0.0000
                      Coef. Legend
    accidents _cons       2.627081  _b[accidents:_cons]
    /lnalpha        .1402425  _b[lnalpha:_cons]
    alpha           1.150553
    Likelihood-ratio test of alpha=0:  chibar2(01) = 122.32  Prob>=chibar2 = 0.000
```

From this output, we see that, when used with univariate data, `nbreg` estimates a regression intercept, $\beta_0$, and the logarithm of some parameter $\alpha$. This parameterization is useful in regression models: $\beta_0$ is the intercept meant to be augmented with other terms of the linear predictor, and $\alpha$ is an overdispersion parameter used for comparison with the Poisson regression model.

However, we need to transform $(\beta_0, \ln\alpha)$ to $(p, r)$. Examining Methods and formulas of [R] nbreg reveals the transformation as

$$p = \left\{1 + \alpha \exp(\beta_0)\right\}^{-1} \quad r = \alpha^{-1}$$

which we apply using `nlcom`:

```
```

```
Given the invariance of maximum likelihood estimators and the properties of the delta method, the above parameter estimates, standard errors, etc., are precisely those we would have obtained had we instead performed the Newton–Raphson optimization in the \((p, r)\) metric.

### Technical note

Note how we referred to the estimate of \(\ln \alpha\) above as \([\lnalpha\]_b[_cons]. This is not entirely evident from the output of \texttt{nbreg}, which is why we redisplayed the results using the \texttt{coeflegend} option so that we would know how to refer to the coefficients; [U] 13.5 Accessing coefficients and standard errors.

### nlcom versus eform

Many Stata estimation commands allow you to display exponentiated regression coefficients, some by default, some optionally. Known as “eform” in Stata terminology, this reparameterization serves many uses: it gives odds ratios for logistic models, hazard ratios in survival models, incidence-rate ratios in Poisson models, and relative-risk ratios in multinomial logit models, to name a few.

For example, consider the following estimation taken directly from the technical note in [R] \texttt{poisson}:

```stata
.use http://www.stata-press.com/data/r13/airline
.generate lnN = ln(n)
.poisson injuries XYZowned lnN
```

```
Iteration 0:  log likelihood = -22.333875
Iteration 1:  log likelihood = -22.332276
Iteration 2:  log likelihood = -22.332276
Poisson regression
Number of obs = 9
LR chi2(2) = 19.15
Prob > chi2 = 0.0001
Log likelihood = -22.332276 Pseudo R2 = 0.3001

|        | Coef.  | Std. Err. | z    | P>|z|    | [95% Conf. Interval] |
|--------|--------|-----------|------|--------|---------------------|
| injuries |        |           |      |        |                     |
| XYZowned | 0.6840667 | 0.3895877 | 1.76 | 0.079  | -0.0795111 1.447645 |
| lnN     | 1.424169 | 0.3725155 | 3.82 | 0.000  | .6940517 2.154285 |
| _cons   | 4.863891 | 0.7090501 | 6.86 | 0.000  | 3.474178 6.253603 |
```
When we replay results and specify the `irr` (incidence-rate ratios) option,

```
.poisson, irr
Poisson regression
```

we obtain the exponentiated regression coefficients and their estimated standard errors.

Contrast this with what we obtain if we exponentiate the coefficients manually by using `nlcom`:

```
.nlcom (E_XYZowned:exp(_b[XYZowned])) (E_lnN:exp(_b[lnN]))
```

| injuries  | IRR    | Std. Err. | z     | P>|z|    | [95% Conf. Interval] |
|-----------|--------|-----------|-------|--------|----------------------|
| XYZowned  | 1.981921 | .7721322 | 1.76  | 0.079  | .9235678 4.253085    |

| _cons     | 129.5272 | 91.84126 | 6.86  | 0.000  | 32.2713 519.8828     |

There are three things to note when comparing `poisson, irr` (and `eform` in general) with `nlcom`:

1. The exponentiated coefficients and standard errors are identical. This is certainly good news.
2. The Wald test statistic (z) and level of significance are different. When using `poisson, irr` and other related `eform` options, the Wald test does not change from what you would have obtained without the `eform` option, and you can see this by comparing both versions of the `poisson` output given previously.
3. You may be surprised to see that, even though the coefficients and standard errors are identical, the confidence intervals (both 95%) are different.
eform confidence intervals are standard confidence intervals with the endpoints transformed. For example, the confidence interval for the coefficient on $\ln N$ is [0.694, 2.154], whereas the confidence interval for the incidence-rate ratio due to $\ln N$ is $[\exp(0.694), \exp(2.154)] = [2.002, 8.619]$, which, except for some roundoff error, is what we see from the output of poisson, irr. For exponentiated coefficients, confidence intervals based on transform-the-endpoints methodology generally have better small-sample properties than their asymptotically equivalent counterparts.

The transform-the-endpoints method, however, gives valid coverage only when the transformation is monotonic. nlcom uses a more general and asymptotically equivalent method for calculating confidence intervals, as described in Methods and formulas.

### Stored results

nlcom stores the following in r():

**Scalars**
- r(N) number of observations
- r(df_r) residual degrees of freedom

**Matrices**
- r(b) vector of transformed coefficients
- r(V) estimated variance–covariance matrix of the transformed coefficients

If `post` is specified, nlcom also stores the following in e():

**Scalars**
- e(N) number of observations
- e(df_r) residual degrees of freedom
- e(N_strata) number of strata $L$, if used after `svy`
- e(N_psu) number of sampled PSUs $n$, if used after `svy`
- e(rank) rank of e(V)

**Macros**
- e(cmd) nlcom
- e(predict) program used to implement predict
- e(properties) b V

**Matrices**
- e(b) vector of transformed coefficients
- e(V) estimated variance–covariance matrix of the transformed coefficients
- e(V_srs) simple-random-sampling-without-replacement (co)variance $\hat{V}_{srs}$, if `svy`
- e(V_srsr) simple-random-sampling-with-replacement (co)variance $\hat{V}_{srsr}$, if `svy` and `fpc()`
- e(V_msp) misspecification (co)variance $\hat{V}_{msp}$, if `svy` and available

**Functions**
- e(sample) marks estimation sample

### Methods and formulas

Given a $1 \times k$ vector of parameter estimates, $\hat{\theta} = (\hat{\theta}_1, \ldots, \hat{\theta}_k)$, consider the estimated $p$-dimensional transformation

$$g(\hat{\theta}) = [g_1(\hat{\theta}), g_2(\hat{\theta}), \ldots, g_p(\hat{\theta})]$$

The estimated variance–covariance of $g(\hat{\theta})$ is given by

$$\hat{\text{Var}} \left\{ g(\hat{\theta}) \right\} = GVG'$$
where $G$ is the $p \times k$ matrix of derivatives for which

$$G_{ij} = \left. \frac{\partial g_i(\theta)}{\partial \theta_j} \right|_{\theta = \hat{\theta}} \quad i = 1, \ldots, p \quad j = 1, \ldots, k$$

and $V$ is the estimated variance–covariance matrix of $\hat{\theta}$. Standard errors are obtained as the square roots of the variances.

The Wald test statistic for testing $H_0: g_i(\theta) = 0$ versus the two-sided alternative is given by

$$Z_i = \frac{g_i(\hat{\theta})}{\sqrt{\text{Var} \{g_i(\hat{\theta})\}^{1/2}}}$$

When the variance–covariance matrix of $\hat{\theta}$ is an asymptotic covariance matrix, $Z_i$ is approximately distributed as Gaussian. For linear regression, $Z_i$ is taken to be approximately distributed as $t_1, r$ where $r$ is the residual degrees of freedom from the original fitted model.

A $(1 - \alpha) \times 100\%$ confidence interval for $g_i(\theta)$ is given by

$$g_i(\hat{\theta}) \pm z_{\alpha/2} \sqrt{\text{Var}^{1/2} \{g(\hat{\theta})\}}$$

for those cases where $Z_i$ is Gaussian and

$$g_i(\hat{\theta}) \pm t_{\alpha/2, r} \sqrt{\text{Var}^{1/2} \{g(\hat{\theta})\}}$$

for those cases where $Z_i$ is $t$ distributed. $z_p$ is the $1 - p$ quantile of the standard normal distribution, and $t_{p, r}$ is the $1 - p$ quantile of the $t$ distribution with $r$ degrees of freedom.

Syntax

Nested logit regression

\[
\text{nlogit } \text{depvar [indepvars] [if] [in] [weight] [|| lev1\_equation}
\]
\[
[|| lev2\_equation . . . ] || altvar: [byaltvarlist] , case(varname) [options]
\]

where the syntax of \text{lev\#\_equation} is

\[
altvar: [byaltvarlist] [ , base(# | lbl) estconst]
\]

Create variable based on specification of branches

\[
\text{nlogitgen newaltvar = altvar (branchlist) [ , nolog]}
\]

where \text{branchlist} is

\[
branch, branch [ , branch . . . ]
\]

and \text{branch} is

\[
[ label: ] alternative [ | alternative [ | alternative . . . ]]
\]

Display tree structure

\[
\text{nlogittree altvarlist [if] [in] [weight] [ , choice(depvar) nolabel nobranches]}
\]
nlogit — Nested logit regression

### Description

nlogit performs full information maximum-likelihood estimation for nested logit models. These models relax the assumption of independently distributed errors and the independence of irrelevant alternatives inherent in conditional and multinomial logit models by clustering similar alternatives into nests.

### Menu

**nlogit**

Statistics > Categorical outcomes > Nested logit regression

**nlogitgen**

Statistics > Categorical outcomes > Setup for nested logit regression

**nlogittree**

Statistics > Categorical outcomes > Display nested logit tree structure
By default, nlogit uses a parameterization that is consistent with random utility maximization (RUM). Before version 10 of Stata, a nonnormalized version of the nested logit model was fit, which you can request by specifying the nonnormalized option.

You must use nlogitgen to generate a new categorical variable to specify the branches of the decision tree before calling nlogit.

Options

Specification and options for lev#_equation

altvar is a variable identifying alternatives at this level of the hierarchy.

byaltvarlist specifies the variables to be used to compute the by-alternative regression coefficients for that level. For each variable specified in the variable list, there will be one regression coefficient for each alternative of that level of the hierarchy. If the variable is constant across each alternative (a case-specific variable), the regression coefficient associated with the base alternative is not identifiable. These regression coefficients are labeled as (base) in the regression table. If the variable varies among the alternatives, a regression coefficient is estimated for each alternative.

base(#) can be specified in each level equation where it identifies the base alternative to be used at that level. The default is the alternative that has the highest frequency.

If vce(bootstrap) or vce(jackknife) is specified, you must specify the base alternative for each level that has a byaltvarlist or if the constants will be estimated. Doing so ensures that the same model is fit with each call to nlogit.

estconst applies to all the level equations except the bottom-level equation. Specifying estconst requests that constants for each alternative (except the base alternative) be estimated. By default, no constant is estimated at these levels. Constants can be estimated in only one level of the tree hierarchy. If you specify estconst for one of the level equations, you must specify noconstant for the bottom-level equation.

Options for nlogit

Model

case(varname) specifies the variable that identifies each case. case() is required.

base(#) can be specified in each level equation where it identifies the base alternative to be used at that level. The default is the alternative that has the highest frequency.

If vce(bootstrap) or vce(jackknife) is specified, you must specify the base alternative for each level that has a byaltvarlist or if the constants will be estimated. Doing so ensures that the same model is fit with each call to nlogit.

noconstant applies only to the equation defining the bottom level of the hierarchy. By default, constants are estimated for each alternative of altvar, less the base alternative. To suppress the constant terms for this level, specify noconstant. If you do not specify noconstant, you cannot specify estconst for the higher-level equations.

nonnormalized requests a nonnormalized parameterization of the model that does not scale the inclusive values by the degree of dissimilarity of the alternatives within each nest. Use this option to replicate results from older versions of Stata. The default is to use the RUM–consistent parameterization.
altwise specifies that alternativewise deletion be used when marking out observations because of missing values in your variables. The default is to use casewise deletion. This option does not apply to observations that are marked out by the if or in qualifier or the by prefix.

constraints(constraints); see [R] estimation options.

The inclusive-valued/dissimilarity parameters are parameterized as $ml$ ancillary parameters. They are labeled as $[\text{alternative}_{-}\tau]\_\text{const}$, where alternative is one of the alternatives defining a branch in the tree. To constrain the inclusive-valued/dissimilarity parameter for alternative $a_1$ to be, say, equal to alternative $a_2$, you would use the following syntax:

```
. constraint 1 [a1_tau]_cons = [a2_tau]_cons
. nlogit ..., constraints(1)
```

collinear prevents collinear variables from being dropped. Use this option when you know that you have collinear variables and you are applying constraints() to handle the rank reduction. See [R] estimation options for details on using collinear with constraints().

nlogit will not allow you to specify an independent variable in more than one level equation. Specifying the collinear option will allow execution to proceed in this case, but it is your responsibility to ensure that the parameters are identified.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

If vce(robust) or vce(cluster clustvar) is specified, the likelihood-ratio test for the independence of irrelevant alternatives (IIA) is not computed.

level(#) ; see [R] estimation options.

notree specifies that the tree structure of the nested logit model not be displayed. See also nolabel and nobranches below for when notree is not specified.

colnsreport; see [R] estimation options.

display_options: cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no] log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

The technique(bhhh) option is not allowed.

**Specification and options for nlogitgen**

newaltvar and altvar are variables identifying alternatives at each level of the hierarchy.

label defines a label to associate with the branch. If no label is given, a numeric value is used.
alternative specifies an alternative, of altvar specified in the syntax, to be included in the branch. It is either a numeric value or the label associated with that value. An example of nlogitgen is

```
. nlogitgen type = restaurant(fast: 1 | 2,
> family: CafeEccell | LosNortenos | WingsNmore, fancy: 6 | 7)
```

nolog suppresses the display of the iteration log.

### Specification and options for nlogittree

altvarlist is a list of alternative variables that define the tree hierarchy. The first variable must define bottom-level alternatives, and the order continues to the variable defining the top-level alternatives.

choice(depvar) defines the choice indicator variable and forces nlogittree to compute and display choice frequencies for each bottom-level alternative.

nolabel forces nlogittree to suppress value labels in tree-structure output.

nobranches forces nlogittree to suppress drawing branches in the tree-structure output.

### Remarks and examples

Remarks are presented under the following headings:

- **Introduction**
- Data setup and the tree structure
- Estimation
- Testing for the IIA
- Nonnormalized model

#### Introduction

nlogit performs full information maximum-likelihood estimation for nested logit models. These models relax the assumption of independently distributed errors and the IIA inherent in conditional and multinomial logit models by clustering similar alternatives into nests. Because the nested logit model is a direct generalization of the alternative-specific conditional logit model (also known as McFadden’s choice model), you may want to read [R] asclogit before continuing.

By default, nlogit uses a parameterization that is consistent with RUM. Before version 10 of Stata, a nonnormalized version of the nested logit model was fit, which you can request by specifying the nonnormalized option. We recommend using the RUM-consistent version of the model for new projects because it is based on a sound model of consumer behavior.

McFadden (1977, 1981) showed how this model can be derived from a rational choice framework. Amemiya (1985, chap. 9) contains a nice discussion of how this model can be derived under the assumption of utility maximization. Hensher, Rose, and Greene (2005) provide a lucid introduction to choice models including nested logit.

Throughout this entry, we consider a model of restaurant choice. We begin by introducing the data.
Example 1

We have fictional data on 300 families and their choice of seven local restaurants. Freebirds and Mama’s Pizza are fast food restaurants; Café Eccell, Los Norteños, and Wings ’N More are family restaurants; and Christopher’s and Mad Cows are fancy restaurants. We want to model the decision of where to eat as a function of household income (\textit{income}, in thousands of dollars), the number of children in the household (\textit{kids}), the rating of the restaurant according to a local restaurant guide (\textit{rating}, coded 0–5), the average meal cost per person (\textit{cost}), and the distance between the household and the restaurant (\textit{distance}, in miles). \textit{Income} and \textit{kids} are attributes of the family, \textit{rating} is an attribute of the alternative (the restaurant), and \textit{cost} and \textit{distance} are attributes of the alternative as perceived by the families—that is, each family has its own cost and distance for each restaurant.

We begin by loading the data and listing some of the variables for the first three families:

```
. use http://www.stata-press.com/data/r13/restaurant
. describe

Contains data from http://www.stata-press.com/data/r13/restaurant.dta

</table>

Because each family chose among seven restaurants, there are 7 observations in the dataset for each family. The variable `chosen` is coded 0/1, with 1 indicating the chosen restaurant and 0 otherwise.

We could fit a conditional logit model to our data. Because `income` and `kids` are constant within each family, we would use the `asclogit` command instead of `clogit`. However, the conditional logit may be inappropriate. That model assumes that the random errors are independent, and as a result it forces the odds ratio of any two alternatives to be independent of the other alternatives, a property known as the IIA. We will discuss the IIA assumption in more detail later.

Assuming that unobserved shocks influencing a decision maker’s attitude toward one alternative have no effect on his attitudes toward the other alternatives may seem innocuous, but often this assumption is too restrictive. Suppose that when a family was deciding which restaurant to visit, they were pressed for time because of plans to attend a movie later. The unobserved shock (being in a hurry) would raise the likelihood that the family goes to either fast food restaurant (Freebirds or Mama’s Pizza). Similarly, another family might be choosing a restaurant to celebrate a birthday and therefore be inclined to attend a fancy restaurant (Christopher’s or Mad Cows).

Nested logit models relax the independence assumption and allow us to group alternatives for which unobserved shocks may have concomitant effects. Here we suspect that restaurants should be grouped by type (fast, family, or fancy). The tree structure of a family’s decision about where to eat might look like this:
At the bottom of the tree are the individual restaurants, indicating that there are some random shocks that affect a family’s decision to eat at each restaurant independently. Above the restaurants are the three types of restaurants, indicating that other random shocks affect the type of restaurant chosen. As is customary when drawing decision trees, at the top level is one box, representing the family making the decision.

We use the following terms to describe nested logit models.

*level*, or decision level, is the level or stage at which a decision is made. The example above has only two levels. In the first level, a type of restaurant is chosen—fast food, family, or fancy—and in the second level, a specific restaurant is chosen.

*bottom level* is the level where the final decision is made. In our example, this is when we choose a specific restaurant.

*alternative set* is the set of all possible alternatives at any given decision level.

*bottom alternative set* is the set of all possible alternatives at the bottom level. This concept is often referred to as the choice set in the economics-choice literature. In our example, the bottom alternative set is all seven of the specific restaurants.

*alternative* is a specific alternative within an alternative set. In the first level of our example, “fast food” is an alternative. In the second or bottom level, “Mad Cows” is an alternative. Not all alternatives within an alternative set are available to someone making a choice at a specific stage, only those that are nested within all higher-level decisions.

*chosen alternative* is the alternative from an alternative set that we observe someone having chosen.

**Technical note**

Although decision trees in nested logit analysis are often interpreted as implying that the highest-level decisions are made first, followed by decisions at lower levels, and finally the decision among alternatives at the bottom level, no such temporal ordering is implied. See Hensher, Rose, and Greene (2005, chap. 13). In our example, we are not assuming that families first choose whether to attend a fast, family, or fancy restaurant and then choose the particular restaurant; we assume merely that they choose one of the seven restaurants.
Data setup and the tree structure

To fit a nested logit model, you must first create a variable that defines the structure of your decision tree.

Example 2

To run nlogit, we need to generate a categorical variable that identifies the first-level set of alternatives: fast food, family restaurants, or fancy restaurants. We can do so easily by using nlogitgen.

```
. nlogitgen type = restaurant(fast: Freebirds | Mama'sPizza, family: CafeEccell | LosNortenos| WingsNmore, fancy: Christophers | MadCows)
new variable type is generated with 3 groups
label list lb_type
lb_type:
  1 fast
  2 family
  3 fancy
. nlogittree restaurant type, choice(chosen)
tree structure specified for the nested logit model

<table>
<thead>
<tr>
<th>type</th>
<th>N</th>
<th>restaurant</th>
<th>N</th>
<th>k</th>
</tr>
</thead>
<tbody>
<tr>
<td>fast</td>
<td>600</td>
<td>Freebirds</td>
<td>300</td>
<td>12</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Mama'sPizza</td>
<td>300</td>
<td>15</td>
</tr>
<tr>
<td>family</td>
<td>900</td>
<td>CafeEccell</td>
<td>300</td>
<td>78</td>
</tr>
<tr>
<td></td>
<td></td>
<td>LosNortenos</td>
<td>300</td>
<td>75</td>
</tr>
<tr>
<td></td>
<td></td>
<td>WingsNmore</td>
<td>300</td>
<td>69</td>
</tr>
<tr>
<td>fancy</td>
<td>600</td>
<td>Christophers</td>
<td>300</td>
<td>27</td>
</tr>
<tr>
<td></td>
<td></td>
<td>MadCows</td>
<td>300</td>
<td>24</td>
</tr>
</tbody>
</table>
```

k = number of times alternative is chosen
N = number of observations at each level

The new categorical variable is type, which takes on value 1 (fast) if restaurant is Freebirds or Mama’s Pizza; value 2 (family) if restaurant is Café Eccell, Los Nortenos, or Wings ’N More; and value 3 (fancy) otherwise. nlogittree displays the tree structure.

Technical note

We could also use values instead of value labels of restaurant in nlogitgen. Value labels are optional, and the default value labels for type are type1, type2, and type3. The vertical bar is also optional.

```
. use http://www.stata-press.com/data/r13/restaurant, clear
. nlogitgen type = restaurant(1 2, 3 4 5, 6 7)
new variable type is generated with 3 groups
label list lb_type
lb_type:
  1 type1

N = number of observations at each level

In our dataset, every family was able to choose among all seven restaurants. However, in other applications some decision makers may not have been able to choose among all possible alternatives. For example, two cases may have choice hierarchies of

</table>

where the second case does not have the restaurant alternatives Café Eccell or Mad Cows available to them. The only restriction is that the relationships between higher- and lower-level alternative sets be the same for all decision makers. In this two-level example, Freebirds and Mama’s Pizza are classified as fast food restaurants for both cases; Café Eccell, Los Norteños, and Wings ’N More are family restaurants; and Christopher’s and Mad Cows are fancy restaurants. nlogit requires only that hierarchy be maintained for all cases.

Estimation

Example 3

With our type variable created that defines the three types of restaurants, we can now examine how the alternative-specific attributes (cost, rating, and distance) apply to the bottom alternative set (the seven restaurants) and how family-specific attributes (income and kid) apply to the alternative set at the first decision level (the three types of restaurants).

LR test for IIA (tau = 1):  chi2(3) = 6.87  Prob > chi2 = 0.0762
First, let’s examine how we called \texttt{nlogit}. The delimiters (|) separate equations. The first equation specifies the dependent variable, \texttt{chosen}, and three alternative-specific variables, \texttt{cost}, \texttt{rating}, and \texttt{distance}. We refer to these variables as alternative-specific because they vary among the bottom-level alternatives, the restaurants. We obtain one parameter estimate for each variable. These estimates are listed in the equation subtable labeled \texttt{restaurant}.

For the second equation, we specify the \texttt{type} variable. It identifies the first-level alternatives, the restaurant types. Following the colon after \texttt{type}, we specify two case-specific variables, \texttt{income} and \texttt{kids}. Here we obtain a parameter estimate for each variable for each alternative at this level. That is why we call these variable lists \texttt{by-alternative} variables. Because \texttt{income} and \texttt{kids} do not vary within each case, to identify the model one alternative’s set of parameters must be set to zero. We specified the \texttt{base(family)} option with this equation to restrict the parameters for the family alternative.

The variable identifying the bottom-level alternatives, \texttt{restaurant}, is specified after the second equation delimiter. We do not specify any variables after the colon delimiter at this level. Had we specified variables here, we would have obtained an estimate for each variable in each equation. As we will see below, these variables parameterize the constant term in the utility equation for each bottom-level alternative. The \texttt{noconstant} option suppresses bottom-level alternative-specific constant terms.

Near the bottom of the output are the dissimilarity parameters, which measure the degree of correlation of random shocks within each of the three types of restaurants. Dissimilarity parameters greater than one imply that the model is inconsistent with RUM; Hensher, Rose, and Greene (2005, sec. 13.6) discuss this in detail. We will ignore the fact that all our dissimilarity parameters exceed one.

The conditional logit model is a special case of nested logit in which all the dissimilarity parameters are equal to one. At the bottom of the output, we find a likelihood-ratio test of this hypothesis. Here we have mixed evidence of the null hypothesis that all the parameters are one. Equivalently, the property known as the IIA imposed by the conditional logit model holds if and only if all dissimilarity parameters are equal to one. We discuss the IIA in more detail now.

\section*{Testing for the IIA}

The IIA is a property of the multinomial and conditional logit models that forces the odds of choosing one alternative over another to be independent of the other alternatives. For simplicity, suppose that a family was choosing only between Freebirds and Mama’s Pizza, and the family was equally likely to choose either of the restaurants. The probability of going to each restaurant is 50%. Now suppose that Bill’s Burritos opens up next door to Freebirds, which is also a burrito restaurant. If the IIA holds, then the probability of going to each restaurant must now be 33.33% so that the family remains equally likely to go to Mama’s Pizza or Freebirds.

The IIA may sometimes be a plausible assumption. However, a more likely scenario would be for the probability of going to Mama’s Pizza to remain at 50% and the probabilities of going to Freebirds and Bill’s Burritos to be 25% each, because the two restaurants are next door to each other and serve the same food. Nested logit analysis would allow us to relax the IIA assumption of conditional logit. We could group Bill’s Burritos and Freebirds into one nest that encompasses all burrito restaurants and create a second nest for pizzerias.

The IIA is a consequence of assuming that the errors are independent and identically distributed (i.i.d.). Because the errors are i.i.d., they cannot contain any alternative-specific unobserved information, and therefore adding a new alternative cannot affect the relationship between a pair of existing alternatives.
In the previous example, we saw that a joint test that the dissimilarity parameters were equal to one is one way to test for IIA. However, that test required us to specify a decision tree for the nested logit model, and different specifications could lead to conflicting results of the test. Hausman and McFadden (1984) suggest that if part of the choice set truly is irrelevant with respect to the other alternatives, omitting that subset from the conditional logit model will not lead to inconsistent estimates. Therefore, Hausman’s (1978) specification test can be used to test for IIA, and this test will not be sensitive to the tree structure we specify for a nested logit model.

Example 4

We want to test the IIA for the subset of family restaurants against the alternatives of fast food and fancy restaurants. To do so, we need to use Stata’s `hausman` command; see [R] `hausman`.

We first run the estimation on the full bottom alternative set, store the results by using `estimates store`, and then run the estimation on the bottom alternative set, excluding the alternatives of family restaurants. We then run the `hausman` test.

 kidFast| .4105386   .2137051   1.92  0.055  -.0083157  .8293928
```
Similar to our findings in example 3, the results of the test of the IIA are mixed. We cannot reject the IIA at the commonly used 5% significance level, but we could at the 10% level. Substantively, a significant test result suggests that the odds of going to one of the fancy restaurants versus going to one of the fast food restaurants changes if we include the family restaurants in the alternative set and that a nested logit specification may be warranted.

Nonnormalized model

Previous versions of Stata fit a nonnormalized nested logit model that is available via the nonnormalized option. The nonnormalized version is presented in, for example, Greene (2012, 768–770). Here we outline the differences between the RUM-consistent and nonnormalized models. Our discussion follows Heiss (2002) and assumes the decision tree has two levels, with $M$ alternatives at the upper level and a total of $J$ alternatives at the bottom level.

In a RUM framework, by consuming alternative $j$, decision maker $i$ obtains utility

$$U_{ij} = V_{ij} + \epsilon_{ij} = \alpha_j + x_{ij}\beta_j + z_i\gamma_j + \epsilon_{ij}$$

where $V_{ij}$ is the deterministic part of utility and $\epsilon_{ij}$ is the random part. $x_{ij}$ are alternative-specific variables and $z_i$ are case-specific variables. The set of errors $\epsilon_{i1}, \ldots, \epsilon_{iJ}$ are assumed to follow the generalized extreme-value (GEV) distribution, which is a generalization of the type 1 extreme-value distribution that allows for alternatives within nests of the tree structure to be correlated. Let $\rho_m$ denote the correlation in nest $m$, and define the dissimilarity parameter $\tau_m = \sqrt{1 - \rho_m}$. $\tau_m = 0$ implies that the alternatives in nest $m$ are perfectly correlated, whereas $\tau_m = 1$ implies independence.

The inclusive value for the $m$th nest corresponds to the expected value of the utility that decision maker $i$ obtains by consuming an alternative in nest $m$. Denote this value by $IV_m$:

$$IV_m = \ln \sum_{j \in B_m} \exp \left( \frac{V_k}{\tau_m} \right)$$

where $B_m$ denotes the set of alternatives in nest $m$. Given the inclusive values, we can show that the probability that random-utility–maximizing decision maker $i$ chooses alternative $j$ is

$$Pr_j = \frac{\exp \left\{ \frac{V_j}{\tau(j)} \right\} \exp \left\{ \tau(j)IV(j) \right\}}{\sum_m \exp \left( \tau_m IV_m \right)}$$
where $\tau(j)$ and $IV(j)$ are the dissimilarity parameter and inclusive value for the nest in which alternative $j$ lies.

In contrast, for the nonnormalized model, we have a latent variable

$$\tilde{V}_{i,j} = \tilde{\alpha}_j + x_{i,j}\tilde{\beta}_j + z_i\tilde{\gamma}_j$$

and corresponding inclusive values

$$\tilde{IV}_m = \ln \sum_{j \in B_m} \exp (\tilde{V}_k)$$

(2)

The probability of choosing alternative $j$ is

$$Pr_j = \frac{\exp (\tilde{V}_j)}{\exp \{\tilde{IV}(j)\} \sum_m \exp (\tau_m \tilde{IV}_m)}$$

Equations (1) and (2) represent the key difference between the RUM-consistent and nonnormalized models. By scaling the $V_{ij}$ within each nest, the RUM-consistent model allows utilities to be compared across nests. Without the rescaling, utilities can be compared only for goods within the same nest. Moreover, adding a constant to each $V_{ij}$ for consumer $i$ will not affect the probabilities of the RUM-consistent model, but adding a constant to each $\tilde{V}_{ij}$ will affect the probabilities from the nonnormalized model. Decisions based on utility maximization can depend only on utility differences and not the scale or zero point of the utility function because utility is an ordinal concept, so the nonnormalized model cannot be consistent with utility maximization.

Heiss (2002) showed that the nonnormalized model can be RUM consistent in the special case where all the variables are specified in the bottom-level equation. Then multiplying the nonnormalized coefficients by the respective dissimilarity parameters results in the RUM-consistent coefficients.

**Technical note**

Degenerate nests occur when there is only one alternative in a branch of the tree hierarchy. The associated dissimilarity parameter of the RUM model is not defined. The inclusive-valued parameter of the nonnormalized model will be identifiable if there are alternative-specific variables specified in (1) of the model specification (the `indepvars` in the model syntax). Numerically, you can skirt the issue of nonidentifiable/undefined parameters by setting constraints on them. For the RUM model constraint, set the dissimilarity parameter to 1. See the description of `constraints()` in `Options` for details on setting constraints on the dissimilarity parameters.

Methods and formulas

Methods and formulas are presented under the following headings:

Two-level nested logit model
Three-level nested logit model
Two-level nested logit model

Consider our two-level nested logit model for restaurant choice. We define \( T = \{1, 2, 3\} \) to be the set of indices denoting the three restaurant types and \( R_1 = \{1, 2\} \), \( R_2 = \{3, 4, 5\} \), and \( R_3 = \{6, 7\} \) to be the set of indices representing each restaurant within type \( t \in T \). Let \( C_1 \) and \( C_2 \) be the random variables that represent the choices made for the first level, restaurant type, and second level, restaurant, of the hierarchy, where we observe the choices \( C_1 = t, t \in T \), and \( C_2 = j, j \in R_t \). Let \( z_t \) and \( x_{tj} \), for \( t \in T \) and \( j \in R_t \), refer to the row vectors of explanatory variables for the first-level alternatives and bottom-level alternatives for one case, respectively. We write the utilities \((\text{latent variables})\) as first-level alternatives and bottom-level alternatives for one case, respectively. We write the utilities \((\text{latent variables})\) as

\[
F_{R|T}(\epsilon | t) = \exp \left[ - \left\{ \sum_{m \in R_t} \exp(\epsilon_{tm} / \tau_t) \right\} \tau_t \right] \tag{3}
\]

where it has been shown that the \( \epsilon_{tj}, j \in R_t, \) are exchangeable with correlation \( 1 - \tau_t^2 \), for \( \tau_t \in (0, 1] \) \((\text{Kotz and Nadarajah 2000})\). For example, the probability of choosing Christopher’s, \( j = 6 \) given type \( t = 3 \), is

\[
\Pr(C_2 = 6 | C_1 = 3) = \Pr(U_{36} - U_{37} > 0) = \Pr(\epsilon_{36} \leq \epsilon_{36} + \eta_{36} - \eta_{37}) = \int_{-\infty}^{\infty} \left\{ \int_{-\infty}^{\epsilon_{36} + \eta_{36} - \eta_{37}} f_{R|T}(\epsilon_{36}, \epsilon_{37}) \, d\epsilon_{37} \right\} \, d\epsilon_{36}
\]

where \( f = \frac{\partial F}{\partial \epsilon_{36} \partial \epsilon_{37}} \) is the joint density function of \( \epsilon \) given \( t \). \( U_{37} \) is the utility of eating at Mad Cows, the other fancy \((t = 3)\) restaurant. Amemiya \((1985)\) demonstrates that this integral evaluates to the logistic function

\[
\Pr(C_2 = 6 | C_1 = 3) = \frac{\exp(\eta_{36} / \tau_3)}{\exp(\eta_{36} / \tau_3) + \exp(\eta_{37} / \tau_3)} = \frac{\exp(x_{36}\beta_6 / \tau_3)}{\exp(x_{36}\beta_6 / \tau_3) + \exp(x_{37}\beta_7 / \tau_3)}
\]

and in general

\[
\Pr(C_2 = j | C_1 = t) = \frac{\exp(x_{tj}\beta_j / \tau_t)}{\sum_{m \in R_t} \exp(x_{tm}\beta_m / \tau_t)} \tag{4}
\]

Letting \( \tau_t = 1 \) in (3) reduces to the product of independent extreme-value distributions, and (4) reduces to the multinomial logistic function.

For the logistic function in (4), we scale the linear predictors by the dissimilarity parameters. Another formulation of the conditional probability of choosing alternative \( j \in R_t \) given choice \( t \in T \) is the logistic function without this normalization:
Pr(C_2 = j | C_1 = t) = \frac{\exp(x_{tj}\beta_j)}{\sum_{m \in R_t} \exp(x_{tm}\beta_m)}

and this is what is used in nlogit’s nonnormalized parameterization.

Amemiya (1985) defines the general form for the joint distribution of the \(\epsilon\)'s as

\[ F_{T,R}(\epsilon) = \exp \left\{ -\sum_{k \in T} \theta_k \left( \sum_{m \in R_k} \exp(-\epsilon_{km}/\tau_k) \right)^{\tau_k} \right\} \]

from which the probability of choice \(t, t \in T\) can be derived as

\[ \Pr(C_1 = t) = \frac{\theta_t \left( \sum_{m \in R_t} \exp(\eta_{tm}/\tau_t) \right)^{\tau_t}}{\sum_{k \in T} \theta_k \left( \sum_{m \in R_k} \exp(\eta_{km}/\tau_k) \right)^{\tau_k}} \]

(5)

nlogit sets \(\theta_t = 1\). Noting that

\[ \left\{ \sum_{m \in R_t} \exp(\eta_{tm}/\tau_t) \right\}^{\tau_t} = \left\{ \sum_{m \in R_t} \exp \left( \frac{z_t\alpha_t + x_{tm}\beta_m}{\tau_t} \right) \right\}^{\tau_t} = \exp(z_t\alpha_t) \left\{ \sum_{m \in R_t} \exp \left( x_{tm}\beta_m/\tau_t \right) \right\}^{\tau_t} = \exp(z_t\alpha_t + \tau_t I_t) \]

we define the inclusive values \(I_t\) as

\[ I_t = \ln \left\{ \sum_{m \in R_t} \exp(x_{tm}\beta_m/\tau_t) \right\} \]

and we can view

\[ \exp(\tau_t I_t) = \left\{ \sum_{m \in R_t} \exp(x_{tm}\beta_m)^{1/\tau_t} \right\}^{\tau_t} \]

as a weighted average of the \(\exp(x_{tm}\beta_m)\), for \(m \in R_t\). For the nlogit RUM parameterization, we can express (5) as

\[ \Pr(C_1 = t) = \frac{\exp(z_t\alpha_t + \tau_t I_t)}{\sum_{k \in T} \exp(z_k\alpha_k + \tau_k I_k)} \]

Next we define inclusive values for the nonnormalized model to be

\[ \tilde{I}_t = \ln \left\{ \sum_{m \in R_t} \exp(x_{tm}\beta_m) \right\} \]

and we express \(\Pr(C_1 = t)\) as

\[ \Pr(C_1 = t) = \frac{\exp(z_t\alpha_t + \tau_t \tilde{I}_t)}{\sum_{k \in T} \exp(z_k\alpha_k + \tau_k \tilde{I}_k)} \]

(6)
Equation (5) is consistent with (6) only when \( \eta_{ij} = x_{ij} \beta_j \), so in general the nlogit nonnormalized model is not consistent with the RUM model.

Now assume that we have \( N \) cases where we add a third subscript, \( i \), to denote case \( i, i = 1, \ldots, N \). Denote \( y_{itj} \) to be a binary variable indicating the choice made by case \( i \) so that for each \( i \) only one \( y_{itj} \) is 1 and the rest are 0 for all \( t \in T \) and \( j \in R_t \). The log likelihood for the two-level RUM-consistent model is

\[
\log \ell = \sum_{i=1}^{N} \sum_{k \in T} \sum_{m \in R_k} y_{itj} \log \{ \Pr(C_{i1} = k) \Pr(C_{i2} = m | C_{i1} = k) \} \\
= \sum_{i=1}^{N} \sum_{k \in T} \sum_{m \in R_k} y_{itj} \left[ z_{ik} \alpha_k + \tau_k I_{ik} - \log \left\{ \sum_{l \in T} \exp(z_{il} \alpha_l + \tau_l I_{il}) \right\} \right] + x_{itj} \beta_m / \tau_k - \log \left\{ \sum_{l \in R_k} \exp(x_{ikl} \beta_l / \tau_k) \right\}
\]

The likelihood for the nonnormalized model has a similar form, replacing \( I \) with \( \tilde{I} \) and by not scaling \( x_{ikj} \beta_j \) by \( \tau_k \).

**Three-level nested logit model**

Here we define a three-level nested logit model that can be generalized to the four-level and higher models. As before, let the integer set \( T \) be the indices for the first level of choices. Let sets \( S_t, t \in T \), be mutually exclusive sets of integers representing the choices of the second level of the hierarchy. Finally, let \( R_j, j \in S_t \), be the bottom-level choices. Let \( U_{tjk} = \eta_{tjk} + \epsilon_{tjk}, k \in R_j \), and the distribution of \( \epsilon_{tjk} \) be Gumbel’s multivariate extreme value of the form

\[
F(\epsilon) = \exp \left( -\sum_{t \in T} \left[ \sum_{j \in S_t} \left\{ \sum_{k \in R_j} \exp(-\eta_{tjk}/\tau_j) \right\}^{\tau_j/\upsilon_t} \right]^{\upsilon_j} \right)
\]

Let \( C_1, C_2, \) and \( C_3 \) represent the choice random variables for levels 1, 2, and the bottom, respectively. Then the set of conditional probabilities is

\[
\Pr(C_3 = k | C_1 = t, C_2 = j) = \frac{\exp(\eta_{tjk}/\tau_j)}{\sum_{l \in R_j} \exp(\eta_{tjl}/\tau_j)}
\]

\[
\Pr(C_2 = j | C_1 = t) = \left\{ \sum_{k \in R_j} \exp(\eta_{tjk}/\tau_j) \right\}^{\tau_j/\upsilon_t} \frac{\sum_{l \in S_t} \left\{ \sum_{k \in R_l} \exp(\eta_{tlk}/\tau_l) \right\}^{\tau_l/\upsilon_t}}{\sum_{l \in S_t} \left\{ \sum_{k \in R_l} \exp(\eta_{tlk}/\tau_l) \right\}^{\tau_l/\upsilon_t}}
\]

\[
\Pr(C_1 = t) = \left[ \sum_{j \in S_t} \left\{ \sum_{k \in R_j} \exp(\eta_{tjk}/\tau_j) \right\}^{\tau_j/\upsilon_t} \right]^{\upsilon_t} \frac{\sum_{j \in S_t} \left\{ \sum_{k \in R_j} \exp(\eta_{tjk}/\tau_j) \right\}^{\tau_j/\upsilon_t}}{\sum_{l \in T} \left[ \sum_{j \in S_t} \left\{ \sum_{k \in R_j} \exp(\eta_{tjk}/\tau_j) \right\}^{\tau_j/\upsilon_t} \right]^{\upsilon_t}}
\]
Assume that we can decompose the linear predictor as \( \eta_{tjk} = z_t \alpha_t + u_{tj} \gamma_j + x_{tjk} \beta_k \). Here \( z_t \), \( u_{tj} \), and \( x_{tjk} \) are the row vectors of explanatory variables for the first, second, and bottom levels of the hierarchy, respectively, and \( \alpha_t \), \( \gamma_j \), and \( \beta_k \) are the corresponding column vectors of regression coefficients for \( t \in T, j \in S_t \), and \( k \in R_j \). We then can define the inclusive values for the first and second levels as

\[
I_{tj} = \log \sum_{k \in R_j} \exp(x_{tjk} \beta_k / \tau_j)
\]

\[
J_t = \log \sum_{j \in S_t} \exp(u_{tj} \gamma_j / v_t + \tau_j I_{tj})
\]

and rewrite the probabilities

\[
Pr(C_3 = k | C_1 = t, C_2 = j) = \frac{\exp(x_{tjk} \beta_k / \tau_j)}{\sum_{l \in R_j} \exp(x_{tjl} \beta_l / \tau_j)}
\]

\[
Pr(C_2 = j | C_1 = t) = \frac{\exp(u_{tj} \gamma_j / v_t + \tau_j I_{tj})}{\sum_{l \in S_t} \exp(u_{tl} \gamma_l / v_l + \tau_l I_{tl})}
\]

\[
Pr(C_1 = t) = \frac{\exp(z_t \alpha_t + v_t I_t)}{\sum_{l \in T} \exp(z_l \alpha_l + v_l I_l)}
\]

We add a fourth index, \( i \), for case and define the indicator variable \( y_{itjk}, i = 1, \ldots, N \), to indicate the choice made by case \( i \), \( t \in T, j \in S_t \), and \( k \in R_j \). The log likelihood for the \texttt{nlogit} RUM-consistent model is

\[
\ell = \sum_{i=1}^{N} \sum_{t \in T} \sum_{j \in S_t} \sum_{k \in R_j} y_{itjk} \left\{ z_{it} \alpha_t + v_t J_{it} - \log \left( \sum_{m \in T} z_{im} \alpha_m + v_m J_{im} \right) + u_{itj} \gamma_j/v_t + \tau_j I_{itj} - \log \left( \sum_{m \in S_t} u_{itm} \gamma_m/v_t + \tau_m I_{itm} \right) + x_{itjk} \beta_k/\tau_k - \sum_{m \in R_t} \exp(x_{itjm} \beta_m/\tau_k) \right\}
\]

and for the nonnormalized \texttt{nlogit} model the log likelihood is

\[
\ell = \sum_{i=1}^{N} \sum_{t \in T} \sum_{j \in S_t} \sum_{k \in R_j} y_{itjk} \left\{ z_{it} \alpha_t + v_t J_{it} - \log \left( \sum_{m \in T} z_{im} \alpha_m + v_m J_{im} \right) + u_{itj} \gamma_j + \tau_j I_{itj} - \log \left( \sum_{m \in S_t} u_{itm} \gamma_m + \tau_m I_{itm} \right) + x_{itjk} \beta_k - \sum_{m \in R_t} \exp(x_{itjm} \beta_m) \right\}
\]

Extending the model to more than three levels is straightforward, albeit notationally cumbersome.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \texttt{[P] _robust}, particularly \texttt{Maximum likelihood estimators} and \texttt{Methods and formulas}.

### Description

The following postestimation command is of special interest after `nlogit`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat alternatives</code></td>
<td>alternative summary statistics</td>
</tr>
</tbody>
</table>

The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat ic</code></td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td><code>estat summarize</code></td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>hausman</code></td>
<td>Hausman’s specification test</td>

<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

### Special-interest postestimation command

`estat alternatives` displays summary statistics about the alternatives in the estimation sample for each level of the tree structure.
Syntax for predict

```
predict [type] newvar [if] [in] [ , statistic hlevel(#) altwise]
```

```
predict [type] { stub* | newvarlist } [if] [in], scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Main</strong></td>
<td></td>
</tr>
<tr>
<td>pr</td>
<td>predicted probabilities of choosing the alternatives at all levels of the hierarchy or at level #, where # is specified by hlevel(#)(^{1}): the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear predictors for all levels of the hierarchy or at level #, where # is specified by hlevel(#)</td>
</tr>
<tr>
<td>condp</td>
<td>predicted conditional probabilities at all levels of the hierarchy or at level #, where # is specified by hlevel(#)</td>
</tr>
<tr>
<td>iv</td>
<td>inclusive values for levels 2, ..., e(levels)(^{2}) or for hlevel(#)</td>
</tr>
</tbody>
</table>

\(^{1}\)hlevel(#) calculates the prediction only for hierarchy level #.

\(^{2}\)The inclusive value for the first-level alternatives is not used in estimation; therefore, it is not calculated.

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

<table>
<thead>
<tr>
<th><strong>Main</strong></th>
<th>pr calculates the probability of choosing each alternative at each level of the hierarchy. Use the hlevel(#) option to compute the alternative probabilities at level #. When hlevel(#) is not specified, (j) new variables must be given, where (j) is the number of levels, or use the stub* option to have predict generate (j) variables with the prefix stub and numbered from 1 to (j). The pr option is the default and if one new variable is given, the probability of the bottom-level alternatives are computed. Otherwise, probabilities for all levels are computed and the stub* option is still valid.</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>xb calculates the linear prediction for each alternative at each level. Use the hlevel(#) option to compute the linear predictor at level #. When hlevel(#) is not specified, (j) new variables must be given, where (j) is the number of levels, or use the stub* option to have predict generate (j) variables with the prefix stub and numbered from 1 to (j).</td>
</tr>
<tr>
<td>condp</td>
<td>condp calculates the conditional probabilities for each alternative at each level. Use the hlevel(#) option to compute the conditional probabilities of the alternatives at level #. When hlevel(#) is not specified, (j) new variables must be given, where (j) is the number of levels, or use the stub* option to have predict generate (j) variables with the prefix stub and numbered from 1 to (j).</td>
</tr>
<tr>
<td>iv</td>
<td>iv calculates the inclusive value for each alternative at each level. Use the hlevel(#) option to compute the inclusive value at level #. There is no inclusive value at level 1. If hlevel(#) is not used, (j-1) new variables are required, where (j) is the number of levels, or use stub* to have predict generate (j-1) variables with the prefix stub and numbered from 2 to (j). See Methods and formulas in [R] nlogit for a definition of the inclusive values.</td>
</tr>
<tr>
<td>hlevel(#)</td>
<td>hlevel(#) calculates the prediction only for hierarchy level #.</td>
</tr>
</tbody>
</table>
altwise specifies that alternativewise deletion be used when marking out observations due to missing values in your variables. The default is to use casewise deletion. The \texttt{xb} option always uses alternativewise deletion.

\texttt{scores} calculates the scores for each coefficient in \texttt{e(b)}. This option requires a new-variable list of length equal to the number of columns in \texttt{e(b)}. Otherwise, use the \texttt{stub*} option to have \texttt{predict} generate enumerated variables with prefix \texttt{stub}.

**Syntax for \texttt{estat alternatives}**

\begin{verbatim}
estat alternatives
\end{verbatim}

**Menu for \texttt{estat}**

Statistics $>$ Postestimation $>$ Reports and statistics

**Remarks and examples**

\texttt{predict} may be used after \texttt{nlogit} to obtain the predicted values of the probabilities, the conditional probabilities, the linear predictions, and the inclusive values for each level of the nested logit model. Predicted probabilities for \texttt{nlogit} must be interpreted carefully. Probabilities are estimated for each case as a whole and not for individual observations.

**Example 1**

Continuing with our model in \texttt{example 3} of \texttt{[R] nlogit}, we refit the model and then examine a summary of the alternatives and their frequencies in the estimation sample.

\begin{verbatim}
. use http://www.stata-press.com/data/r13/restaurant
. nlogitgen type = restaurant(fast: Freebirds | MamasPizza, > family: CafeEccell | LosNortenos | WingsNmore, fancy: Christophers | MadCows)
(output omitted)
. nlogit chosen cost rating distance || type: income kids, base(family) || > restaurant:, noconst case(family_id)
(output omitted)
\end{verbatim}
Next we predict \( p_2 = \Pr(\text{restaurant}) \); \( p_1 = \Pr(\text{type}) \); \( \text{condp} = \Pr(\text{restaurant} | \text{type}) \); \( \text{xb2} \), the linear prediction for the bottom-level alternatives; \( \text{xb1} \), the linear prediction for the first-level alternatives; and \( \text{iv} \), the inclusive values for the bottom-level alternatives.

\[
\begin{align*}
\text{. predict } p_* \\
(\text{option } pr \text{ assumed}) \\
\text{. predict } \text{condp}, \text{condp hlevel(2)} \\
\text{. sort family_id type restaurant} \\
\text{. list restaurant type chosen p2 p1 condp in 1/14, sepby(family_id) divider}
\end{align*}
\]
. list restaurant type chosen xb* iv in 1/14, sepby(family_id) divider

## Syntax

### Interactive version

```
nlsur (depvar_1 = <sexp_1>) (depvar_2 = <sexp_2>) ... [if] [in] [weight] [ , options]
```

### Programmed substitutable expression version

```
nlsur sexp_prog : depvar_1 depvar_2 ... [varlist] [if] [in] [weight] [ , options]
```

### Function evaluator program version

```
nlsur func_prog @ depvar_1 depvar_2 ... [varlist] [if] [in] [weight],
    nequations(#) { parameters(namelist) | nparameters(#)} [options]
```

where

- `depvar_j` is the dependent variable for equation `j`;
- `<sexp>_j` is the substitutable expression for equation `j`;
- `sexp_prog` is a substitutable expression program; and
- `func_prog` is a function evaluator program.

* You must specify parameters(namelist), nparameters(#), or both.

bootstrap, by, jackknife, rolling, and statsby are allowed; see [U] 11.1.10 Prefix commands.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
aweights are not allowed with the jackknife prefix; see [R] jackknife.
aweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.
coeflegend does not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Menu
Statistics > Linear models and related > Multiple-equation models > Nonlinear seemingly unrelated regression
```
Description

*nl*sur fits a system of nonlinear equations by feasible generalized nonlinear least squares (FGNLS). With the interactive version of the command, you enter the system of equations on the command line or in the dialog box by using *substitutable expressions*. If you have a system that you use regularly, you can write a *substitutable expression program* and use the second syntax to avoid having to reenter the system every time. The function evaluator program version gives you the most flexibility in exchange for increased complexity; with this version, your program is given a vector of parameters and a variable list, and your program computes the system of equations.

When you write a substitutable expression program or a function evaluator program, the first five letters of the name must be *nl*sur. *sexp* _prog_ and *func* _prog_ refer to the name of the program without the first five letters. For example, if you wrote a function evaluator program named *nl*surregss, you would type *nl*sur regss @ ... to estimate the parameters.

Options

```
Model

fgnls requests the two-step FGNLS estimator; this is the default.
ifgnls requests the iterative FGNLS estimator. For the nonlinear systems estimator, this is equivalent to maximum likelihood estimation.
nls requests the nonlinear least-squares (NLS) estimator.
```

```
variables(varlist) specifies the variables in the system. *nl*sur ignores observations for which any of these variables has missing values. If you do not specify variables(), *nl*sur issues an error message if the estimation sample contains any missing values.
```

```
initial(initial_values) specifies the initial values to begin the estimation. You can specify a 1 × k matrix, where k is the total number of parameters in the system, or you can specify a parameter name, its initial value, another parameter name, its initial value, and so on. For example, to initialize alpha to 1.23 and delta to 4.57, you would type
```
.nlsur ... , initial(alpha 1.23 delta 4.57) ...
```

Initial values declared using this option override any that are declared within substitutable expressions. If you specify a matrix, the values must be in the same order in which the parameters are declared in your model. *nl*sur ignores the row and column names of the matrix.

```
equations(#) specifies the number of equations in the system.
```

```
parameters(namelist) specifies the names of the parameters in the system. The names of the parameters must adhere to the naming conventions of Stata’s variables; see [U] 11.3 Naming conventions. If you specify both parameters() and nparameters(), the number of names in the former must match the number specified in the latter.
```

```
nparameters(#) specifies the number of parameters in the system. If you do not specify names with the parameters() options, *nl*sur names them b1, b2, ..., b#. If you specify both parameters() and nparameters(), the number of names in the former must match the number specified in the latter.
```

```
sexp_options refer to any options allowed by your *sexp* _prog_.
func_options refer to any options allowed by your *func* _prog_.
```
vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (gnr), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

vce(gnr), the default, uses the conventionally derived variance estimator for nonlinear models fit using Gauss–Newton regression.

level(#) ; see [R] estimation options.

title(string) specifies an optional title that will be displayed just above the table of parameter estimates.

title2(string) specifies an optional subtitle that will be displayed between the title specified in title() and the table of parameter estimates. If title2() is specified but title() is not, title2() has the same effect as title().

display_options: cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] estimation options.

optimization_options: iterate(#), [no] log, trace. iterate() specifies the maximum number of iterations to use for NLS at each round of FGNLS estimation. This option is different from ifgnlsiterate(), which controls the maximum rounds of FGNLS estimation to use when the ifgnls option is specified. log/nolog specifies whether to show the iteration log, and trace specifies that the iteration log should include the current parameter vector.

eps(#) specifies the convergence criterion for successive parameter estimates and for the residual sum of squares (RSS). The default is eps(1e-5) (0.00001). eps() also specifies the convergence criterion for successive parameter estimates between rounds of iterative FGNLS estimation when ifgnls is specified.

ifgnlsiterate(#) specifies the maximum number of FGNLS iterations to perform. The default is the number set using set maxiter (see [R] maximize), which is 16,000 by default. To use this option, you must also specify the ifgnls option.

ifgnlseps(#) specifies the convergence criterion for successive estimates of the error covariance matrix during iterative FGNLS estimation. The default is ifgnlseps(1e-10). To use this option, you must also specify the ifgnls option.

delta(#) specifies the relative change in a parameter, \( \delta \), to be used in computing the numeric derivatives. The derivative for parameter \( \beta_i \) is computed as

\[
\left\{ f_i \left( x_i, \beta_1, \beta_2, \ldots, \beta_i + d, \beta_{i+1}, \ldots \right) - f_i \left( x_i, \beta_1, \beta_2, \ldots, \beta_i, \beta_{i+1}, \ldots \right) \right\} / d
\]

where \( d = \delta(|\beta_i| + \delta) \). The default is delta(4e-7).

noconstants indicates that none of the equations in the system includes constant terms. This option is generally not needed, even if there are no constant terms in the system; though in rare cases without this option, nlsur may claim that there is one or more constant terms even if there are none.
The following options are available with \texttt{nlsur} but are not shown in the dialog box: \texttt{coeflegend}; see \texttt{R estimation options}.

**Remarks and examples**

Remarks are presented under the following headings:

- \textit{Introduction}
- \textit{Substitutable expression programs}
- \textit{Function evaluator programs}

**Introduction**

\texttt{nlsur} fits a system of nonlinear equations by FGNLS. It can be viewed as a nonlinear variant of Zellner's seemingly unrelated regression model (Zellner 1962; Zellner and Huang 1962; Zellner 1963) and is therefore commonly called nonlinear SUR or nonlinear SURE. The model is also discussed in textbooks such as Davidson and MacKinnon (1993, 2004) and Greene (2012, 305–306). Formally, the model fit by \texttt{nlsur} is

\[ y_{i1} = f_1(x_i, \beta) + u_{i1} \]
\[ y_{i2} = f_2(x_i, \beta) + u_{i2} \]
\[ \vdots \quad = \quad \vdots \]
\[ y_{iM} = f_M(x_i, \beta) + u_{iM} \]

for \( i = 1, \ldots, N \) observations and \( m = 1, \ldots, M \) equations. The errors for the \( i \)th observation, \( u_{i1}, u_{i2}, \ldots, u_{iM} \), may be correlated, so fitting the \( m \) equations jointly may lead to more efficient estimates. Moreover, fitting the equations jointly allows us to impose cross-equation restrictions on the parameters. Not all elements of the parameter vector \( \beta \) and data vector \( x_i \) must appear in all the equations, though each element of \( \beta \) must appear in at least one equation for \( \beta \) to be identified. For this model, iterative FGNLS estimation is equivalent to maximum likelihood estimation with multivariate normal disturbances.

The syntax you use with \texttt{nlsur} closely mirrors that used with \texttt{nl}. In particular, you use substitutable expressions with the interactive and programmed substitutable expression versions to define the functions in your system. See \texttt{R nl} for more information on substitutable expressions. Here we reiterate the three rules that you must follow:

1. Parameters of the model are bound in braces: \{\texttt{b0}\}, \{\texttt{param}\}, etc.
2. Initial values for parameters are given by including an equal sign and the initial value inside the braces: \{\texttt{b0=1}\}, \{\texttt{param=3.571}\}, etc. If you do not specify an initial value, that parameter is initialized to zero. The \texttt{initial()} option overrides initial values in substitutable expressions.
3. Linear combinations of variables can be included using the notation \{\text{eqname}: \text{varlist}\}, for example, \{\text{xb: mpg price weight}\}, \{\text{score: w x z}\}, etc. Parameters of linear combinations are initialized to zero.

Example 1: Interactive version using two-step FGNLS estimator

We have data from an experiment in which two closely related types of bacteria were placed in a Petri dish, and the number of each type of bacteria were recorded every hour. We suspect a two-parameter exponential growth model can be used to model each type of bacteria, but because they shared the same dish, we want to allow for correlation in the error terms. We want to fit the system of equations

\[
\begin{align*}
    p_1 &= \beta_1 \beta_2^t + u_1 \\
    p_2 &= \gamma_1 \gamma_2^t + u_2
\end{align*}
\]

where \(p_1\) and \(p_2\) are the two populations and \(t\) is time, and we want to allow for nonzero correlation between \(u_1\) and \(u_2\). We type

```

The header of the output contains a summary of each equation, including the number of observations and parameters and the root mean squared error of the residuals. \textit{nlsur} checks to see whether each equation contains a constant term, and if an equation does contain a constant term, an \(R^2\) statistic is
presented. If an equation does not have a constant term, an uncentered $R^2$ is instead reported. The $R^2$ statistic for each equation measures the percentage of variance explained by the nonlinear function and may be useful for descriptive purposes, though it does not have the same formal interpretation in the context of FGNLS as it does with NLS estimation. As we would expect, $\beta_2$ and $\gamma_2$ are both greater than one, indicating the two bacterial populations increased in size over time.

The model we fit in the next three examples is in fact linear in the parameters, so it could be fit using the `sureg` command. However, we will fit the model using `nlsur` so that we can focus on the mechanics of using the command. Moreover, using `nlsur` will obviate the need to generate several variables as well as the need to use the `constraint` command to impose parameter restrictions.

### Example 2: Interactive version using iterative FGNLS estimator—the translog production function

Greene (1997, sec. 15.6) discusses the transcendental logarithmic (translog) cost function and provides cost and input price data for capital, labor, energy, and materials for the U.S. economy. One way to fit the translog production function to these data is to fit the system of three equations

\[
\begin{align*}
    s_k &= \beta_k + \delta_{kk} \ln \left( \frac{p_k}{p_m} \right) + \delta_{kl} \ln \left( \frac{p_l}{p_m} \right) + \delta_{ke} \ln \left( \frac{p_e}{p_m} \right) + u_1 \\
    s_l &= \beta_l + \delta_{kl} \ln \left( \frac{p_k}{p_m} \right) + \delta_{ll} \ln \left( \frac{p_l}{p_m} \right) + \delta_{le} \ln \left( \frac{p_e}{p_m} \right) + u_2 \\
    s_e &= \beta_e + \delta_{ke} \ln \left( \frac{p_k}{p_m} \right) + \delta_{le} \ln \left( \frac{p_l}{p_m} \right) + \delta_{ee} \ln \left( \frac{p_e}{p_m} \right) + u_3
\end{align*}
\]

where $s_k$ is capital’s cost share, $s_l$ is labor’s cost share, and $s_e$ is energy’s cost share; $p_k$, $p_l$, $p_e$, and $p_m$ are the prices of capital, labor, energy, and materials, respectively; the $u$’s are regression error terms; and the $\beta$s and $\delta$s are parameters to be estimated. There are three cross-equation restrictions on the parameters: $\delta_{kl}$, $\delta_{ke}$, and $\delta_{le}$ each appear in two equations. To fit this model by using the iterative FGNLS estimator, we type
. use http://www.stata-press.com/data/r13/mfgcost
. nlsur (s_k = {bk} + {dkk}*ln(pk/pm) + {dkl}*ln(pl/pm) + {dke}*ln(pe/pm))

We draw your attention to the iteration log at the top of the output. When iterative FGNLS estimation is used, the final scaled RSS will equal the product of the number of observations in the estimation sample and the number of equations; see Methods and formulas for details. Because the RSS is scaled by the error covariance matrix during each round of FGNLS estimation, the scaled RSS is not comparable from one FGNLS iteration to the next.

Technical note

You may have noticed that we mentioned having data for four factors of production, yet we fit only three share equations. Because the four shares sum to one, we must drop one of the equations to avoid having a singular error covariance matrix. The iterative FGNLS estimator is equivalent to maximum likelihood estimation, and thus it is invariant to which one of the four equations we choose to drop. The (linearly restricted) parameters of the fourth equation can be obtained using the lincom command. Nonlinear functions of the parameters, such as the elasticities of substitution, can be computed using nlcom.
Substitutable expression programs

If you fit the same model repeatedly or you want to share code with colleagues, you can write a substitutable expression program to define your system of equations and avoid having to retype the system every time. The first five letters of the program’s name must be nlsur, and the program must set the r-class macro r(n_eq) to the number of equations in your system. The first equation’s substitutable expression must be returned in r(eq_1), the second equation’s in r(eq_2), and so on. You may optionally set r(title) to label your output; that has the same effect as specifying the title() option.

Example 3: Programmed substitutable expression version

We return to our translog cost function, for which a substitutable expression program is

```
program nlsurtranslog, rclass
    version 13
    syntax varlist(min=7 max=7) [if]
    tokenize ‘varlist’
    args sk sl se pk pl pe pm
    local pkpm ln(‘pk’/’pm’)
    local plpm ln(‘pl’/’pm’)
    local pepm ln(‘pe’/’pm’)
    return scalar n_eq = 3
    return local eq_1 "‘sk’= {bk} + {dkk}*’pkpm’ + {dkl}*’plpm’ + {dke}*’pepm’"
    return local eq_2 "‘sl’= {bl} + {dkl}*’pkpm’ + {dll}*’plpm’ + {dle}*’pepm’"
    return local eq_3 "‘se’= {be} + {dke}*’pkpm’ + {dle}*’plpm’ + {dee}*’pepm’"
    return local title "4-factor translog cost function"
end
```

We made our program accept seven variables, for the three dependent variables $s_k$, $s_l$, and $s_e$, and the four factor prices $p_k$, $p_l$, $p_m$, and $p_e$. The `tokenize` command assigns to macros ‘1’, ‘2’, ..., ‘7’ the seven variables stored in ‘varlist’, and the `args` command transfers those numbered macros to macros ‘sk’, ‘sl’, ..., ‘pm’. Because we knew our substitutable expressions were going to be somewhat long, we created local macros to hold the log price ratios. These are simply macros that hold strings such as ln(pk/pm), not variables, and they will save us some repetitious typing when we define our substitutable expressions. Our program returns the number of equations in r(n_eq), and we defined our substitutable expressions in eq_1, eq_2, and eq_3. We do not bind the expressions in parentheses as we do with the interactive version of nlsur. Finally, we put a title in r(title) to label our output.

Our `syntax` command also accepts an if clause, and that is how nlsur indicates the estimation sample to our program. In this application, we can safely ignore it, because our program does not compute initial values. However, had we used commands such as summarize or regress to obtain initial values, then we would need to restrict those commands to analyze only the estimation sample. In those cases, typically, you simply need to include ‘if’ with the commands you are using. For example, instead of the command

```
summarize ‘depvar’, meanonly
```

you would use

```
summarize ‘depvar’ ‘if’, meanonly
```
We can check our program by typing

```
.nlsurtranslog s_k s_l s_e pk pl pe pm
.return list

scalars:
  r(n_eq) = 3

macros:
  r(title) : "4-factor translog cost function"
  r(eq_3) : "s_e= {be} + {dke}*ln(pk/pm) + {dle}*ln(pl/pm) + {.."
  r(eq_2) : "s_l= {bl} + {dkl}*ln(pk/pm) + {dll}*ln(pl/pm) + {.."
  r(eq_1) : "s_k= {bk} + {dkk}*ln(pk/pm) + {dkl}*ln(pl/pm) + {.."
```

Now that we know that our program works, we fit our model by typing

```
.nlsur translog: s_k s_l s_e pk pl pe pm, ifgnls
(obs = 25)
```

| /dee   | .0183415 | .0049858 | 3.68  | 0.000 | .0085694 - .0281135 |

Because we set r(title) in our substitutable expression program, the coefficient table has a title attached to it. The estimates are identical to those we obtained in example 2.
Technical note

nlsur accepts frequency and analytic weights as well as pweights (sampling weights) and iweights (importance weights). You do not need to modify your substitutable expressions in any way to perform weighted estimation, though you must make two changes to your substitutable expression program. The general outline of a sexp_prog program is

```plaintext
program nlsur name, rclass
    version 13
    syntax varlist [fw aw pw iw] [if]
    // Obtain initial values incorporating weights. For example,
    summarize varname ['weight''exp'] 'if'
    ...
    // Return n_eqn and substitutable expressions
    return scalar n_eq =#
    return local eq_1 = ...
    ...
end
```

First, we wrote the syntax statement to accept a weight expression. Here we allow all four types of weights, but if you know that your estimator is valid, say, for only frequency weights, then you should modify the syntax line to accept only fweights. Second, if your program computes starting values, then any commands you use must incorporate the weights passed to the program; you do that by including ['weight''exp'] when calling those commands.

Function evaluator programs

Although substitutable expressions are extremely flexible, there are some problems for which the nonlinear system cannot be defined using them. You can use the function evaluator program version of nlsur in these cases. We present two examples, a simple one to illustrate the mechanics of function evaluator programs and a more complicated one to illustrate the power of nlsur.
Example 4: Function evaluator program version

Here we write a function evaluator program to fit the translog cost function used in examples 2 and 3. The function evaluator program is

```stata
program nlsurtranslog2
version 13
syntax varlist(min=7 max=7) [if], at(name)
tokenize `varlist'
args sk sl se pk pl pe pm
tempname bk dkk dkl dke bl dll dle be dee
scalar `bk' = `at'[1,1]
scalar `dkk' = `at'[1,2]
scalar `dkl' = `at'[1,3]
scalar `dke' = `at'[1,4]
scalar `bl' = `at'[1,5]
scalar `dll' = `at'[1,6]
scalar `dle' = `at'[1,7]
scalar `be' = `at'[1,8]
scalar `dee' = `at'[1,9]
local pkpm ln(`pk'/'pm')
local plpm ln(`pl'/'pm')
local pepm ln(`pe'/'pm')
quietly {
    replace `sk' = `bk' + `dkk'*`pkpm' + `dkl'*`plpm' + ///
        `dke'*`pepm' 'if'
    replace `sl' = `bl' + `dkl'*`pkpm' + `dll'*`plpm' + ///
        `dle'*`pepm' 'if'
    replace `se' = `be' + `dke'*`pkpm' + `dle'*`plpm' + ///
        `dee'*`pepm' 'if'
}
end
```

Unlike the substitutable expression program we wrote in example 3, nlsurtranslog2 is not declared as r-class because we will not be returning any stored results. We are again expecting seven variables: three shares and four factor prices, and nlsur will again mark the estimation sample with an if expression.

Our function evaluator program also accepts an option named at(), which will receive a parameter vector at which we are to evaluate the system of equations. All function evaluator programs must accept this option. Our model has nine parameters to estimate, and we created nine temporary scalars to hold the elements of the `at' matrix.

Because our model has three equations, the first three variables passed to our program are the dependent variables that we are to fill in with the function values. We replaced only the observations in our estimation sample by including the `if' qualifier in the replace statements. Here we could have ignored the `if' qualifier because nlsur will skip over observations not in the estimation sample and we did not perform any computations requiring knowledge of the estimation sample. However, including the `if' is good practice and may result in a slight speed improvement if the functions of your model are complicated and the estimation sample is much smaller than the dataset in memory.

We could have avoided creating temporary scalars to hold our individual parameters by writing the replace statements as, for example,

```stata
    replace `sk' = `at'[1,1] + `at'[1,2]*`pkpm' + `at'[1,3]*`plpm' + `at'[1,4]*`pepm' 'if'
```

You can use whichever method you find more appealing, though giving the parameters descriptive names reduces the chance for mistakes and makes debugging easier.
To fit our model by using the function evaluator program version of `nlsur`, we type

```
. nlsur translog2 @ s_k s_l s_e pk pl pe pm, ifgnls nequations(3)
> parameters(bk dkk dkl dke bl dll dle be dee)
> hasconstants(bk bl be)

```
When we use the function evaluator program version, \texttt{nlsur} requires us to specify the number of equations in \texttt{nequations()}, and it requires us to either specify names for each of our parameters or the number of parameters in the model. Here we used the \texttt{parameters()} option to name our parameters; the order in which we specified them in this option is the same as the order in which we extracted them from the ‘at’ matrix in our program. Had we instead specified \texttt{nparameters(9)}, our parameters would have been labeled /b1, /b2, ..., /b9 in the output.

\texttt{nlsur} has no way of telling how many parameters appear in each equation, so the \texttt{Parms} column in the header contains missing values. Moreover, the function evaluator program version of \texttt{nlsur} does not attempt to identify constant terms, so we used the \texttt{hasconstant} option to tell \texttt{nlsur} which parameter in each equation is a constant term.

The estimates are identical to those we obtained in examples 2 and 3.

### Technical note

As with substitutable expression programs, if you intend to do weighted estimation with a function evaluator program, you must modify your \texttt{func\_prog} program’s \texttt{syntax} statement to accept weights. Moreover, if you use any statistical commands when computing your nonlinear functions, then you must include the weight expression with those commands.

### Example 5: Fitting the basic AIDS model using \texttt{nlsur}

Deaton and Muellbauer (1980) introduce the almost ideal demand system (AIDS), and Poi (2012) presents a set of commands and several extensions for fitting the AIDS automatically. Here we show how to fit the basic AIDS model, which is a common example of a nonlinear system of equations, by manually using \texttt{nlsur}. The dataset \texttt{food.dta} contains household expenditures, expenditure shares, and log prices for four broad food groups. For a four-good demand system, we need to fit the following system of three equations:

\[
\begin{align*}
    s_k &= \beta_k + \epsilon_k \\
    s_l &= \beta_l + \epsilon_l \\
    s_e &= \beta_e + \epsilon_e
\end{align*}
\]
\[ w_1 = \alpha_1 + \gamma_{11} \ln p_1 + \gamma_{12} \ln p_2 + \gamma_{13} \ln p_3 + \beta_1 \ln \left( \frac{m}{P(p)} \right) + u_1 \]

\[ w_2 = \alpha_2 + \gamma_{12} \ln p_1 + \gamma_{22} \ln p_2 + \gamma_{23} \ln p_3 + \beta_2 \ln \left( \frac{m}{P(p)} \right) + u_2 \]

\[ w_3 = \alpha_3 + \gamma_{13} \ln p_1 + \gamma_{23} \ln p_2 + \gamma_{33} \ln p_3 + \beta_3 \ln \left( \frac{m}{P(p)} \right) + u_3 \]

where \( w_k \) denotes a household’s fraction of expenditures on good \( k \), \( \ln p_k \) denotes the logarithm of the price paid for good \( k \), \( m \) denotes a household’s total expenditure on all four goods, the \( u \)’s are regression error terms, and

\[ \ln P(p) = \alpha_0 + \sum_{i=1}^{4} \alpha_i \ln p_i + \frac{1}{2} \sum_{i=1}^{4} \sum_{j=1}^{4} \gamma_{ij} \ln p_i \ln p_j \]

The parameters for the fourth good’s share equation can be recovered from the following constraints that are imposed by economic theory:

\[ \sum_{i=1}^{4} \alpha_i = 1 \quad \sum_{i=1}^{4} \beta_i = 0 \quad \gamma_{ij} = \gamma_{ji} \quad \text{and} \quad \sum_{i=1}^{4} \gamma_{ij} = 0 \text{ for all } j \]

Our model has a total of 12 unrestricted parameters. We will not estimate \( \alpha_0 \) directly. Instead, we will set it equal to 5; see Deaton and Muellbauer (1980) for a discussion of why treating \( \alpha_0 \) as fixed is acceptable.
Our function evaluator program is

```

quietly {
    tempvar lnpindex
    gen double 'lnpindex' = 5 + 'a1'*'lnp1' + 'a2'*'lnp2' + 'a3'*'lnp3' + 'a4'*'lnp4'
    forvalues i = 1/4 {
        forvalues j = 1/4 {
            replace 'lnpindex' = 'lnpindex' + 0.5*'g'i''j''*'lnp'i''*'lnp'j''  
        }
    }
    replace 'w1' = 'a1' + 'g11'*'lnp1' + 'g12'*'lnp2' + 'g13'*'lnp3' + 'g14'*'lnp4' + 'b1'*(lm - lnpindex)
    replace 'w2' = 'a2' + 'g21'*'lnp1' + 'g22'*'lnp2' + 'g23'*'lnp3' + 'g24'*'lnp4' + 'b2'*(lm - lnpindex)
    replace 'w3' = 'a3' + 'g31'*'lnp1' + 'g32'*'lnp2' + 'g33'*'lnp3' + 'g34'*'lnp4' + 'b3'*(lm - lnpindex)
}
end
```

The `syntax` statement accepts eight variables: three expenditure share variables, all four log-price variables, and a variable for log expenditures (\textit{lnm}). Most of the code simply extracts the parameters
from the ‘at’ matrix. Although we are estimating only 12 parameters, to calculate the price index term and the expenditure share equations, we need the restricted parameters as well. Notice how we impose the constraints on the parameters. We then created a temporary variable to hold \( \ln P(p) \), and we filled the three dependent variables with the predicted expenditure shares.

To fit our model, we type

To get the restricted parameters for the fourth share equation, we can use `lincom`. For example, to obtain $\alpha_4$, we type

```
   . lincom 1 - [a1]_cons - [a2]_cons - [a3]_cons
   ( 1) - [a1]_cons - [a2]_cons - [a3]_cons = -1
```

|        | Coef. | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|--------|-------|-----------|-------|------|---------------------|
| (1)    | .3083643 | .0052611 | 58.61 | 0.000 | .2980528 – .3186758 |

For more information on `lincom`, see [R] `lincom`.

---

**Stored results**

`nlsur` stores the following in `e()`:

Scalars

- `e(N)` number of observations
- `e(k)` number of parameters
- `e(k_=#)` number of parameters for equation #
- `e(k_eq)` number of equation names in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(n_eq)` number of equations
- `e(mss_=#)` model sum of squares for equation #
- `e(rss_=#)` RSS for equation #
- `e(rmse_=#)` root mean squared error for equation #
- `e(r2_=#)` $R^2$ for equation #
- `e(ll)` Gaussian log likelihood (if `iflgs` version only)
- `e(N_clust)` number of clusters
- `e(rank)` rank of `e(V)`
- `e(converge)` 1 if converged, 0 otherwise

Macros

- `e(cmd)` `nlsur`
- `e(cmdline)` command as typed
- `e(method)` `fgnl±s, ifgnl±s, or nls`
- `e(depvar)` names of dependent variables
- `e(depvar_=#)` dependent variable for equation #
- `e(vtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(title_2)` secondary title in estimation output
- `e(clustvar)` name of cluster variable
- `e(vce)` `vcetype` specified in `vce()`
- `e(vctype)` title used in label Std. Err.
- `e(type)`
  - 1 = interactively entered expression

Write the system of equations for the \( i \)th observation as
\[
y_i = f(x_i, \beta) + u_i
\]  
\[\text{(1)}\]
where \( y_i \) and \( u_i \) are \( 1 \times M \) vectors, for \( i = 1, \ldots, N \); \( f \) is a function that returns a \( 1 \times M \) vector; \( x_i \) represents all the exogenous variables in the system; and \( \beta \) is a \( 1 \times k \) vector of parameters. The generalized nonlinear least-squares system estimator is defined as
\[
\hat{\beta} \equiv \arg\min_{\beta} \sum_{i=1}^{N} \{ y_i - f(x_i, \beta) \} \Sigma^{-1} \{ y_i - f(x_i, \beta) \}'
\]
where \( \Sigma = E(u'_i u_i) \) is an \( M \times M \) positive-definite weight matrix. Let \( T \) be the Cholesky decomposition of \( \Sigma^{-1} \); that is, \( TT' = \Sigma^{-1} \). Postmultiply (1) by \( T \):
\[
y_i T = f(x_i, \beta) T + u_i T
\]  
\[\text{(2)}\]
Because \( E(T'u'_i u_i T) = I \), we can “stack” the columns of (2) and write
\[
y_1 T_1 = f(x_1, \beta) T_1 + \tilde{u}_{11}
y_1 T_2 = f(x_1, \beta) T_2 + \tilde{u}_{12}
\vdots
y_1 T_M = f(x_1, \beta) T_M + \tilde{u}_{1M}
y_N T_1 = f(x_N, \beta) T_1 + \tilde{u}_{N1}
y_N T_2 = f(x_N, \beta) T_2 + \tilde{u}_{N2}
\vdots
y_N T_M = f(x_N, \beta) T_M + \tilde{u}_{NM}
\]  
\[\text{(3)}\]
where \( T_j \) denotes the \( j \)th column of \( T \). By construction, all \( \tilde{u}_{ij} \) are independently distributed with unit variance. As a result, by transforming the model in (1) to that shown in (3), we have reduced the multivariate generalized nonlinear least-squares system estimator to a univariate nonlinear least-squares problem; and the same parameter estimation technique used by \texttt{n1} can be used here. See \texttt{R nl} for the details. Moreover, because the \( \tilde{u}_{ij} \) all have variance 1, the final scaled \( \text{RSS} \) reported by \texttt{nlsur} is equal to \( NM \).
To make the estimator feasible, we require an estimate $\hat{\Sigma}$ of $\Sigma$. \texttt{nlsur} first sets $\hat{\Sigma} = I$. Although not efficient, the resulting estimate, $\hat{\beta}_{NLS}$, is consistent. If the \texttt{nls} option is specified, estimation is complete. Otherwise, the residuals

$$\hat{u}_i = y_i - f(x_i, \hat{\beta}_{NLS})$$

are calculated and used to compute

$$\hat{\Sigma} = \frac{1}{N} \sum_{i=1}^{N} \hat{u}_i' \hat{u}_i$$

With $\hat{\Sigma}$ in hand, a new estimate $\hat{\beta}$ is then obtained.

If the \texttt{ifgnls} option is specified, the new $\hat{\beta}$ is used to recompute the residuals and obtain a new estimate of $\hat{\Sigma}$, from which $\hat{\beta}$ can then be reestimated. Iterations stop when the relative change in $\hat{\beta}$ is less than $\text{eps}()$, the relative change in $\hat{\Sigma}$ is less than $\text{ifgnlseps}()$, or if \texttt{ifgnlsiterate()} iterations have been performed.

If the \texttt{vce(robust)} and \texttt{vce(cluster clustvar)} options were not specified, then

$$V(\hat{\beta}) = \left( \sum_{i=1}^{N} X_i' \hat{\Sigma}^{-1} X_i \right)^{-1}$$

where the $M \times k$ matrix $X_i$ has typical element $X_{ist}$, the derivative of the $s$th element of $f$ with respect to the $t$th element of $\beta$, evaluated at $x_i$ and $\hat{\beta}$. As a practical matter, once the model is written in the form of (3), the variance–covariance matrix can be calculated via a Gauss–Newton regression; see Davidson and MacKinnon (1993, chap. 6).

If \texttt{robust} is specified, then

$$V_R(\hat{\beta}) = \left( \sum_{i=1}^{N} X_i' \hat{\Sigma}^{-1} X_i \right)^{-1} \sum_{i=1}^{N} X_i' \hat{\Sigma}^{-1} \hat{u}_i \hat{\Sigma}^{-1} X_i \left( \sum_{i=1}^{N} X_i' \hat{\Sigma}^{-1} X_i \right)^{-1}$$

The cluster–robust variance matrix is

$$V_C(\hat{\beta}) = \left( \sum_{i=1}^{N} X_i' \hat{\Sigma}^{-1} X_i \right)^{-1} \sum_{c=1}^{N_C} w_c' w_c \left( \sum_{i=1}^{N} X_i' \hat{\Sigma}^{-1} X_i \right)^{-1}$$

where $N_C$ is the number of clusters and

$$w_c = \sum_{j \in C_k} X_j' \hat{\Sigma}^{-1} \hat{u}_j'$$

with $C_k$ denoting the set of observations in the $k$th cluster. In evaluating these formulas, we use the value of $\hat{\Sigma}$ used in calculating the final estimate of $\hat{\beta}$. That is, we do not recalculate $\hat{\Sigma}$ after we obtain the final value of $\hat{\beta}$. 
The RSS for the \( j \)th equation, \( \text{RSS}_j \), is

\[
\text{RSS}_j = \sum_{i=1}^{N} (\hat{y}_{ij} - y_{ij})^2
\]

where \( \hat{y}_{ij} \) is the predicted value of the \( i \)th observation on the \( j \)th dependent variable; the total sum of squares (TSS) for the \( j \)th equation, \( \text{TSS}_j \), is

\[
\text{TSS}_j = \sum_{i=1}^{N} (y_{ij} - \bar{y}_j)^2
\]

if there is a constant term in the \( j \)th equation, where \( \bar{y}_j \) is the sample mean of the \( j \)th dependent variable, and

\[
\text{TSS}_j = \sum_{i=1}^{N} y_{ij}^2
\]

if there is no constant term in the \( j \)th equation; and the model sum of squares (MSS) for the \( j \)th equation, \( \text{MSS}_j \), is \( \text{TSS}_j - \text{RSS}_j \).

The \( R^2 \) for the \( j \)th equation is \( \frac{\text{MSS}_j}{\text{TSS}_j} \). If an equation does not have a constant term, then the reported \( R^2 \) for that equation is “uncentered” and based on the latter definition of \( \text{TSS}_j \).

Under the assumption that the \( u_i \) are independent and identically distributed \( N(0, \hat{\Sigma}) \), the log likelihood for the model is

\[
\ln L = -\frac{MN}{2} \{1 + \ln(2\pi)\} - \frac{N}{2} \ln |\hat{\Sigma}|
\]

The log likelihood is reported only when the `ifgnls` option is specified.

¹ You must specify the variables() option with nlsur.

Syntax for predict

`predict [type] newvar [if] [in] [ , equation(#eqno) yhat residuals]`

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.
Options for predict

equation(#eqno) specifies to which equation you are referring. equation(#1) would mean that the
calculation is to be made for the first equation, equation(#2) would mean the second, and so on.
If you do not specify equation(), results are the same as if you had specified equation(#1).
yhat, the default, calculates the fitted values for the specified equation.
residuals calculates the residuals for the specified equation.

Remarks and examples

Example 1

In example 2 of [R] nlsur, we fit a four-factor translog cost function to data for the U.S. economy.
The own-price elasticity for a factor measures the percentage change in its usage as a result of a
1% increase in the factor’s price, assuming that output is held constant. For the translog production
function, the own-price factor elasticities are

$$\eta_i = \frac{\delta_{ii} + s_i(s_i - 1)}{s_i}$$

Here we compute the elasticity for capital at the sample mean of capital’s factor share. First, we
use summarize to get the mean of s_k and store that value in a scalar:

```
. summarize s_k

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>s_k</td>
<td>25</td>
<td>.053488</td>
<td>.0044795</td>
<td>.04602</td>
<td>.06185</td>
</tr>
</tbody>
</table>
```

. scalar kmean = r(mean)

Now we can use nlcom to calculate the elasticity:

```
. nlcom (([dkk]_cons + kmean*(kmean-1)) / kmean)

_nl_1: ( [dkk]_cons + kmean*(kmean-1) ) / kmean

| Coef. | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|-------|-----------|------|------|----------------------|
| _nl_1 | -.3952986 | .1083535 | -3.65 | 0.000 | -.6076676 | -.1829295 |
```

If the price of capital increases by 1%, its usage will decrease by about 0.4%. To maintain its current
level of output, a firm would increase its usage of other inputs to compensate for the lower capital
usage. The standard error reported by nlcom reflects the sampling variance of the estimated parameter
$\hat{\delta}_{kk}$, but nlcom treats the sample mean of s_k as a fixed parameter that does not contribute to the
sampling variance of the estimated elasticity.

[R] nlsur — Estimation of nonlinear systems of equations
[U] 20 Estimation and postestimation commands
**Syntax**

```
nptrend varname [if] [in], by(groupvar) [nodetail score(scorevar)]
```

**Menu**

Statistics > Nonparametric analysis > Tests of hypotheses > Trend test across ordered groups

**Description**

*nptrend* performs a nonparametric test for trend across ordered groups.

**Options**

- **Main**
  - `by(groupvar)` is required; it specifies the group on which the data are to be ordered.
  - `nodetail` suppresses the listing of group rank sums.
  - `score(scorevar)` defines scores for groups. When it is not specified, the values of `groupvar` are used for the scores.

**Remarks and examples**

*nptrend* performs the nonparametric test for trend across ordered groups developed by Cuzick (1985), which is an extension of the Wilcoxon rank-sum test (see [R] ranksum). A correction for ties is incorporated into the test. *nptrend* is a useful adjunct to the Kruskal–Wallis test; see [R] kwallis.

If your data are not grouped, you can test for trend with the *sign*test and *spearman* commands; see [R] signrank and [R] spearman. With *sign*test, you can perform the Cox and Stuart test, a sign test applied to differences between equally spaced observations of `varname`. With *spearman*, you can perform the Daniels test, a test of zero Spearman correlation between `varname` and a time index. See Conover (1999, 169–175, 323) for a discussion of these tests and their asymptotic relative efficiency.
Example 1

The following data (Altman 1991, 217) show ocular exposure to ultraviolet radiation for 32 pairs of sunglasses classified into three groups according to the amount of visible light transmitted.

<table>
<thead>
<tr>
<th>Transmission of visible light</th>
<th>Ocular exposure to ultraviolet radiation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Group</td>
<td></td>
</tr>
<tr>
<td>1</td>
<td>1.4 1.4 1.4 1.6 2.3 2.3</td>
</tr>
<tr>
<td>2</td>
<td>0.9 1.0 1.1 1.1 1.2 1.5 2.2 2.6 2.6</td>
</tr>
<tr>
<td>3</td>
<td>2.6 2.8 3.2 3.5 4.3 5.1</td>
</tr>
</tbody>
</table>

Entering these data into Stata, we have

```
. use http://www.stata-press.com/data/r13/sg
. list, sep(6)
```

<table>
<thead>
<tr>
<th>group</th>
<th>exposure</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1.4</td>
</tr>
<tr>
<td>2</td>
<td>1.4</td>
</tr>
<tr>
<td>3</td>
<td>1.4</td>
</tr>
<tr>
<td>4</td>
<td>1.6</td>
</tr>
<tr>
<td>5</td>
<td>2.3</td>
</tr>
<tr>
<td>6</td>
<td>2.3</td>
</tr>
<tr>
<td>7</td>
<td>0.9</td>
</tr>
</tbody>
</table>

(output omitted)

| 31    | 3 8.9    |
| 32    | 3 13.5   |

We use `nptrend` to test for a trend of (increasing) exposure across the three groups by typing

```
. nptrend exposure, by(group)
```

<table>
<thead>
<tr>
<th>group</th>
<th>score</th>
<th>obs</th>
<th>sum of ranks</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>6</td>
<td>76</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>18</td>
<td>290</td>
</tr>
<tr>
<td>3</td>
<td>3</td>
<td>8</td>
<td>162</td>
</tr>
</tbody>
</table>

`z = 1.52`

`Prob > |z| = 0.129`

When the groups are given any equally spaced scores (such as −1, 0, 1), we will obtain the same answer as above. To illustrate the effect of changing scores, an analysis of these data with scores 1, 2, and 5 (admittedly not sensible here) produces

```
. gen mysc = cond(group==3,5,group)
. nptrend exposure, by(group) score(mysc)
```

<table>
<thead>
<tr>
<th>group</th>
<th>score</th>
<th>obs</th>
<th>sum of ranks</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>6</td>
<td>76</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>18</td>
<td>290</td>
</tr>
<tr>
<td>3</td>
<td>5</td>
<td>8</td>
<td>162</td>
</tr>
</tbody>
</table>

`z = 1.46`

`Prob > |z| = 0.143`

This example suggests that the analysis is not all that sensitive to the scores chosen.
Technical note

The grouping variable may be either a string variable or a numeric variable. If it is a string variable and no score variable is specified, the natural numbers 1, 2, 3, ... are assigned to the groups in the sort order of the string variable. This may not always be what you expect. For example, the sort order of the strings “one”, “two”, “three” is “one”, “three”, “two”.

Stored results

`nptrend` stores the following in `r()`:

Scalars
- `r(N)`: number of observations
- `r(z)`: z statistic
- `r(p)`: two-sided p-value
- `r(T)`: test statistic

Methods and formulas

`nptrend` is based on a method in Cuzick (1985). The following description of the statistic is from Altman (1991, 215–217). We have $k$ groups of sample sizes $n_i$ ($i = 1, \ldots, k$). The groups are given scores, $l_i$, which reflect their ordering, such as 1, 2, and 3. The scores do not have to be equally spaced, but they usually are. $N = \sum n_i$ observations are ranked from 1 to $N$, and the sums of the ranks in each group, $R_i$, are obtained. $L$, the weighted sum of all the group scores, is

$$L = \sum_{i=1}^{k} l_i n_i$$

The statistic $T$ is calculated as

$$T = \sum_{i=1}^{k} l_i R_i$$

Under the null hypothesis, the expected value of $T$ is $E(T) = 0.5(N + 1)L$, and its standard error is

$$se(T) = \sqrt{\frac{N + 1}{12} \left( N \sum_{i=1}^{k} l_i^2 n_i - L^2 \right)}$$

so that the test statistic, $z$, is given by $z = \{ T - E(T) \} / se(T)$, which has an approximately standard normal distribution when the null hypothesis of no trend is true.

The correction for ties affects the standard error of $T$. Let $\tilde{N}$ be the number of unique values of the variable being tested ($\tilde{N} \leq N$), and let $t_j$ be the number of times the $j$th unique value of the variable appears in the data. Define

$$a = \frac{\sum_{j=1}^{\tilde{N}} t_j (t_j^2 - 1)}{N (N^2 - 1)}$$

The corrected standard error of $T$ is $\tilde{se}(T) = \sqrt{1 - a \ se(T)}$. 
Acknowledgments

nptrend was written by K. A. Stepniewska and D. G. Altman (1992) of the Cancer Research UK.

`indepvars` may contain factor variables; see [U] 11.4.3 Factor variables.

`depvar` and `indepvars` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`bootstrap, by, fp, jackknife, mfp, mi estimate, nestreg, rolling, statsby, stepwise, and svy` are allowed; see [U] 11.1.10 Prefix commands.

`vce(bootstrap)` and `vce(jackknife)` are not allowed with the `mi estimate` prefix; see [MI] mi estimate.

Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap.

`vce()` and weights are not allowed with the `svy` prefix; see [SVY] svy.

`fweights, iweights, and pweights` are allowed; see [U] 11.1.6 weight.

`coeflegend` does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

### Menu

Statistics > Ordinal outcomes > Ordered logistic regression
Description

ologit fits ordered logit models of ordinal variable \textit{depvar} on the independent variables \textit{indepvars}. The actual values taken on by the dependent variable are irrelevant, except that larger values are assumed to correspond to “higher” outcomes.

See \texttt{[R] logistic} for a list of related estimation commands.

Options

\begin{itemize}
\item \texttt{offset(\textit{varname})}, \texttt{constraints(\textit{constraints})}, \texttt{collinear}; see \texttt{[R] estimation options}.
\item \texttt{vce(\textit{vcetype})} specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\textit{oim}), that are robust to some kinds of misspecification (\textit{robust}), that allow for intragroup correlation (\texttt{cluster \textit{clustvar}}), and that use bootstrap or jackknife methods (\texttt{bootstrap}, \texttt{jackknife}); see \texttt{[R] vce_option}.
\item \texttt{level(\#)}; see \texttt{[R] estimation options}.
\item \texttt{nocnsreport}; see \texttt{[R] estimation options}.
\item \texttt{display_option}: \texttt{nomitted}, \texttt{vsquish}, \texttt{noemptycells}, \texttt{baselevels}, \texttt{allbaselevels}, \texttt{nolabel}, \texttt{fwrap(\#)}, \texttt{fwrapon(style)}, \texttt{cformat(\%\textit{fmt})}, \texttt{pformat(\%\textit{fmt})}, \texttt{sformat(\%\textit{fmt})}, and \texttt{nolstretch}; see \texttt{[R] estimation options}.
\item \texttt{maximize_option}: \texttt{difficult}, \texttt{technique(algorithm_spec)}, \texttt{iterate(\#)}, \texttt{no\text{log}}, \texttt{trace}, \texttt{gradient}, \texttt{showstep}, \texttt{hessian}, \texttt{showtolerance}, \texttt{tolerance(\#)}, \texttt{ltolerance(\#)}, \texttt{nlrtolerance(\#)}, \texttt{nonlrtolerance}, and \texttt{from(init_specs)}; see \texttt{[R] maximize}. These options are seldom used.
\end{itemize}

The following option is available with \texttt{ologit} but is not shown in the dialog box:
\texttt{coeflegend}; see \texttt{[R] estimation options}.

Remarks and examples

Ordered logit models are used to estimate relationships between an ordinal dependent variable and a set of independent variables. An \textit{ordinal} variable is a variable that is categorical and ordered, for instance, “poor”, “good”, and “excellent”, which might indicate a person’s current health status or the repair record of a car. If there are only two outcomes, see \texttt{[R] logistic}, \texttt{[R] logit}, and \texttt{[R] probit}. This entry is concerned only with more than two outcomes. If the outcomes cannot be ordered (for example, residency in the north, east, south, or west), see \texttt{[R] mlogit}. This entry is concerned only with models in which the outcomes can be ordered.
In ordered logit, an underlying score is estimated as a linear function of the independent variables and a set of cutpoints. The probability of observing outcome \( i \) corresponds to the probability that the estimated linear function, plus random error, is within the range of the cutpoints estimated for the outcome:

\[
\Pr(\text{outcome}_j = i) = \Pr(\kappa_{i-1} < \beta_1 x_{1j} + \beta_2 x_{2j} + \cdots + \beta_k x_{kj} + u_j \leq \kappa_i)
\]

\( u_j \) is assumed to be logistically distributed in ordered logit. In either case, we estimate the coefficients \( \beta_1, \beta_2, \ldots, \beta_k \) together with the cutpoints \( \kappa_1, \kappa_2, \ldots, \kappa_{k-1} \), where \( k \) is the number of possible outcomes. \( \kappa_0 \) is taken as \(-\infty\), and \( \kappa_k \) is taken as \(+\infty\). All of this is a direct generalization of the ordinary two-outcome logit model.

### Example 1

We wish to analyze the 1977 repair records of 66 foreign and domestic cars. The data are a variation of the automobile dataset described in [U] 1.2.2 Example datasets. The 1977 repair records, like those in 1978, take on values “Poor”, “Fair”, “Average”, “Good”, and “Excellent”. Here is a cross-tabulation of the data:

```
. use http://www.stata-press.com/data/r13/fullauto
(Automobile Models)
. tabulate rep77 foreign, chi2

<table>
<thead>
<tr>
<th>Repair Record 1977</th>
<th>Foreign</th>
<th></th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Domestic</td>
<td>Foreign</td>
<td></td>
</tr>
<tr>
<td>Poor</td>
<td>2</td>
<td>1</td>
<td>3</td>
</tr>
<tr>
<td>Fair</td>
<td>10</td>
<td>1</td>
<td>11</td>
</tr>
<tr>
<td>Average</td>
<td>20</td>
<td>7</td>
<td>27</td>
</tr>
<tr>
<td>Good</td>
<td>13</td>
<td>7</td>
<td>20</td>
</tr>
<tr>
<td>Excellent</td>
<td>0</td>
<td>5</td>
<td>5</td>
</tr>
<tr>
<td>Total</td>
<td>45</td>
<td>21</td>
<td>66</td>
</tr>
</tbody>
</table>
```

Although it appears that `foreign` takes on the values `Domestic` and `Foreign`, it is actually a numeric variable taking on the values 0 and 1. Similarly, `rep77` takes on the values 1, 2, 3, 4, and 5, corresponding to `Poor`, `Fair`, and so on. The more meaningful words appear because we have attached value labels to the data; see [U] 12.6.3 Value labels.

Because the chi-squared value is significant, we could claim that there is a relationship between `foreign` and `rep77`. Literally, however, we can only claim that the distributions are different; the chi-squared test is not directional. One way to model these data is to model the categorization that took place when the data were created. Cars have a true frequency of repair, which we will assume is given by \( S_j = \beta_{\text{foreign}_j} + u_j \), and a car is categorized as “poor” if \( S_j \leq \kappa_0 \), as “fair” if \( \kappa_0 < S_j \leq \kappa_1 \), and so on:
Our model is \( S_j = 1.46 \text{foreign}_j + u_j \); the expected value for foreign cars is 1.46 and, for domestic cars, 0; foreign cars have better repair records.

The estimated cutpoints tell us how to interpret the score. For a foreign car, the probability of a poor record is the probability that 1.46 + u_j \( \leq -2.77 \), or equivalently, u_j \( \leq -4.23 \). Making this calculation requires familiarity with the logistic distribution: the probability is 1/(1 + e^{4.23}) = 0.014. On the other hand, for domestic cars, the probability of a poor record is the probability u_j \( \leq -2.77 \), which is 0.059.

This, it seems to us, is a far more reasonable prediction than we would have made based on the table alone. The table showed that 2 of 45 domestic cars had poor records, whereas 1 of 21 foreign cars had poor records—corresponding to probabilities 2/45 = 0.044 and 1/21 = 0.048. The predictions from our model imposed a smoothness assumption—foreign cars should not, overall, have better repair records without the difference revealing itself in each category. In our data, the fractions of foreign and domestic cars in the poor category are virtually identical only because of the randomness associated with small samples.

Thus if we were asked to predict the true fractions of foreign and domestic cars that would be classified in the various categories, we would choose the numbers implied by the ordered logit model:

\[
\begin{array}{lcccc}
\text{tabulate} & \text{logit} \\
\text{Poor} & 0.044 & 0.048 & 0.059 & 0.014 \\
\text{Fair} & 0.222 & 0.048 & 0.210 & 0.065 \\
\text{Average} & 0.444 & 0.333 & 0.450 & 0.295 \\
\text{Good} & 0.289 & 0.333 & 0.238 & 0.467 \\
\text{Excellent} & 0.000 & 0.238 & 0.043 & 0.159 \\
\end{array}
\]

See \[R\] ologit postestimation for a more complete explanation of how to generate predictions from an ordered logit model.
Technical note

Here ordered logit provides an alternative to ordinary two-outcome logistic models with an arbitrary dichotomization, which might otherwise have been tempting. We could, for instance, have summarized these data by converting the five-outcome rep77 variable to a two-outcome variable, combining cars in the average, fair, and poor categories to make one outcome and combining cars in the good and excellent categories to make the second.

Another even less appealing alternative would have been to use ordinary regression, arbitrarily labeling “excellent” as 5, “good” as 4, and so on. The problem is that with different but equally valid labelings (say, 10 for “excellent”), we would obtain different estimates. We would have no way of choosing one metric over another. That assertion is not, however, true of ologit. The actual values used to label the categories make no difference other than through the order they imply.

In fact, our labeling was 5 for “excellent”, 4 for “good”, and so on. The words “excellent” and “good” appear in our output because we attached a value label to the variables; see [U] 12.6.3 Value labels. If we were to now go back and type replace rep77=10 if rep77==5, changing all the 5s to 10s, we would still obtain the same results when we refit our model.

Example 2

In the example above, we used ordered logit as a way to model a table. We are not, however, limited to including only one explanatory variable or to including only categorical variables. We can explore the relationship of rep77 with any of the variables in our data. We might, for instance, model rep77 not only in terms of the origin of manufacture, but also including length (a proxy for size) and mpg:

```
. ologit rep77 foreign length mpg
```

```
Iteration 0: log likelihood = -89.895098
Iteration 1: log likelihood = -78.775147
Iteration 2: log likelihood = -78.254294
Iteration 3: log likelihood = -78.250719
Iteration 4: log likelihood = -78.250719

Ordered logistic regression

Number of obs = 66
LR chi2(3) = 23.29
Prob > chi2 = 0.0000
Log likelihood = -78.250719 Pseudo R2 = 0.1295

rep77 | Coef. Std. Err. z P>|z| [95% Conf. Interval]
-------------+--------------------------------------------------
foreign | 2.896807 .7906411 3.66 0.000 1.347179 4.446435
length | .0828275 .02272 3.65 0.000 .0382972 .1273579
mpg | .2307677 .0704548 3.28 0.001 .0926788 .3688566
|/cut1 | 17.92748 5.551191 3.28 0.001 7.047344 28.80761
|/cut2 | 19.86506 5.95968 3.35 0.001 8.896161 30.83396
|/cut3 | 22.10331 5.708936 3.91 0.000 10.914 33.29262
|/cut4 | 24.69213 5.890754 4.17 0.000 13.14647 36.2378

```

Foreign still plays a role—and an even larger role than previously. We find that larger cars tend to have better repair records, as do cars with better mileage ratings.
Stored results

`ologit` stores the following in `e()`:

Scalars

- `e(N)` number of observations
- `e(N_cd)` number of completely determined observations
- `e(k_cat)` number of categories
- `e(k)` number of parameters
- `e(k_aux)` number of auxiliary parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(r2_p)` pseudo-$R$-squared
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(N_clust)` number of clusters
- `e(chi2)` \(\chi^2\)
- `e(p)` significance of model test
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

Macros

- `e(cmd)` `ologit`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(offset)` linear offset variable
- `e(chi2type)` Wald or LR; type of model \(\chi^2\) test
- `e(vcex)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` max or min; whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of `ml` method
- `e(user)` name of likelihood- evaluator program
- `e(technique)` maximization technique
- `e(properties)` `b V`
- `e(predict)` program used to implement predict
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

Matrices

- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(ilog)` iteration log (up to 20 iterations)
- `e(gradient)` gradient vector
- `e(cat)` category values
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

Functions

- `e(sample)` marks estimation sample
Methods and formulas

See Long and Freese (2014, chap. 7) for a discussion of models for ordinal outcomes and examples that use Stata. Cameron and Trivedi (2005, chap. 15) describe multinomial models, including the model fit by ologit. When you have a qualitative dependent variable, several estimation procedures are available. A popular choice is multinomial logistic regression (see [R] mlogit), but if you use this procedure when the response variable is ordinal, you are discarding information because multinomial logit ignores the ordered aspect of the outcome. Ordered logit and probit models provide a means to exploit the ordering information.

There is more than one “ordered logit” model. The model fit by ologit, which we will call the ordered logit model, is also known as the proportional odds model. Another popular choice, not fit by ologit, is known as the stereotype model; see [R] ologit. All ordered logit models have been derived by starting with a binary logit/probit model and generalizing it to allow for more than two outcomes.

The proportional-odds ordered logit model is so called because, if we consider the odds 

\[ \text{odds}(k) = \frac{P(Y \leq k)}{P(Y > k)} \]

then \( \text{odds}(k_1) \) and \( \text{odds}(k_2) \) have the same ratio for all independent variable combinations. The model is based on the principle that the only effect of combining adjoining categories in ordered categorical regression problems should be a loss of efficiency in estimating the regression parameters (McCullagh 1980). This model was also described by McKelvey and Zavoina (1975) and, previously, by Aitchison and Silvey (1957) in a different algebraic form. Brant (1990) offers a set of diagnostics for the model.

Peterson and Harrell (1990) suggest a model that allows nonproportional odds for a subset of the explanatory variables. ologit does not allow this, but a model similar to this was implemented by Fu (1998).

The stereotype model rejects the principle on which the ordered logit model is based. Anderson (1984) argues that there are two distinct types of ordered categorical variables: “grouped continuous”, such as income, where the “type a” model applies; and “assessed”, such as extent of pain relief, where the stereotype model applies. Greenland (1985) independently developed the same model. The stereotype model starts with a multinomial logistic regression model and imposes constraints on this model.

Goodness of fit for ologit can be evaluated by comparing the likelihood value with that obtained by fitting the model with mlogit. Let \( \ln L_1 \) be the log-likelihood value reported by ologit, and let \( \ln L_0 \) be the log-likelihood value reported by mlogit. If there are \( p \) independent variables (excluding the constant) and \( k \) categories, mlogit will estimate \( p(k-1) \) additional parameters. We can then perform a “likelihood-ratio test”, that is, calculate \( -2(\ln L_1 - \ln L_0) \), and compare it with \( \chi^2 \{ p(k-2) \} \). This test is suggestive only because the ordered logit model is not nested within the multinomial logit model. A large value of \( -2(\ln L_1 - \ln L_0) \) should, however, be taken as evidence of poorness of fit. Marginally large values, on the other hand, should not be taken too seriously.

The coefficients and cutpoints are estimated using maximum likelihood as described in [R] maximize. In our parameterization, no constant appears, because the effect is absorbed into the cutpoints.

ologit and oprobit begin by tabulating the dependent variable. Category \( i = 1 \) is defined as the minimum value of the variable, \( i = 2 \) as the next ordered value, and so on, for the empirically determined \( k \) categories.
The probability of a given observation for ordered logit is

\[ p_{ij} = Pr(y_j = i) = Pr\left(\kappa_{i-1} < x_j\beta + u \leq \kappa_i\right) = \frac{1}{1 + \exp(-\kappa_i + x_j\beta)} - \frac{1}{1 + \exp(-\kappa_{i-1} + x_j\beta)} \]

\(\kappa_0\) is defined as \(-\infty\) and \(\kappa_k\) as \(+\infty\).

For ordered probit, the probability of a given observation is

\[ p_{ij} = Pr(y_j = i) = Pr\left(\kappa_{i-1} < x_j\beta + u \leq \kappa_i\right) = \Phi\left(\kappa_i - x_j\beta\right) - \Phi\left(\kappa_{i-1} - x_j\beta\right) \]

where \(\Phi(\cdot)\) is the standard normal cumulative distribution function.

The log likelihood is

\[ \ln L = \sum_{j=1}^{N} \sum_{i=1}^{k} \ln p_{ij} \]

where \(w_j\) is an optional weight and

\[ I_i(y_j) = \begin{cases} 1, & \text{if } y_j = i \\ 0, & \text{otherwise} \end{cases} \]

ologit and oprobit support the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \texttt{[P] \_robust}, particularly Maximum likelihood estimators and Methods and formulas.

These commands also support estimation with survey data. For details on VCEs with survey data, see \texttt{[SVY] variance estimation}.

Syntax for predict

predict [type] { stub* | newvar | newvarlist } [if] [in] [, statistic
outcome(outcome) nooffset]

predict [type] { stub* | newvarlist } [if] [in], scores

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>predicted probabilities; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

If you do not specify outcome(), pr (with one new variable specified) assumes outcome(#1).
You specify one or k new variables with pr, where k is the number of outcomes.
You specify one new variable with xb and stdp.
These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for
the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

pr, the default, calculates the predicted probabilities. If you do not also specify the outcome() option, you specify k new variables, where k is the number of categories of the dependent variable. Say that you fit a model by typing ologit result x1 x2, and result takes on three values. Then you could type predict p1 p2 p3 to obtain all three predicted probabilities. If you specify the outcome() option, you must specify one new variable. Say that result takes on the values 1, 2, and 3. Typing predict p1, outcome(1) would produce the same p1.

xb calculates the linear prediction. You specify one new variable, for example, predict linear, xb. The linear prediction is defined, ignoring the contribution of the estimated cutpoints.

stdp calculates the standard error of the linear prediction. You specify one new variable, for example, predict se, stdp.

outcome(outcome) specifies for which outcome the predicted probabilities are to be calculated. outcome() should contain either one value of the dependent variable or one of #1, #2, ..., with #1 meaning the first category of the dependent variable, #2 meaning the second category, etc.

nooffset is relevant only if you specified offset(varname) for ologit. It modifies the calculations made by predict so that they ignore the offset variable; the linear prediction is treated as x_jb rather than as x_jb + offset_j.
scores calculates equation-level score variables. The number of score variables created will equal
the number of outcomes in the model. If the number of outcomes in the model was \( k \), then
the first new variable will contain \( \frac{\partial \ln L}{\partial (x_j b)} \);
the second new variable will contain \( \frac{\partial \ln L}{\partial \kappa_1} \);
the third new variable will contain \( \frac{\partial \ln L}{\partial \kappa_2} \);
... and the \( k \)th new variable will contain \( \frac{\partial \ln L}{\partial \kappa_{k-1}} \), where \( \kappa_i \) refers to the \( i \)th cutpoint.

Remarks and examples

See [U] 20 Estimation and postestimation commands for instructions on obtaining the variance–
covariance matrix of the estimators, predicted values, and hypothesis tests. Also see [R] lrtest for
performing likelihood-ratio tests.

Example 1

In example 2 of [R] ologit, we fit the model ologit rep77 foreign length mpg. The predict
command can be used to obtain the predicted probabilities.

We type predict followed by the names of the new variables to hold the predicted probabilities,
ordering the names from low to high. In our data, the lowest outcome is “poor”, and the highest is
“excellent”. We have five categories, so we must type five names following predict; the choice of
names is up to us:

```
use http://www.stata-press.com/data/r13/fullauto
(Automobile Models)
. ologit rep77 foreign length mpg
(output omitted)
. predict poor fair avg good exc
(option pr assumed; predicted probabilities)
. list exc good make model rep78 if rep77>=., sep(4) divider
```

<table>
<thead>
<tr>
<th></th>
<th>exc</th>
<th>good</th>
<th>make</th>
<th>model</th>
<th>rep78</th>
</tr>

<td>57</td>
<td>0.0261461</td>
<td>0.2371926</td>
<td>Plym.</td>
<td>Sapporo</td>
<td>.</td>
</tr>
</tbody>
</table>

The eight cars listed were introduced after 1977, so they do not have 1977 repair records in our data.
We predicted what their 1977 repair records might have been using the fitted model. We see that,
based on its characteristics, the Peugeot 604 had about a 41.65 + 6.53 ≈ 48.2% chance of a good or
excellent repair record. The Ford Fiesta, which had only a 3% chance of a good or excellent repair
record, in fact, had a good record when it was introduced in the following year.
Technical note

For ordered logit, `predict, xb` produces \[ S_j = x_{1j}\beta_1 + x_{2j}\beta_2 + \cdots + x_{kj}\beta_k. \] The ordered-logit predictions are then the probability that \( S_j + u_j \) lies between a pair of cutpoints, \( \kappa_{i-1} \) and \( \kappa_i \). Some handy formulas are

\[
\begin{align*}
\Pr(S_j + u_j < \kappa) &= 1/(1 + e^{S_j-\kappa}) \\
\Pr(S_j + u_j > \kappa) &= 1 - 1/(1 + e^{S_j-\kappa}) \\
\Pr(\kappa_1 < S_j + u_j < \kappa_2) &= 1/(1 + e^{S_j-\kappa_2}) - 1/(1 + e^{S_j-\kappa_1})
\end{align*}
\]

Rather than using `predict` directly, we could calculate the predicted probabilities by hand. If we wished to obtain the predicted probability that the repair record is excellent and the probability that it is good, we look back at `ologit`’s output to obtain the cutpoints. We find that “good” corresponds to the interval \(/cut3 < S_j + u < /cut4\) and “excellent” to the interval \( S_j + u > /cut4\):

\[
\begin{align*}
\text{. predict score, xb} \\
\text{. generate probgood = 1/(1+exp(score_-b[/cut4])) - 1/(1+exp(score_-b[/cut3]))} \\
\text{. generate probexc = 1 - 1/(1+exp(score_-b[/cut4]))}
\end{align*}
\]

The results of our calculation will be the same as those produced in the previous example. We refer to the estimated cutpoints just as we would any coefficient, so \( _b[/cut3] \) refers to the value of the \(/cut3 \) coefficient; see [U] 13.5 Accessing coefficients and standard errors.

### Remarks and examples

by is allowed; see [D] by.

aweights and fweights are allowed; see [U] 11.1.6 weight.

### Menu

Statistics > Linear models and related > ANOVA/MANOVA > One-way ANOVA

### Description

The oneway command reports one-way analysis-of-variance (ANOVA) models and performs multiple-comparison tests.

If you wish to fit more complicated ANOVA layouts or wish to fit analysis-of-covariance (ANCOVA) models, see [R] anova.

See [D] encode for examples of fitting ANOVA models on string variables.

See [R] loneway for an alternative oneway command with slightly different features.
### Options

**bonferroni** reports the results of a Bonferroni multiple-comparison test.

**scheffe** reports the results of a Scheffé multiple-comparison test.

**sidak** reports the results of a Šidák multiple-comparison test.

**tabulate** produces a table of summary statistics of the `response_var` by levels of the `factor_var`. The table includes the mean, standard deviation, frequency, and, if the data are weighted, the number of observations. Individual elements of the table may be included or suppressed by using the `[no]means`, `[no]standard`, `[no]freq`, and `[no]obs` options. For example, typing

```
oneway response factor, tabulate means standard
```

produces a summary table that contains only the means and standard deviations. You could achieve the same result by typing

```
oneway response factor, tabulate nofreq
```

[no]means includes or suppresses only the means from the table produced by the `tabulate` option. See `tabulate` above.

[no]standard includes or suppresses only the standard deviations from the table produced by the `tabulate` option. See `tabulate` above.

[no]freq includes or suppresses only the frequencies from the table produced by the `tabulate` option. See `tabulate` above.

[no]obs includes or suppresses only the reported number of observations from the table produced by the `tabulate` option. If the data are not weighted, only the frequency is reported. If the data are weighted, the frequency refers to the sum of the weights. See `tabulate` above.

**noanova** suppresses the display of the ANOVA table.

**nolabel** causes the numeric codes to be displayed rather than the value labels in the ANOVA and multiple-comparison test tables.

**wrap** requests that Stata not break up wide tables to make them more readable.

**missing** requests that missing values of `factor_var` be treated as a category rather than as observations to be omitted from the analysis.

### Remarks and examples

Remarks are presented under the following headings:

- **Introduction**
- **Obtaining observed means**
- **Multiple-comparison tests**
- **Weighted data**
- **Video example**

### Introduction

The `oneway` command reports one-way ANOVA models. To perform a one-way layout of a variable called `endog` on `exog`, type `oneway endog exog`. 
Example 1

We run an experiment varying the amount of fertilizer used in growing apple trees. We test four concentrations, using each concentration in three groves of 12 trees each. Later in the year, we measure the average weight of the fruit.

If all had gone well, we would have had 3 observations on the average weight for each of the four concentrations. Instead, two of the groves were mistakenly leveled by a confused man on a large bulldozer. We are left with the following dataset:

```
. use http://www.stata-press.com/data/r13/apple
         (Apple trees)
. describe
    obs: 10   Apple trees
    vars: 2   16 Jan 2013 11:23
    size: 100

storage  display variable name      type    format  value          variable label
          label
--- --------------------------------- -------- --------- --------------- ---------------
treatment int          %8.0g Fertilizer
weight    double       %10.0g Average weight in grams

Sorted by:
. list, abbreviate(10)

<table>
<thead>
<tr>
<th>treatment</th>
<th>weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>117.5</td>
</tr>
<tr>
<td>2</td>
<td>113.8</td>
</tr>
<tr>
<td>3</td>
<td>104.4</td>
</tr>
<tr>
<td>4</td>
<td>48.9</td>
</tr>
<tr>
<td>5</td>
<td>50.4</td>
</tr>
<tr>
<td>6</td>
<td>58.9</td>

<tr>
<td>8</td>
<td>86.9</td>
</tr>
<tr>
<td>9</td>
<td>87.7</td>
</tr>
<tr>
<td>10</td>
<td>67.3</td>
</tr>
</tbody>
</table>
```

To obtain the one-way ANOVA results, we type

```
. oneway weight treatment
```

```
Analysis of Variance
Source   SS       df  MS      F      Prob > F
Between groups 5295.54433  3  1765.18144 21.46 0.0013
Within groups 493.591667  6  82.2652778
Total 5789.136  9  643.237333
```

Bartlett’s test for equal variances: chi2(3) = 1.3900 Prob>chi2 = 0.708

We find significant (at better than the 1% level) differences among the four concentrations.
Technical note

Rather than using the `oneway` command, we could have performed this analysis by using `anova`. Example 1 in [R] `anova` repeats this same analysis. You may wish to compare the output.

You will find the `oneway` command quicker than the `anova` command, and, as you will learn, `oneway` allows you to perform multiple-comparison tests. On the other hand, `anova` will let you generate predictions, examine the covariance matrix of the estimators, and perform more general hypothesis tests.

Technical note

Although the output is a usual ANOVA table, let’s run through it anyway. The between-group sum of squares for the model is 5295.5 with 3 degrees of freedom, resulting in a mean square of $5295.5/3 \approx 1765.2$. The corresponding $F$ statistic is 21.46 and has a significance level of 0.0013. Thus the model appears to be significant at the 0.13% level.

The second line summarizes the within-group (residual) variation. The within-group sum of squares is 493.59 with 6 degrees of freedom, resulting in a mean squared error of 82.27.

The between- and residual-group variations sum to the total sum of squares (TSS), which is reported as 5789.1 in the last line of the table. This is the TSS of weight after removal of the mean. Similarly, the between plus residual degrees of freedom sum to the total degrees of freedom, 9. Remember that there are 10 observations. Subtracting 1 for the mean, we are left with 9 total degrees of freedom.

At the bottom of the table, Bartlett’s test for equal variances is reported. The value of the statistic is 1.39. The corresponding significance level ($\chi^2$ with 3 degrees of freedom) is 0.708, so we cannot reject the assumption that the variances are homogeneous.

Obtaining observed means

Example 2

We typed `oneway weight treatment` to obtain an ANOVA table of weight of fruit by fertilizer concentration. Although we obtained the table, we obtained no information on which fertilizer seems to work the best. If we add the `tabulate` option, we obtain that additional information:

```
. oneway weight treatment, tabulate
```

<table>
<thead>

</tbody>
</table>

Bartlett’s test for equal variances: chi2(3) = 1.3900 Prob>chi2 = 0.708
We find that the average weight was largest when we used fertilizer concentration 1.

---

**Multiple-comparison tests**

> Example 3: Bonferroni multiple-comparison test

_oneway_ can also perform multiple-comparison tests using either Bonferroni, Scheffé, or Šidák normalizations. For instance, to obtain the Bonferroni multiple-comparison test, we specify the `bonferroni` option:

```plaintext
oneway weight treatment, bonferroni
```

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Between groups</td>
<td>5295.54433</td>
<td>3</td>
<td>1765.18144</td>
<td>21.46</td>
<td>0.0013</td>
</tr>
<tr>
<td>Within groups</td>
<td>493.591667</td>
<td>6</td>
<td>82.2652778</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Total</strong></td>
<td><strong>5789.136</strong></td>
<td>9</td>
<td><strong>643.237333</strong></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Bartlett’s test for equal variances: ch2(3) = 1.3900 Prob>ch2 = 0.708

Comparison of Average weight in grams by Fertilizer (Bonferroni)

<table>
<thead>
<tr>
<th>Row Mean - Col Mean</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
</tr>
<tr>
<td>2</td>
</tr>
<tr>
<td>3</td>
</tr>
<tr>
<td>4</td>
</tr>
</tbody>
</table>

The results of the Bonferroni test are presented as a matrix. The first entry, −59.17, represents the difference between fertilizer concentrations 2 and 1 (labeled “Row Mean − Col Mean” in the upper stub of the table). Remember that in the previous example we requested the `tabulate` option. Looking back, we find that the means of concentrations 1 and 2 are 111.90 and 52.73, respectively. Thus $52.73 - 111.90 = -59.17$.

Underneath that number is reported “0.001”. This is the Bonferroni-adjusted significance of the difference. The difference is significant at the 0.1% level. Looking down the column, we see that concentration 3 is also worse than concentration 1 (4.2% level), as is concentration 4 (3.6% level).

On the basis of this evidence, we would use concentration 1 if we grew apple trees.

---

> Example 4: Scheffé multiple-comparison test

We can just as easily obtain the Scheffé-adjusted significance levels. Rather than specifying the `bonferroni` option, we specify the `scheffe` option.
We will also add the `noanova` option to prevent Stata from redisplaying the `ANOVA` table:

```
. oneway weight treatment, noanova scheffe
```

### Comparison of Average weight in grams by Fertilizer (Scheffe)

<table>
<thead>
<tr>
<th>Row Mean-</th>
<th>Col Mean</th>
<th>1</th>
<th>2</th>
<th>3</th>
</tr>
</thead>
<tbody>
<tr>
<td>2</td>
<td>-59.1667</td>
<td>0.001</td>
<td></td>
<td></td>
</tr>
<tr>
<td>3</td>
<td>-33.25</td>
<td>25.9167</td>
<td>0.039</td>
<td>0.101</td>
</tr>
<tr>
<td>4</td>
<td>-34.4</td>
<td>24.7667</td>
<td>-1.15</td>
<td>0.034</td>
</tr>
</tbody>
</table>

The differences are the same as those we obtained in the Bonferroni output, but the significance levels are not. According to the Bonferroni-adjusted numbers, the significance of the difference between fertilizer concentrations 1 and 3 is 4.2%. The Scheffé-adjusted significance level is 3.9%.

We will leave it to you to decide which results are more accurate.

Example 5: Šidák multiple-comparison test

Let’s conclude this example by obtaining the Šidák-adjusted multiple-comparison tests. We do this to illustrate Stata’s capabilities to calculate these results, because searching across adjustment methods until you find the results you want is not a valid technique for obtaining significance levels.

```
. oneway weight treatment, noanova sidak
```

### Comparison of Average weight in grams by Fertilizer (Sidak)

<table>
<thead>
<tr>
<th>Row Mean-</th>
<th>Col Mean</th>
<th>1</th>
<th>2</th>
<th>3</th>
</tr>
</thead>
<tbody>
<tr>
<td>2</td>
<td>-59.1667</td>
<td>0.001</td>
<td></td>
<td></td>
</tr>
<tr>
<td>3</td>
<td>-33.25</td>
<td>25.9167</td>
<td>0.041</td>
<td>0.116</td>
</tr>
<tr>
<td>4</td>
<td>-34.4</td>
<td>24.7667</td>
<td>-1.15</td>
<td>0.035</td>
</tr>
</tbody>
</table>

We find results that are similar to the Bonferroni-adjusted numbers.

Henry Scheffé (1907–1977) was born in New York. He studied mathematics at the University of Wisconsin, gaining a doctorate with a dissertation on differential equations. He taught mathematics at Wisconsin, Oregon State University, and Reed College, but his interests changed to statistics and he joined Wilks at Princeton. After periods at Syracuse, UCLA, and Columbia, Scheffé settled in Berkeley from 1953. His research increasingly focused on linear models and particularly ANOVA, on which he produced a celebrated monograph. His death was the result of a bicycle accident.
Weighted data

Example 6

`oneway` can work with both weighted and unweighted data. Let’s assume that we wish to perform a one-way layout of the death rate on the four census regions of the United States using state data. Our data contain three variables, `drate` (the death rate), `region` (the region), and `pop` (the population of the state).

To fit the model, we type `oneway drate region [weight=pop]`, although we typically abbreviate `weight` as `w`. We will also add the `tabulate` option to demonstrate how the table of summary statistics differs for weighted data:

```stata
use http://www.stata-press.com/data/r13/census8
(1980 Census data by state)
.oneway drate region [w=pop], tabulate
(analytic weights assumed)
```

<table>
<thead>

<td></td>
<td></td>
</tr>
</tbody>
</table>

Bartlett’s test for equal variances: chi2(3) = 5.4971  Prob>chi2 = 0.139

When the data are weighted, the summary table has four columns rather than three. The column labeled “Freq.” reports the sum of the weights. The overall frequency is $2.259 \times 10^8$, meaning that there are approximately 226 million people in the United States.

The ANOVA table is appropriately weighted. Also see [U] 11.1.6 weight.

Video example

One-way ANOVA in Stata
oneway — One-way analysis of variance

Stored results

oneway stores the following in r():

Scalars

| r(N)     | number of observations | r(df_m) | between-group degrees of freedom |
| r(F)     | F statistic            | r(rss)  | within-group sum of squares     |
| r(df_r)  | within-group degrees of freedom | r(chi2bart) | Bartlett’s χ² |
| r(mss)   | between-group sum of squares | r(df_bart) | Bartlett’s degrees of freedom |

Methods and formulas

Methods and formulas are presented under the following headings:

One-way analysis of variance
Bartlett’s test
Multiple-comparison tests

One-way analysis of variance

The model of one-way ANOVA is

\[ y_{ij} = \mu + \alpha_i + \epsilon_{ij} \]

for levels \( i = 1, \ldots, k \) and observations \( j = 1, \ldots, n_i \). Define \( \overline{y}_j \) as the (weighted) mean of \( y_{ij} \) over \( j \) and \( \overline{y} \) as the overall (weighted) mean of \( y_{ij} \). Define \( w_{ij} \) as the weight associated with \( y_{ij} \), which is 1 if the data are unweighted. \( w_{ij} \) is normalized to sum to \( n = \sum_i n_i \) if aweights are used and is otherwise not normalized. \( w_i \) refers to \( \sum_j w_{ij} \), and \( w \) refers to \( \sum_i w_i \).

The between-group sum of squares is then

\[ S_1 = \sum_i w_i (\overline{y}_i - \overline{y})^2 \]

The TSS is

\[ S = \sum_i \sum_j w_{ij} (y_{ij} - \overline{y})^2 \]

The within-group sum of squares is given by \( S_e = S - S_1 \).

The between-group mean square is \( s_1^2 = S_1/(k-1) \), and the within-group mean square is \( s_e^2 = S_e/(w-k) \). The test statistic is \( F = s_1^2/s_e^2 \). See, for instance, Snedecor and Cochran (1989).

Bartlett’s test

Bartlett’s test assumes that you have \( m \) independent, normal, random samples and tests the hypothesis \( \sigma_1^2 = \sigma_2^2 = \cdots = \sigma_m^2 \). The test statistic, \( M \), is defined as

\[
M = \frac{(T - m) \ln \tilde{\sigma}^2 - \sum (T_i - 1) \ln \tilde{\sigma}_i^2}{1 + \frac{1}{3(m-1)} \left\{ \left( \sum \frac{1}{T_i - 1} \right) - \frac{1}{T - m} \right\}}
\]
where there are $T$ overall observations, $T_i$ observations in the $i$th group, and

$$(T_i - 1)\hat{\sigma}_i^2 = \sum_{j=1}^{T_i} (y_{ij} - \overline{y}_i)^2$$

$$(T - m)\hat{\sigma}^2 = \sum_{i=1}^{m} (T_i - 1)\hat{\sigma}_i^2$$

An approximate test of the homogeneity of variance is based on the statistic $M$ with critical values obtained from the $\chi^2$ distribution of $m - 1$ degrees of freedom. See Bartlett (1937) or Draper and Smith (1998, 56–57).

**Multiple-comparison tests**

Let’s begin by reviewing the logic behind these adjustments. The “standard” $t$ statistic for the comparison of two means is

$$t = \frac{\overline{y}_i - \overline{y}_j}{s \sqrt{\frac{1}{n_i} + \frac{1}{n_j}}}$$

where $s$ is the overall standard deviation, $\overline{y}_i$ is the measured average of $y$ in group $i$, and $n_i$ is the number of observations in the group. We perform hypothesis tests by calculating this $t$ statistic. We simultaneously choose a critical level, $\alpha$, and look up the $t$ statistic corresponding to that level in a table. We reject the hypothesis if our calculated $t$ exceeds the value we looked up. Alternatively, because we have a computer at our disposal, we calculate the significance level $e$ corresponding to our calculated $t$ statistic, and if $e < \alpha$, we reject the hypothesis.

This logic works well when we are performing one test. Now consider what happens when we perform several separate tests, say, $n$ of them. Let’s assume, just for discussion, that we set $\alpha$ equal to 0.05 and that we will perform six tests. For each test, we have a 0.05 probability of falsely rejecting the equality-of-means hypothesis. Overall, then, our chances of falsely rejecting at least one of the hypotheses is $1 - (1 - 0.05)^6 \approx 0.26$ if the tests are independent.

The idea behind multiple-comparison tests is to control for the fact that we will perform multiple tests and to reduce our overall chances of falsely rejecting each hypothesis to $\alpha$ rather than letting our chances increase with each additional test. (See Miller [1981] and Hochberg and Tamhane [1987] for rather advanced texts on multiple-comparison procedures.)

The Bonferroni adjustment (see Miller [1981]; also see van Belle et al. [2004, 534–537]) does this by (falsely but approximately) asserting that the critical level we should use, $a$, is the true critical level, $\alpha$, divided by the number of tests, $n$; that is, $a = \alpha/n$. For instance, if we are going to perform six tests, each at the 0.05 significance level, we want to adopt a critical level of $0.05/6 \approx 0.00833$.

We can just as easily apply this logic to $e$, the significance level associated with our $t$ statistic, as to our critical level $\alpha$. If a comparison has a calculated significance of $e$, then its “real” significance, adjusted for the fact of $n$ comparisons, is $n \times e$. If a comparison has a significance level of, say, 0.012, and we perform six tests, then its “real” significance is 0.072. If we adopt a critical level of 0.05, we cannot reject the hypothesis. If we adopt a critical level of 0.10, we can reject it.

Of course, this calculation can go above 1, but that just means that there is no $\alpha < 1$ for which we could reject the hypothesis. (This situation arises because of the crude nature of the Bonferroni adjustment.) Stata handles this case by simply calling the significance level 1. Thus the formula for the Bonferroni significance level is

$$e_b = \min(1, en)$$

where $n = k(k - 1)/2$ is the number of comparisons.
The Šidák adjustment (Šidák [1967]; also see Winer, Brown, and Michels [1991, 165–166]) is slightly different and provides a tighter bound. It starts with the assertion that

\[ a = 1 - (1 - \alpha)^{1/n} \]

Turning this formula around and substituting calculated significance levels, we obtain

\[ e_s = \min\left\{ 1, 1 - (1 - e)^n \right\} \]

For example, if the calculated significance is 0.012 and we perform six tests, the “real” significance is approximately 0.07.

The Scheffé test (Scheffé [1953, 1959]; also see Kuehl [2000, 97–98]) differs in derivation, but it attacks the same problem. Let there be \( k \) means for which we want to make all the pairwise tests. Two means are declared significantly different if

\[ t \geq \sqrt{(k - 1)F(\alpha; k - 1, \nu)} \]

where \( F(\alpha; k - 1, \nu) \) is the \( \alpha \)-critical value of the \( F \) distribution with \( k - 1 \) numerator and \( \nu \) denominator degrees of freedom. Scheffé’s test has the nicety that it never declares a contrast significant if the overall \( F \) test is not significant.

Turning the test around, Stata calculates a significance level

\[ \hat{e} = F\left( \frac{t^2}{k - 1}, k - 1, \nu \right) \]

For instance, you have a calculated \( t \) statistic of 4.0 with 50 degrees of freedom. The simple \( t \) test says that the significance level is 0.00021. The \( F \) test equivalent, 16 with 1 and 50 degrees of freedom, says the same. If you are comparing three means, however, you calculate an \( F \) test of 8.0 with 2 and 50 degrees of freedom, which says that the significance level is 0.0010.

Menu

Statistics > Ordinal outcomes > Ordered probit regression
oprobit — Ordered probit regression

Description

oprobit fits ordered probit models of ordinal variable depvar on the independent variables indepvars. The actual values taken on by the dependent variable are irrelevant, except that larger values are assumed to correspond to “higher” outcomes.

See [R] logistic for a list of related estimation commands.

Options

Model

offset(varname), constraints(constraints), collinear; see [R] estimation options.

SE/Robust

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting

level(#) ; see [R] estimation options.
nocnsreport ; see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch ; see [R] estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no] log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), itolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs) ; see [R] maximize. These options are seldom used.

The following option is available with oprobit but is not shown in the dialog box:

coeflegend ; see [R] estimation options.

Remarks and examples

An ordered probit model is used to estimate relationships between an ordinal dependent variable and a set of independent variables. An ordinal variable is a variable that is categorical and ordered, for instance, “poor”, “good”, and “excellent”, which might indicate a person’s current health status or the repair record of a car. If there are only two outcomes, see [R] logistic, [R] logit, and [R] probit. This entry is concerned only with more than two outcomes. If the outcomes cannot be ordered (for example, residency in the north, east, south, or west), see [R] mlogit. This entry is concerned only with models in which the outcomes can be ordered.
In ordered probit, an underlying score is estimated as a linear function of the independent variables and a set of cutpoints. The probability of observing outcome $i$ corresponds to the probability that the estimated linear function, plus random error, is within the range of the cutpoints estimated for the outcome:

$$\Pr(\text{outcome}_j = i) = \Pr(\kappa_{i-1} < \beta_1 x_{1j} + \beta_2 x_{2j} + \cdots + \beta_k x_{kj} + u_j \leq \kappa_i)$$

$u_j$ is assumed to be normally distributed. In either case, we estimate the coefficients $\beta_1$, $\beta_2$, ..., $\beta_k$ together with the cutpoints $\kappa_1$, $\kappa_2$, ..., $\kappa_{I-1}$, where $I$ is the number of possible outcomes. $\kappa_0$ is taken as $-\infty$, and $\kappa_I$ is taken as $+\infty$. All of this is a direct generalization of the ordinary two-outcome probit model.

**Example 1**

In example 2 of [R] ologit, we use a variation of the automobile dataset (see [U] 1.2.2 Example datasets) to analyze the 1977 repair records of 66 foreign and domestic cars. We use ordered logit to explore the relationship of rep77 in terms of foreign (origin of manufacture), length (a proxy for size), and mpg. Here we fit the same model using ordered probit rather than ordered logit:

```stata
. oprobit rep77 foreign length mpg
Iteration 0: log likelihood = -89.895098
Iteration 1: log likelihood = -78.106316
Iteration 2: log likelihood = -78.020086
Iteration 3: log likelihood = -78.020025
Iteration 4: log likelihood = -78.020025
```

Ordered probit regression

|            | Coef.  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|------------|--------|-----------|-------|------|---------------------|
| rep77      |        |           |       |      |                     |
| foreign    | 1.704861 | .4246796 | 4.01  | 0.000 | .8725037 - 2.537217 |
| length     | .0468675 | .012648 | 3.71  | 0.000 | .022078 - .0716571  |
| mpg        | .1304559 | .0378628 | 3.45  | 0.001 | .0562463 - .2046656 |
| /cut1      | 10.1589 | 3.076754 | 4.13  | 0.000 | 16.18923            |
| /cut2      | 11.21003 | 3.107527 | 5.19  | 0.000 | 17.30067            |
| /cut3      | 12.54561 | 3.155233 | 5.11  | 0.000 | 18.72975            |
| /cut4      | 13.98059 | 3.218793 | 5.85  | 0.000 | 20.28931            |

We find that foreign cars have better repair records, as do larger cars and cars with better mileage ratings.
**Stored results**

oprobit stores the following in **e()**:

**Scalars**
- `e(N)` number of observations
- `e(N_cd)` number of completely determined observations
- `e(k_cat)` number of categories
- `e(k)` number of parameters
- `e(k_aux)` number of auxiliary parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(r2_p)` pseudo-$R^2$-squared
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(p)` significance of model test
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

**Macros**
- `e(cmd)` oprobit
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(offset)` linear offset variable
- `e(chi2type)` Wald or LR; type of model $\chi^2$ test
- `e(vce)` vcetype specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` max or min; whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of ml method
- `e(user)` name of likelihood-evaluator program
- `e(technique)` maximization technique
- `e(properties)` b V
- `e(predict)` program used to implement predict
- `e(asbalanced)` factor variables fvset as asbalanced
- `e(asobserved)` factor variables fvset as asobserved

**Matrices**
- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(ilog)` iteration log (up to 20 iterations)
- `e(gradient)` gradient vector
- `e(cat)` category values
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

**Functions**
- `e(sample)` marks estimation sample

2. `lrtest` is not appropriate with `svy` estimation results.
Syntax for predict

```
predict [type] { stub* | newvar | newvarlist } [ if ] [ in ] [ , statistic
    outcome(outcome) nooffset ]
```

```
predict [type] { stub* | newvarlist } [ if ] [ in ] , scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>predicted probabilities; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

If you do not specify outcome(), pr (with one new variable specified) assumes outcome(#1).
You specify one or k new variables with pr, where k is the number of outcomes.
You specify one new variable with xb and stdp.
These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

Main

- **pr**, the default, calculates the predicted probabilities. If you do not also specify the outcome() option, you specify k new variables, where k is the number of categories of the dependent variable. Say that you fit a model by typing `oprobit result x1 x2`, and result takes on three values. Then you could type `predict p1 p2 p3` to obtain all three predicted probabilities. If you specify the outcome() option, you must specify one new variable. Say that result takes on values 1, 2, and 3. Typing `predict p1, outcome(1)` would produce the same p1.

- **xb** calculates the linear prediction. You specify one new variable, for example, `predict linear, xb`. The linear prediction is defined, ignoring the contribution of the estimated cutpoints.

- **stdp** calculates the standard error of the linear prediction. You specify one new variable, for example, `predict se, stdp`.

outcome(outcome) specifies for which outcome the predicted probabilities are to be calculated. outcome() should contain either one value of the dependent variable or one of #1, #2, ..., with #1 meaning the first category of the dependent variable, #2 meaning the second category, etc.

nooffset is relevant only if you specified offset(varname) for oprobit. It modifies the calculations made by predict so that they ignore the offset variable; the linear prediction is treated as $x_j b$ rather than as $x_j b + \text{offset}_j$. 

scores calculates equation-level score variables. The number of score variables created will equal the number of outcomes in the model. If the number of outcomes in the model was $k$, then the first new variable will contain $\frac{\partial \ln L}{\partial (x_j b)}$; the second new variable will contain $\frac{\partial \ln L}{\partial \kappa_1}$; the third new variable will contain $\frac{\partial \ln L}{\partial \kappa_2}$; ...

and the $k$th new variable will contain $\frac{\partial \ln L}{\partial \kappa_{k-1}}$, where $\kappa_i$ refers to the $i$th cutpoint.

**Remarks and examples**

See [U] 20 Estimation and postestimation commands for instructions on obtaining the variance-covariance matrix of the estimators, predicted values, and hypothesis tests. Also see [R] lrtest for performing likelihood-ratio tests.

Example 1

In example 1 of [R] oprobit, we fit the model oprobit rep77 foreign length mpg. The predict command can be used to obtain the predicted probabilities. We type predict followed by the names of the new variables to hold the predicted probabilities, ordering the names from low to high. In our data, the lowest outcome is “poor” and the highest is “excellent”. We have five categories, so we must type five names following predict; the choice of names is up to us:

```
use http://www.stata-press.com/data/r13/fullauto
(opassword Models)
oprobit rep77 foreign length mpg
(output omitted)
predict poor fair avg good exc
(option pr assumed; predicted probabilities)
list make model exc good if rep77>=., sep(4) divider
```

<table>
<thead>

Technical note

For ordered probit, predict, xb produces \( S_j = x_1j\beta_1 + x_2j\beta_2 + \cdots + x_kj\beta_k \). Ordered probit is identical to ordered logit, except that we use different distribution functions for calculating probabilities. The ordered-probit predictions are then the probability that \( S_j + u_j \) lies between a pair of cutpoints \( \kappa_{i-1} \) and \( \kappa_i \). The formulas for ordered probit are

\[
\begin{align*}
Pr(S_j + u < \kappa) &= \Phi(\kappa - S_j) \\
Pr(S_j + u > \kappa) &= 1 - \Phi(\kappa - S_j) = \Phi(S_j - \kappa) \\
Pr(\kappa_1 < S_j + u < \kappa_2) &= \Phi(\kappa_2 - S_j) - \Phi(\kappa_1 - S_j)
\end{align*}
\]

Rather than using predict directly, we could calculate the predicted probabilities by hand.

\[
\begin{align*}
&\text{. predict pscore, xb} \\
&\text{. generate probexc = normal(pscore-_b[/cut4])} \\
&\text{. generate probgood = normal(_b[/cut4]-pscore) - normal(_b[/cut3]-pscore)}
\end{align*}
\]

[U] 20 Estimation and postestimation commands
Orthogonalize variables and compute orthogonal polynomials

### Syntax

**Orthogonalize variables**

```plaintext
orthog [varlist] [if] [in] [weight], generate(newvarlist) [matrix(matname)]
```

**Compute orthogonal polynomial**

```plaintext
orthopoly varname [if] [in] [weight],
   { generate(newvarlist) | poly(matname) } [degree(#)]]
```

**orthopoly** requires that `generate(newvarlist)` or `poly(matname)`, or both, be specified.

`varlist` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`iweights`, `aweights`, `fweights`, and `pweights` are allowed, see [U] 11.1.6 weight.

### Menu

- **orthog**
  - Data > Create or change data > Other variable-creation commands > Orthogonalize variables
- **orthopoly**
  - Data > Create or change data > Other variable-creation commands > Orthogonal polynomials

### Description

`orthog` orthogonalizes a set of variables, creating a new set of orthogonal variables (all of type `double`), using a modified Gram–Schmidt procedure (Golub and Van Loan 1996). The order of the variables determines the orthogonalization; hence, the “most important” variables should be listed first.

Execution time is proportional to the square of the number of variables. With many (>10) variables, `orthog` will be fairly slow.

`orthopoly` computes orthogonal polynomials for one variable.

### Options for orthog

- `generate(newvarlist)` is required. `generate()` creates new orthogonal variables of type `double`. For `orthog`, `newvarlist` will contain the orthogonalized `varlist`. If `varlist` contains `d` variables, then so will `newvarlist`. `newvarlist` can be specified by giving a list of exactly `d` new variable names, or it can be abbreviated using the styles `newvar1-newvar#` or `newvar*`. For these two styles of abbreviation, new variables `newvar1`, `newvar2`, ..., `newvar#` are generated.
**orthog** — Orthogonalize variables and compute orthogonal polynomials

matrix(matname) creates a \((d+1) \times (d+1)\) matrix containing the matrix \(R\) defined by \(X = QR\), where \(X\) is the \(N \times (d+1)\) matrix representation of \(varlist\) plus a column of ones and \(Q\) is the \(N \times (d+1)\) matrix representation of \(newvarlist\) plus a column of ones \((d = \text{number of variables in } varlist, \text{ and } N = \text{number of observations})\).

**Options for orthpoly**

- **generate(newvarlist)** or **poly()**, or both, must be specified. **generate()** creates new orthogonal variables of type double. **newvarlist** will contain orthogonal polynomials of degree 1, 2, ..., \(d\) evaluated at \(varname\), where \(d\) is as specified by **degree(d)**. **newvarlist** can be specified by giving a list of exactly \(d\) new variable names, or it can be abbreviated using the styles **newvar1-newvar\(d\)** or **newvar\(*\)**. For these two styles of abbreviation, new variables **newvar\(1\)**, **newvar\(2\)**, ..., **newvar\(d\)** are generated.

- **poly(matname)** creates a \((d+1) \times (d+1)\) matrix called **matname** containing the coefficients of the orthogonal polynomials. The orthogonal polynomial of degree \(i \leq d\) is

\[
\text{matname}[i, d+1] + \text{matname}[i, 1]\*\text{varname} + \text{matname}[i, 2]\*\text{varname}^2 \\
+ \cdots + \text{matname}[i, i]\*\text{varname}^i
\]

The coefficients corresponding to the constant term are placed in the last column of the matrix. The last row of the matrix is all zeros, except for the last column, which corresponds to the constant term.

- **degree(#)** specifies the highest-degree polynomial to include. Orthogonal polynomials of degree 1, 2, ..., \(d = #\) are computed. The default is \(d = 1\).

**Remarks and examples**

Orthogonal variables are useful for two reasons. The first is numerical accuracy for highly collinear variables. Stata’s **regress** and other estimation commands can face much collinearity and still produce accurate results. But, at some point, these commands will drop variables because of collinearity. If you know with certainty that the variables are not perfectly collinear, you may want to retain all their effects in the model. If you use **orthog** or **orthopoly** to produce a set of orthogonal variables, all variables will be present in the estimation results.

Users are more likely to find orthogonal variables useful for the second reason: ease of interpreting results. **orthog** and **orthopoly** create a set of variables such that the “effects” of all the preceding variables have been removed from each variable. For example, if we issue the command

```
. orthog x1 x2 x3, generate(q1 q2 q3)
```

the effect of the constant is removed from \(x1\) to produce \(q1\); the constant and \(x1\) are removed from \(x2\) to produce \(q2\); and finally the constant, \(x1\), and \(x2\) are removed from \(x3\) to produce \(q3\). Hence,

\[
q1 = r_{01} + r_{11} x1 \\
q2 = r_{02} + r_{12} x1 + r_{22} x2 \\
q3 = r_{03} + r_{13} x1 + r_{23} x2 + r_{33} x3
\]

This effect can be generalized and written in matrix notation as

\[
X = QR
\]
where $X$ is the $N \times (d + 1)$ matrix representation of $\text{varlist}$ plus a column of ones, and $Q$ is the $N \times (d + 1)$ matrix representation of $\text{newvarlist}$ plus a column of ones ($d =$ number of variables in $\text{varlist}$ and $N =$ number of observations). The $(d + 1) \times (d + 1)$ matrix $R$ is a permuted upper-triangular matrix, that is, $R$ would be upper triangular if the constant were first, but the constant is last, so the first row/column has been permuted with the last row/column. Because Stata’s estimation commands list the constant term last, this allows $R$, obtained via the $\text{matrix()}$ option, to be used to transform estimation results.

### Example 1: orthog

Consider Stata’s auto.dta dataset. Suppose that we postulate a model in which $\text{price}$ depends on the car’s $\text{length}$, $\text{weight}$, $\text{headroom}$, and trunk size ($\text{trunk}$). These predictors are collinear, but not extremely so—the correlations are not that close to 1:

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. correlate length weight headroom trunk
   (obs=74)

<table>
<thead>
<tr>
<th></th>
<th>length</th>
<th>weight</th>
<th>headroom</th>
<th>trunk</th>
</tr>
</thead>
<tbody>
<tr>
<td>length</td>
<td>1.0000</td>
<td>0.9460</td>
<td>0.5163</td>
<td>0.7266</td>
</tr>
<tr>
<td>weight</td>
<td>1.0000</td>
<td>1.0000</td>
<td>0.4835</td>
<td>0.6722</td>
</tr>
<tr>
<td>headroom</td>
<td>1.0000</td>
<td>1.0000</td>
<td>1.0000</td>
<td>1.0000</td>
</tr>
<tr>
<td>trunk</td>
<td>1.0000</td>
<td>1.0000</td>
<td>1.0000</td>
<td>1.0000</td>
</tr>
</tbody>
</table>
```

The `regress` command certainly has no trouble fitting this model:

```
. regress price length weight headroom trunk

Source | SS           | df | MS           | Number of obs = 74
Model   | 236016580    | 4  | 59004145     | F(  4,  69) = 10.20 Prob > F = 0.0000
Residual| 399048816    | 69 | 5783316.17   | R-squared = 0.3716
         | 635065396    | 73 | 8699525.97   | Adj R-squared = 0.3352
Total   | 635065396    | 73 | 8699525.97   | Root MSE = 2404.9

| price | Coef. | Std. Err. | t     | P>|t| | [95% Conf. Interval]|
|-------|-------|-----------|-------|-----|-------------------|
| length| -101.7092 | 42.12534 | -2.41 | 0.018 | -185.747 | -17.67147|
| weight| 4.753066  | 1.120054 | 4.24  | 0.000 | 2.518619 | 6.987512 |
| headroom| -711.5679 | 445.0204 | -1.60 | 0.114 | -1599.359 | 176.2236 |
| trunk | 114.0859  | 109.9488 | 1.04  | 0.303 | -105.2559 | 333.4277 |
| _cons | 11488.47  | 4543.902 | 2.53  | 0.014 | 2423.638 | 20553.31 |
```

However, we may believe a priori that $\text{length}$ is the most important predictor, followed by $\text{weight}$, $\text{headroom}$, and $\text{trunk}$. We would like to remove the “effect” of $\text{length}$ from all the other predictors, remove $\text{weight}$ from $\text{headroom}$ and $\text{trunk}$, and remove $\text{headroom}$ from $\text{trunk}$. We can do this by running `orthog`, and then we fit the model again using the orthogonal variables:
. orthog length weight headroom trunk, gen(olength oweight oheadroom otrunk)
> matrix(R)
. regress price olength oweight oheadroom otrunk

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>236016580</td>
<td>4</td>
<td>59004145</td>
<td>F( 4, 69) = 10.20</td>
</tr>
<tr>
<td>Residual</td>
<td>399048816</td>
<td>69</td>
<td>5783316.17</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Total</td>
<td>635065396</td>
<td>73</td>
<td>8699525.97</td>
<td>R-squared = 0.3716</td>
</tr>
</tbody>
</table>

Adj R-squared = 0.3352

| price | Coef. | Std. Err. | t    | P>|t|    | [95% Conf. Interval] |
|-------|-------|-----------|------|--------|---------------------|
| olength | 1265.049 | 279.5584 | 4.53 | 0.000  | 707.3454 1822.753 |
| oweight | 1175.765 | 279.5584 | 4.21 | 0.000  | 618.0617 1733.469 |
| oheadroom | -349.9916 | 279.5584 | -1.25 | 0.215  | -907.6955 207.7122 |
| otrunk | 290.0776 | 279.5584 | 1.04 | 0.303  | -267.6262 847.7815 |
| _cons  | 6165.257  | 279.5584 | 22.05 | 0.000  | 5607.553 6722.961 |

Using the matrix R, we can transform the results obtained using the orthogonal predictors back to the metric of original predictors:

. matrix b = e(b)*inv(R)'
. matrix list b

<table>
<thead>
<tr>
<th>b[1,5]</th>
<th>length</th>
<th>weight</th>
<th>headroom</th>
<th>trunk</th>
<th>_cons</th>
</tr>
</thead>
<tbody>
<tr>
<td>y1</td>
<td>-101.70924</td>
<td>4.7530659</td>
<td>-711.56789</td>
<td>114.08591</td>
<td>11488.475</td>
</tr>
</tbody>
</table>

## Technical note

The matrix R obtained using the matrix() option with orthog can also be used to recover X (the original varlist) from Q (the orthogonalized newvarlist), one variable at a time. Continuing with the previous example, we illustrate how to recover the trunk variable:

. matrix C = R[1...,"trunk"]'
. matrix score double rtrunk = C
. compare rtrunk trunk

<table>
<thead>
<tr>
<th>difference</th>
<th>count</th>
<th>minimum</th>
<th>average</th>
<th>maximum</th>
</tr>
</thead>
<tbody>
<tr>
<td>rtrunk&gt;trunk</td>
<td>74</td>
<td>1.42e-14</td>
<td>2.27e-14</td>
<td>3.55e-14</td>
</tr>
<tr>
<td>jointly defined</td>
<td>74</td>
<td>1.42e-14</td>
<td>2.27e-14</td>
<td>3.55e-14</td>
</tr>
<tr>
<td>total</td>
<td>74</td>
<td>1.42e-14</td>
<td>2.27e-14</td>
<td>3.55e-14</td>
</tr>
</tbody>
</table>

Here the recovered variable rtrunk is almost exactly the same as the original trunk variable. When you are orthogonalizing many variables, this procedure can be performed to check the numerical soundness of the orthogonalization. Because of the ordering of the orthogonalization procedure, the last variable and the variables near the end of the varlist are the most important ones to check.

The orthpoly command effectively does for polynomial terms what the orthog command does for an arbitrary set of variables.
Example 2: orthpoly

Again consider the auto.dta dataset. Suppose that we wish to fit the model

\[ mpg = \beta_0 + \beta_1 \text{weight} + \beta_2 \text{weight}^2 + \beta_3 \text{weight}^3 + \beta_4 \text{weight}^4 + \epsilon \]

We will first compute the regression with natural polynomials:

```
. gen double w1 = weight
. gen double w2 = w1*w1
. gen double w3 = w2*w1
. gen double w4 = w3*w1
. correlate w1-w4
(obs=74)

         w1     w2     w3     w4
     w1  1.0000
     w2  0.9915  1.0000
     w3  0.9665  0.9916  1.0000
     w4  0.9279  0.9679  0.9922  1.0000
```

```
. regress mpg w1-w4

Source | SS      | df  | MS
-------+---------+-----+---------
Model   | 1652.74 | 4   | 413.18  
Residual| 790.72  | 69  | 11.46   
Total   | 2443.46 | 73  | 33.47   

mpg    | Coef.   | Std. Err. | t   | P>|t|  | [95% Conf. Interval] 
-------+---------+------------+-----+-------+-----------------------------------
     w1  | 0.0289  | 0.1162     | 0.25| 0.804 | -0.2028704 to 0.2607307           
     w2  | -0.0000 | 0.0006     | -0.40| 0.687 | -0.0001359 to 0.0000901           
     w3  | 5.74e-09| 1.19e-08   | 0.48| 0.631 | -1.80e-08 to 2.95e-08             
     w4  | -4.86e-13| 9.14e-13  | -0.53| 0.596 | -2.31e-12 to 1.34e-12             
_\text{cons}| 23.94   | 86.61      | 0.28| 0.783 | -148.83 to 196.71                 
```

Some of the correlations among the powers of weight are very large, but this does not create any problems for regress. However, we may wish to look at the quadratic trend with the constant removed, the cubic trend with the quadratic and constant removed, etc. orthpoly will generate polynomial terms with this property:

```
. orthpoly weight, generate(pw*) deg(4) poly(P)
. regress mpg pw1-pw4
```

```
mpg    | Coef.   | Std. Err. | t   | P>|t|  | [95% Conf. Interval] 
-------+---------+------------+-----+-------+-----------------------------------
pw1    | -4.64   | 0.39       | -11.79| 0.000 | -5.42 to -3.85                  
pw2    | 0.83    | 0.39       | 2.10 | 0.039 | 0.042 to 1.61                   
pw3    | -3.07   | 0.39       | -0.78| 0.438 | -1.09 to 0.78                   
pw4    | -2.09   | 0.39       | -0.53| 0.596 | -0.99 to 0.58                   
_\text{cons}| 21.29  | 0.39       | 54.12| 0.000 | 20.51 to 22.08                  
```
Compare the \( p \)-values of the terms in the natural polynomial regression with those in the orthogonal polynomial regression. With orthogonal polynomials, it is easy to see that the pure cubic and quartic trends are not significant and that the constant, linear, and quadratic terms each have \( p < 0.05 \).

The matrix \( P \) obtained with the `poly()` option can be used to transform coefficients for orthogonal polynomials to coefficients for natural polynomials:

```
. orthpoly weight, poly(P) deg(4)
. matrix b = e(b)*P
. matrix list b
b[1,5]      deg1         deg2         deg3         deg4        _cons
y1  .02893016  -.00002291  5.745e-09  -4.862e-13  23.944212
```

**Methods and formulas**

`orthog`’s orthogonalization can be written in matrix notation as

\[
X = QR
\]

where \( X \) is the \( N \times (d + 1) \) matrix representation of `varlist` plus a column of ones and \( Q \) is the \( N \times (d + 1) \) matrix representation of `newvarlist` plus a column of ones (\( d \) = number of variables in `varlist`, and \( N \) = number of observations). The \( (d + 1) \times (d + 1) \) matrix \( R \) is a permuted upper-triangular matrix; that is, \( R \) would be upper triangular if the constant were first, but the constant is last, so the first row/column has been permuted with the last row/column.

\( Q \) and \( R \) are obtained using a modified Gram–Schmidt procedure; see Golub and Van Loan (1996, 218–219) for details. The traditional Gram–Schmidt procedure is notoriously unsound, but the modified procedure is good. `orthog` performs two passes of this procedure.

`orthopoly` uses the Christoffel–Darboux recurrence formula (Abramowitz and Stegun 1972).

Both `orthog` and `orthopoly` normalize the orthogonal variables such that

\[
Q'WQ = MI
\]

where \( W = \text{diag}(w_1, w_2, \ldots, w_N) \) with weights \( w_1, w_2, \ldots, w_N \) (all 1 if weights are not specified), and \( M \) is the sum of the weights (the number of observations if weights are not specified).

[R] `regress` — Linear regression
**pcorr** — Partial and semipartial correlation coefficients

### Syntax
```
pcorr varname1 varlist [if] [in] [weight]
```

*varname1* and *varlist* may contain time-series operators; see [U] 11.4.4 Time-series varlists. by is allowed; see [D] by.

aweights and fweights are allowed; see [U] 11.1.6 weight.

### Menu
Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Partial correlations

### Description
`pcorr` displays the partial and semipartial correlation coefficients of *varname* with each variable in *varlist* after removing the effects of all other variables in *varlist*. The squared correlations and corresponding significance are also reported.

### Remarks and examples
Assume that *y* is determined by *x*₁, *x*₂, ..., *x*ₖ. The partial correlation between *y* and *x*₁ is an attempt to estimate the correlation that would be observed between *y* and *x*₁ if the other *x*’s did not vary. The semipartial correlation, also called part correlation, between *y* and *x*₁ is an attempt to estimate the correlation that would be observed between *y* and *x*₁ after the effects of all other *x*’s are removed from *x*₁ but not from *y*.

Both squared correlations estimate the proportion of the variance of *y* that is explained by each predictor. The squared semipartial correlation between *y* and *x*₁ represents the proportion of variance in *y* that is explained by *x*₁ only. This squared correlation can also be interpreted as the decrease in the model’s $R^2$ value that results from removing *x*₁ from the full model. Thus one could use the squared semipartial correlations as criteria for model selection. The squared partial correlation between *y* and *x*₁ represents the proportion of variance in *y* not associated with any other *x*’s that is explained by *x*₁. Thus the squared partial correlation gives an estimate of how much of the variance of *y* not explained by the other *x*’s is explained by *x*₁.

### Example 1
Using our automobile dataset (described in [U] 1.2.2 Example datasets), we can obtain the simple correlations between price, mpg, weight, and foreign from `correlate` (see [R] correlate):
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. correlate price mpg weight foreign
   (obs=74)

<table>
<thead>
<tr>
<th></th>
<th>price</th>
<th>mpg</th>
<th>weight</th>
<th>foreign</th>
</tr>
</thead>
<tbody>
<tr>
<td>price</td>
<td>1.0000</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>mpg</td>
<td>-0.4686</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>weight</td>
<td>0.5386</td>
<td>-0.8072</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td>foreign</td>
<td>0.0487</td>
<td>0.3934</td>
<td>-0.5928</td>
<td>1.0000</td>
</tr>
</tbody>
</table>

Although correlate gave us the full correlation matrix, our interest is in just the first column. We find, for instance, that the higher the mpg, the lower the price. We obtain the partial and semipartial correlation coefficients by using pcorr:

. pcorr price mpg weight foreign
   (obs=74)

<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>0.0352</td>
<td>0.0249</td>
<td>0.0012</td>
<td>0.0006</td>
<td>0.7693</td>
</tr>
<tr>
<td>weight</td>
<td>0.5488</td>
<td>0.4644</td>
<td>0.3012</td>
<td>0.2157</td>
<td>0.0000</td>
</tr>
<tr>
<td>foreign</td>
<td>0.5402</td>
<td>0.4541</td>
<td>0.2918</td>
<td>0.2062</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

We now find that the partial and semipartial correlations of price with mpg are near 0. In the simple correlations, we found that price and foreign were virtually uncorrelated. In the partial and semipartial correlations, we find that price and foreign are positively correlated. The nonsignificance of mpg tells us that the amount in which $R^2$ decreases by removing mpg from the model is not significant. We find that removing either weight or foreign results in a significant drop in the $R^2$ of the model.

Technical note

Use caution when interpreting the above results. As we said at the outset, the partial and semipartial correlation coefficients are an attempt to estimate the correlation that would be observed if the effects of all other variables were taken out of both $y$ and $x$ or only $x$. pcorr makes it too easy to ignore the fact that we are fitting a model. In the example above, the model is

$$price = \beta_0 + \beta_1 mpg + \beta_2 weight + \beta_3 foreign + \epsilon$$

which is, in all honesty, a rather silly model. Even if we accept the implied economic assumptions of the model—that consumers value mpg, weight, and foreign—do we really believe that consumers place equal value on every extra 1,000 pounds of weight? That is, have we correctly parameterized the model? If we have not, then the estimated partial and semipartial correlation coefficients may not represent what they claim to represent. Partial and semipartial correlation coefficients are a reasonable way to summarize data if we are convinced that the underlying model is reasonable. We should not, however, pretend that there is no underlying model and that these correlation coefficients are unaffected by the assumptions and parameterization.
Stored results

`pcorr` stores the following in `r()`:

 Scalars
  `r(N)` number of observations
  `r(df)` degrees of freedom

 Matrices
  `r(p_corr)` partial correlation coefficient vector
  `r(sp_corr)` semipartial correlation coefficient vector

Methods and formulas

Results are obtained by fitting a linear regression of `varname_1` on `varlist`; see `[R] regress`. The partial correlation coefficient between `varname_1` and each variable in `varlist` is then calculated as

\[
\frac{t}{\sqrt{t^2 + n - k}}
\]

(Greene 2012, 37), where \( t \) is the \( t \) statistic, \( n \) is the number of observations, and \( k \) is the number of independent variables, including the constant but excluding any dropped variables.

The semipartial correlation coefficient between `varname_1` and each variable in `varlist` is calculated as

\[
\text{sign}(t)\sqrt{\frac{t^2(1-R^2)}{n-k}}
\]

(Cohen et al. 2003, 89), where \( R^2 \) is the model \( R^2 \) value, and \( t \), \( n \), and \( k \) are as described above.

The significance is given by \( 2\Pr(t_{n-k} > |t|) \), where \( t_{n-k} \) follows a Student’s \( t \) distribution with \( n - k \) degrees of freedom.

Acknowledgment

The addition of semipartial correlation coefficients to `pcorr` is based on the `pcorr2` command by Richard Williams of the Department of Sociology at the University of Notre Dame.

---

1573
permute estimates p-values for permutation tests on the basis of Monte Carlo simulations. Typing

`. permute permvar exp_list, reps(#): command`

randomly permutes the values in `permvar` # times, each time executing `command` and collecting the associated values from the expression in `exp_list`.

These p-value estimates can be one-sided: \( \Pr(T^* \leq T) \) or \( \Pr(T^* \geq T) \). The default is two-sided: \( \Pr(|T^*| \geq |T|) \). Here \( T^* \) denotes the value of the statistic from a randomly permuted dataset, and \( T \) denotes the statistic as computed on the original data.

`permvar` identifies the variable whose observed values will be randomly permuted.
*command* defines the statistical command to be executed. Most Stata commands and user-written programs can be used with *permute*, as long as they follow standard Stata syntax; see [U] 11 Language syntax. The by prefix may not be part of *command*.

*exp_list* specifies the statistics to be collected from the execution of *command*.

*permute* may be used for replaying results, but this feature is appropriate only when a dataset generated by *permute* is currently in memory or is identified by the *using* option. The variables specified in *varlist* in this context must be present in the respective dataset.

**Options**

- **Main**
  - `reps(#)` specifies the number of random permutations to perform. The default is 100.
  - `left` or `right` requests that one-sided *p*-values be computed. If `left` is specified, an estimate of \( \Pr(T^* \leq T) \) is produced, where \( T^* \) is the test statistic and \( T \) is its observed value. If `right` is specified, an estimate of \( \Pr(T^* \geq T) \) is produced. By default, two-sided *p*-values are computed; that is, \( \Pr(|T^*| \geq |T|) \) is estimated.

- **Options**
  - `strata(varlist)` specifies that the permutations be performed within each stratum defined by the values of `varlist`.
  - `saving(filename [, suboptions])` creates a Stata data file (.dta file) consisting of (for each statistic in `exp_list`) a variable containing the replicates.
    - `double` specifies that the results for each replication be saved as doubles, meaning 8-byte reals. By default, they are saved as floats, meaning 4-byte reals.
    - `every(#)` specifies that results are to be written to disk every #th replication. `every()` should be specified only in conjunction with `saving()` when *command* takes a long time for each replication. This will allow recovery of partial results should some other software crash your computer. See [P] postfile.
    - `replace` specifies that `filename` be overwritten if it exists. This option does not appear in the dialog box.

- **Reporting**
  - `level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by *set level*; see [R] level.
  - `noheader` suppresses display of the table header. This option implies the `nolegend` option.
  - `nolegend` suppresses display of the table legend. The table legend identifies the rows of the table with the expressions they represent.
  - `verbose` requests that the full table legend be displayed. By default, coefficients and standard errors are not displayed.
  - `nodrop` prevents *permute* from dropping observations outside the if and in qualifiers. `nodrop` will also cause *permute* to ignore the contents of *e(sample)* if it exists as a result of running *command*. By default, *permute* temporarily drops out-of-sample observations.
nodots suppresses display of the replication dots. By default, one dot character is displayed for each successful replication. A red ‘x’ is displayed if command returns an error or if one of the values in exp_list is missing.

noisily requests that any output from command be displayed. This option implies the nodots option.

trace causes a trace of the execution of command to be displayed. This option implies the noisily option.

title(text) specifies a title to be displayed above the table of permutation results; the default title is Monte Carlo permutation results.

eps(#) specifies the numerical tolerance for testing $|T^*| \geq |T|$, $T^* \leq T$, or $T^* \geq T$. These are considered true if, respectively, $|T^*| \geq |T| - #$, $T^* \leq T + #$, or $T^* \geq T - #$. The default is 1e-7. You will not have to specify eps() under normal circumstances.

nowarn suppresses the printing of a warning message when command does not set e(sample).

force suppresses the restriction that command may not specify weights or be a svy command. permute is not suited for weighted estimation, thus permute should not be used with weights or svy. permute reports an error when it encounters weights or svy in command if the force option is not specified. This is a seldom used option, so use it only if you know what you are doing!

reject(exp) identifies an expression that indicates when results should be rejected. When exp is true, the resulting values are reset to missing values.

seed(#) sets the random-number seed. Specifying this option is equivalent to typing the following command prior to calling permute:

```
    . set seed #
```

Remarks and examples

Permutation tests determine the significance of the observed value of a test statistic in light of rearranging the order (permuting) of the observed values of a variable.

Example 1: A simple two-sample test

Suppose that we conducted an experiment to determine the effect of a treatment on the development of cells. Further suppose that we are restricted to six experimental units because of the extreme cost of the experiment. Thus three units are to be given a placebo, and three units are given the treatment. The measurement is the number of newly developed healthy cells. The following listing gives the hypothetical data, along with some summary statistics.

```
. input y treatment
    y   treatment
  1.  7   0
  2.  9   0
  3. 11   0
  4. 10   1
  5. 12   1
  6. 14   1
  7.  end
. sort treatment
```
Clearly, there are more cells in the treatment group than in the placebo group, but a statistical test is needed to conclude that the treatment does affect the development of cells. If the sum of the treatment measures is our test statistic, we can use `permute` to determine the probability of observing 36 or more cells, given the observed data and assuming that there is no effect due to the treatment.

```
. set seed 1234
. permute y sum=r(sum), saving(permdish) right nodrop nowarn: sum y if treatment
   (running summarize on estimation sample)
   Permutation replications (100)
                      1    2    3    4    5
.................................................. 50
.................................................. 100
Monte Carlo permutation results Number of obs = 6
   command:  summarize y if treatment
   sum:  r(sum)
   permute var:  y

<table>
<thead>
<tr>
<th>T</th>
<th>T(obs)</th>
<th>c</th>
<th>n</th>
<th>p=c/n</th>
<th>SE(p)</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>sum</td>
<td>36</td>
<td>10</td>
<td>100</td>
<td>0.1000</td>
<td>0.0300</td>
<td>0.0490047 .1762226</td>
</tr>
</tbody>
</table>
```

Note: confidence interval is with respect to p=c/n.
Note: c = #{T >= T(obs)}

We see that 10 of the 100 randomly permuted datasets yielded sums from the treatment group larger than or equal to the observed sum of 36. Thus the evidence is not strong enough, at the 5% level, to reject the null hypothesis that there is no effect of the treatment.

Because of the small size of this experiment, we could have calculated the exact permutation p-value from all possible permutations. There are six units, but we want the sum of the treatment units. Thus there are \( \binom{6}{3} = 20 \) permutation sums from the possible unique permutations.
Two of the 20 permutation sums are greater than or equal to 36. Thus the exact \( p \)-value for this permutation test is 0.1. Tied values will decrease the number of unique permutations.

When the `saving()` option is supplied, `permute` saves the values of the permutation statistic to the indicated file, in our case, `permdish.dta`. This file can be used to replay the result of `permute`. The `level()` option controls the confidence level of the confidence interval for the permutation \( p \)-value. This confidence interval is calculated using `cii` with the reported \( n \) (number of nonmissing replications) and \( c \) (the counter for events of significance).

Example 2: Permutation tests with ANOVA

Consider some fictional data from a randomized complete-block design in which we wish to determine the significance of five treatments.

```
. use http://www.stata-press.com/data/r13/permute1, clear
. list y treatment in 1/10, abbrev(10)
```

<table>
<thead>

<td>5.904368</td>
<td>2</td>
</tr>
<tr>
<td>10</td>
<td>3.010556</td>
<td>2</td>
</tr>
</tbody>
</table>
These data may be analyzed using *anova*.

```plaintext
. anova y treatment subject
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>16.5182188</td>
<td>13</td>
<td>1.27063221</td>
<td>1.52</td>
<td>0.1574</td>
</tr>
<tr>
<td>treatment</td>
<td>13.0226706</td>
<td>9</td>
<td>1.4496341</td>
<td>1.73</td>
<td>0.1174</td>
</tr>
<tr>
<td>subject</td>
<td>3.49554813</td>
<td>4</td>
<td>0.87387032</td>
<td>1.05</td>
<td>0.3973</td>
</tr>
<tr>
<td>Residual</td>
<td>30.0847503</td>
<td>36</td>
<td>0.835687509</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>46.6029691</td>
<td>49</td>
<td>0.951081002</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Suppose that we want to compute the significance of the $F$ statistic for `treatment` by using *permute*. All we need to do is write a short program that will save the result of this statistic for *permute* to use. For example,

```plaintext
program panova, rclass
version 13
args response fac_intrst fac_other
anova 'response' 'fac_intrst' 'fac_other'
return scalar Fmodel = e(F)
test 'fac_intrst'
return scalar F = r(F)
end
```

Now in *panova*, *test* saves the $F$ statistic for the factor of interest in $r(F)$. This is different from $e(F)$, which is the overall model $F$ statistic for the model fit by *anova* that *panova* saves in $r(Fmodel)$. In the following example, we use the `strata()` option so that the treatments are randomly rearranged within each `subject`. It should not be too surprising that the estimated $p$-values are equal for this example, because the two $F$ statistics are equivalent when controlling for differences between subjects. However, we would not expect to always get the same $p$-values every time we reran *permute*.

```plaintext
. set seed 1234
. permute treatment treatmentF=r(F) modelF=e(F), reps(1000) strata(subject)
    > saving(permanova) nodots: panova y treatment subject
Monte Carlo permutation results
```

<table>
<thead>
<tr>
<th>T</th>
<th>T(obs)</th>
<th>c</th>
<th>n</th>
<th>p=c/n</th>
<th>SE(p) [95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>treatmentF</td>
<td>1.731465</td>
<td>118</td>
<td>1000</td>
<td>0.1180</td>
<td>0.0102</td>
</tr>
<tr>
<td>modelF</td>
<td>1.520463</td>
<td>118</td>
<td>1000</td>
<td>0.1180</td>
<td>0.0102</td>
</tr>
</tbody>
</table>

Note: confidence intervals are with respect to $p=c/n$.
Note: $c = \#\{|T| >= |T(obs)|\}$
Example 3: Wilcoxon rank-sum test

As a final example, let’s consider estimating the $p$-value of the $Z$ statistic returned by `ranksum`. Suppose that we collected data from some experiment: $y$ is some measure we took on 17 individuals, and `group` identifies the group that an individual belongs to.

```
use http://www.stata-press.com/data/r13/permute2
list
```

<table>
<thead>
<tr>
<th>group</th>
<th>y</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>6</td>
</tr>
<tr>
<td>2</td>
<td>11</td>
</tr>
<tr>
<td>3</td>
<td>20</td>
</tr>
<tr>
<td>4</td>
<td>2</td>
</tr>
<tr>
<td>5</td>
<td>9</td>
</tr>
<tr>
<td>6</td>
<td>5</td>
</tr>
<tr>
<td>7</td>
<td>2</td>
</tr>
<tr>
<td>8</td>
<td>1</td>
</tr>
<tr>
<td>9</td>
<td>6</td>
</tr>
<tr>
<td>10</td>
<td>0</td>
</tr>
<tr>
<td>11</td>
<td>2</td>
</tr>
<tr>
<td>12</td>
<td>3</td>
</tr>
<tr>
<td>13</td>
<td>3</td>
</tr>
<tr>
<td>14</td>
<td>12</td>
</tr>
<tr>
<td>15</td>
<td>4</td>
</tr>
<tr>
<td>16</td>
<td>1</td>
</tr>
<tr>
<td>17</td>
<td>5</td>
</tr>
</tbody>
</table>

Next we analyze the data using `ranksum` and notice that the observed value of the test statistic (stored as $r(z)$) is $-2.02$ with an approximate $p$-value of 0.0434.

```
ranksum y, by(group)
```

Two-sample Wilcoxon rank-sum (Mann-Whitney) test

<table>
<thead>
<tr>
<th>group</th>
<th>obs</th>
<th>rank sum</th>
<th>expected</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>11</td>
<td>79</td>
<td>99</td>
</tr>
<tr>
<td>1</td>
<td>6</td>
<td>74</td>
<td>54</td>
</tr>
<tr>
<td>combined</td>
<td>17</td>
<td>153</td>
<td>153</td>
</tr>
</tbody>
</table>

unadjusted variance 99.00
adjustment for ties -0.97
adjusted variance 98.03
Ho: $y(group==0) = y(group==1)$

$z = -2.020$

Prob > $|z|$ = 0.0434

The observed value of the rank-sum statistic is 79, with an expected value (under the null hypothesis of no group effect) of 99. There are 17 observations, so the permutation distribution contains $\binom{17}{6} = 12,376$ possible values of the rank-sum statistic if we ignore ties. With ties, we have fewer possible values but still too many to want to count them. Thus we use `permute` with 10,000 replications and see that the Monte Carlo permutation test agrees with the result of the test based on the normal approximation.
. set seed 18385766
. permute y z=r(z), reps(10000) nowarn nodots: ranksum y, by(group)

Monte Carlo permutation results

command:  ranksum y, by(group)

<th>SE(p) [95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>z</td>
<td>-2.020</td>
<td>468</td>
<td>10000</td>
<td>0.0468</td>
<td>0.0021 [.0427429 .0511236]</td>
</tr>
</tbody>
</table>

Note: confidence interval is with respect to p=c/n.
Note: c = #{|T| >= |T(obs)|}

For an application of a permutation test to a problem in epidemiology, see Hayes and Moulton (2009, 190–193).

Technical note

permute reports confidence intervals for p to emphasize that it is based on the binomial estimator for proportions. When the variability implied by the confidence interval makes conclusions difficult, you may increase the number of replications to determine more precisely the significance of the test statistic of interest. In other words, the value of p from permute will converge to the true permutation p-value as the number of replications gets arbitrarily large.

Stored results

permute stores the following in r():

Scalars
- r(N) sample size
- r(N_reps) number of requested replications
- r(level) confidence level
- r(k_exp) number of standard expressions
- r(k_eexp) number of _b/_se expressions

Macros
- r(cmd) permute
- r(command) command following colon
- r(left) left or empty
- r(right) right or empty
- r(permvar) permutation variable
- r(seed) initial random-number seed
- r(title) title in output
- r(event) T <= T(obs), T >= T(obs), or |T| <= |T(obs)|
- r(exp#) #th expression

Matrices
- r(b) observed statistics
- r(c) count when r(event) is true
- r(reps) number of nonmissing results
- r(p) observed proportions
- r(se) standard errors of observed proportions
- r(ci) confidence intervals of observed proportions

**Description**

The term pk refers to pharmacokinetic data and the Stata commands, all of which begin with the letters pk, designed to do some of the analyses commonly performed in the pharmaceutical industry. The system is intended for the analysis of pharmacokinetic data, although some of the commands are for general use.

The pk commands are

- **pkexamine** [R] **pkexamine** Calculate pharmacokinetic measures
- **pksumm** [R] **pksumm** Summarize pharmacokinetic data
- **pkshape** [R] **pkshape** Reshape (pharmacokinetic) Latin-square data
- **pkcross** [R] **pkcross** Analyze crossover experiments
- **pkequiv** [R] **pkequiv** Perform bioequivalence tests
- **pkcollapse** [R] **pkcollapse** Generate pharmacokinetic measurement dataset

**Remarks and examples**

Several types of clinical trials are commonly performed in the pharmaceutical industry. Examples include combination trials, multicenter trials, equivalence trials, and active control trials. For each type of trial, there is an optimal study design for estimating the effects of interest. Currently, the pk system can be used to analyze equivalence trials, which are usually conducted using a crossover design; however, it is possible to use a parallel design and still draw conclusions about equivalence.

Equivalence trials assess bioequivalence between two drugs. Although proving that two drugs behave the same is impossible, the United States Food and Drug Administration believes that if the absorption properties of two drugs are similar, the two drugs will produce similar effects and have similar safety profiles. Generally, the goal of an equivalence trial is to assess the equivalence of a generic drug to an existing drug. This goal is commonly accomplished by comparing a confidence interval about the difference between a pharmacokinetic measurement of two drugs with a confidence limit constructed from U.S. federal regulations. If the confidence interval is entirely within the confidence limit, the drugs are declared bioequivalent. Another approach to assessing bioequivalence is to use the method of interval hypotheses testing. pkequiv is used to conduct these tests of bioequivalence.

Several pharmacokinetic measures can be used to ascertain how available a drug is for cellular absorption. The most common measure is the area under the time-versus-concentration curve (AUC). Another common measure of drug availability is the maximum concentration ($C_{\text{max}}$) achieved by the drug during the follow-up period. Stata reports these and other less common measures of drug availability, including the time at which the maximum drug concentration was observed and the duration of the period during which the subject was being measured. Stata also reports the elimination rate, that is, the rate at which the drug is metabolized, and the drug’s half-life, that is, the time it takes for the drug concentration to fall to one-half of its maximum concentration.
pkexamine computes and reports all the pharmacokinetic measures that Stata produces, including four calculations of the area under the time-versus-concentration curve. The standard area under the curve from 0 to the maximum observed time ($\text{AUC}_{0,t_{\text{max}}}$) is computed using cubic splines or the trapezoidal rule. Additionally, pkexamine also computes the area under the curve from 0 to infinity by extending the standard time-versus-concentration curve from the maximum observed time by using three different methods. The first method simply extends the standard curve by using a least-squares linear fit through the last few data points. The second method extends the standard curve by fitting a decreasing exponential curve through the last few data points. Finally, the third method extends the curve by fitting a least-squares linear regression line on the log concentration. The mathematical details of these extensions are described in Methods and formulas of [R] pkexamine.

Data from an equivalence trial may also be analyzed using methods appropriate to the particular study design. When you have a crossover design, pkcross can be used to fit an appropriate ANOVA model. As an aside, a crossover design is simply a restricted Latin square; therefore, pkcross can also be used to analyze any Latin-square design.

There are some practical concerns when dealing with data from equivalence trials. Primarily, the data must be organized in a manner that Stata can use. The pk commands include pkcollapse and pkshape, which are designed to help transform data from a common format to one that is suitable for analysis with Stata.

In the following example, we illustrate several different data formats that are often encountered in pharmaceutical research and describe how these formats can be transformed to formats that can be analyzed with Stata.

Example 1

Assume that we have one subject and are interested in determining the drug profile for that subject. A reasonable experiment would be to give the subject the drug and then measure the concentration of the drug in the subject’s blood over a given period. For example, here is a part of a dataset from Chow and Liu (2009, 13):

```
. use http://www.stata-press.com/data/r13/auc
. list, abbrev(14)
```

</tbody>
</table>

Examining these data, we notice that the concentration quickly increases, plateaus for a short period, and then slowly decreases over time. pkexamine is used to calculate the pharmacokinetic measures of interest. pkexamine is explained in detail in [R] pkexamine. The output is
pk — Pharmacokinetic (biopharmaceutical) data

Fit based on last 3 points.

Clinical trials, however, require that data be collected on more than one subject. There are several ways to enter raw measured data collected on several subjects. It would be reasonable to enter for each subject the drug concentration value at specific points in time. Such data could be

<table>
<thead>
<tr>
<th>id</th>
<th>conc1</th>

</tr>
</tbody>
</table>

where conc1 is the concentration at the first measured time, conc2 is the concentration at the second measured time, etc. This format requires that each drug concentration measurement be made at the same time on each subject. Another more flexible way to enter the data is to have an observation with three variables for each time measurement on a subject. Each observation would have a subject ID, the time at which the measurement was made, and the corresponding drug concentration at that time. The data would be
Stata expects the data to be organized in the second form. If your data are organized as described in the first dataset, you will need to use `reshape` to change the data to the second form; see [D] reshape. Because the data in the second (or long) format contain information for one drug on several subjects, `pksumm` can be used to produce summary statistics of the pharmacokinetic measurements. The output is

```
. pksumm id time concA
...............  
```

Until now, we have been concerned with the profile of only one drug. We have characterized the profile of that drug by individual subjects by using \texttt{pkexamine} and by a group of subjects by using \texttt{pksumm}. The goal of an equivalence trial, however, is to compare two drugs, which we will do in the rest of this example.

For equivalence trials, the study design most often used is the crossover design. For a complete discussion of crossover designs, see Ratkowsky, Evans, and Alldredge (1993).

In brief, crossover designs require that each subject be given both treatments at two different times. The order in which the treatments are applied changes between groups. For example, if we had 20 subjects numbered 1–20, the first 10 would receive treatment A during the first period of the study, and then they would be given treatment B. The second 10 subjects would be given treatment B during the first period of the study, and then they would be given treatment A. Each subject in the study will have four variables that describe the observation: a subject identifier, a sequence identifier that indicates the order of treatment, and two outcome variables, one for each treatment. The outcome variables for each subject are the pharmacokinetic measures. The data must be transformed from a series of measurements on individual subjects to data containing the pharmacokinetic measures for each subject. In Stata parlance, this is referred to as a collapse, which can be done with \texttt{pkcollapse}; see \texttt{[R] pkcollapse}.

\end{verbatim}
This format is similar to the second format described above, except that now we have measurements for two drugs at each time for each subject. We transform these data with `pkcollapse`:

```
. pkcollapse time concA concB, id(id) keep(seq) stat(auc)
```

```
1. 1 1 150.9643 218.5551
2. 2 1 146.7606 133.3201
3. 3 1 160.6548 126.0635
4. 4 1 157.8622 96.17461
5. 5 1 133.6957 188.9038
6. 7 1 160.639 223.6922
7. 8 1 131.2604 104.0139
8. 9 1 168.5186 237.8962
9. 10 2 137.0627 139.7382
10. 12 2 153.4038 202.3942
11. 13 2 163.4593 136.7848
12. 14 2 146.0462 104.5191
13. 15 2 158.1457 165.8654
14. 18 2 147.1977 139.235
15. 19 2 164.9988 166.2391
16. 20 2 145.3823 158.5146
```

For this example, we chose to use the AUC for two drugs as our pharmacokinetic measure. We could have used any of the measures computed by `pkexamine`. In addition to the AUCs, the dataset also contains a sequence variable for each subject indicating when each treatment was administered.

The data produced by `pkcollapse` are in what Stata calls wide format; that is, there is one observation per subject containing two or more outcomes. To use `pkcross` and `pkequiv`, we need to transform these data to long format. This goal can be accomplished using `pkshape`; see [R] `pkshape`.

Consider the first subject in the dataset. This subject is in sequence one, which means that treatment A was applied during the first period of the study and treatment B was applied in the second period of the study. We need to split the first observation into two observations so that the outcome measure is only in one variable. Also we need two new variables, one indicating the treatment the subject received and another recording the period of the study when the subject received that treatment. We might expect the expansion of the first subject to be

```
<table>
<thead>
<tr>
<th>id</th>
<th>sequence</th>
<th>auc</th>
<th>treat</th>
<th>period</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>150.9643</td>
<td>A</td>
<td>1</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>218.5551</td>
<td>B</td>
<td>2</td>
</tr>
</tbody>
</table>
```

We see that subject number 1 was in sequence 1, had an AUC of 150.9643 when treatment A was applied in the first period of the study, and had an AUC of 218.5551 when treatment B was applied.

Similarly, the expansion of subject 10 (the first subject in sequence 2) would be

```
<table>
<thead>
<tr>
<th>id</th>
<th>sequence</th>
<th>auc</th>
<th>treat</th>
<th>period</th>
</tr>
</thead>
<tbody>
<tr>
<td>10</td>
<td>2</td>
<td>137.0627</td>
<td>B</td>
<td>1</td>
</tr>
<tr>
<td>10</td>
<td>2</td>
<td>139.7382</td>
<td>A</td>
<td>2</td>
</tr>
</tbody>
</table>
```

Here treatment B was applied to the subject during the first period of the study, and treatment A was applied to the subject during the second period of the study.

An additional complication is common in crossover study designs. The treatment applied in the first period of the study might still have some effect on the outcome in the second period. In this example,
each subject was given one treatment followed by another treatment. To get accurate estimates of
treatment effects, it is necessary to account for the effect that the first treatment has in the second
period of the study. This is called the carryover effect. We must, therefore, have a variable that
indicates which treatment was applied in the first treatment period. `pkshape` creates a variable that
indicates the carryover effect. For treatments applied during the first treatment period, there will never
be a carryover effect. Thus the expanded data created by `pkshape` for subject 1 will be

<table>
<thead>
<tr>
<th>id</th>
<th>sequence</th>
<th>outcome</th>
<th>treat</th>
<th>period</th>
<th>carry</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>150.9643</td>
<td>A</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>218.5551</td>
<td>B</td>
<td>2</td>
<td>A</td>
</tr>
</tbody>
</table>

and the data for subject 10 will be

<table>
<thead>
<tr>
<th>id</th>
<th>sequence</th>
<th>outcome</th>
<th>treat</th>
<th>period</th>
<th>carry</th>
</tr>
</thead>
<tbody>
<tr>
<td>10</td>
<td>2</td>
<td>137.0627</td>
<td>B</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>10</td>
<td>2</td>
<td>139.7382</td>
<td>A</td>
<td>2</td>
<td>B</td>
</tr>
</tbody>
</table>

We `pkshape` the data:

```plaintext
. pkshape id seq auc*, order(ab ba)
. sort id sequence period
. list, sep(16)
```

<table>
<thead>
<tr>
<th>id</th>
<th>sequence</th>
<th>outcome</th>
<th>treat</th>

</tr>
<tr>
<td>16</td>
<td>9</td>
<td>237.8962</td>
<td>B</td>
<td>2</td>
<td>1</td>
</tr>
</tbody>
</table>

As an aside, crossover designs do not require that each subject receive each treatment, but if they
do, the crossover design is referred to as a complete crossover design.
The last dataset is organized in a manner that can be analyzed with Stata. To fit an ANOVA model to these data, we can use `anova` or `pkcross`. To conduct equivalence tests, we can use `pkequiv`. This example is further analyzed in [R] `pkcross` and [R] `pkequiv`.

References

Syntax

```
pkcollapse time concentration [if], id(id_var) [options]
```

### Description

**Main**

- `id(id_var)`: subject ID variable
- `stat(measures)`: create specified `measures`; default is all
- `trapezoid`: use trapezoidal rule; default is cubic splines
- `fit(#)`: use `#` points to estimate $AUC_{0,\infty}$; default is `fit(3)`
- `keep(varlist)`: keep variables in `varlist`
- `force`: force collapse
- `nodots`: suppress dots during calculation

*`id(id_var)` is required.

Menu

- Statistics > Epidemiology and related > Other > Generate pharmacokinetic measurement dataset

Description

`pkcollapse` generates new variables with the pharmacokinetic summary measures of interest. `pkcollapse` is one of the pk commands. Please read [R] pk before reading this entry.
pkcollapse — Generate pharmacokinetic measurement dataset

**Options**

id(id_var) is required and specifies the variable that contains the subject ID over which pkcollapse is to operate.

stat(measures) specifies the measures to be generated. The default is to generate all the measures.

trapezoid tells Stata to use the trapezoidal rule when calculating the AUC. The default is to use cubic splines, which give better results for most functions. When the curve is irregular, trapezoid may give better results.

fit(#) specifies the number of points to use in estimating the AUC₀,∞. The default is fit(3), the last three points. This number should be viewed as a minimum; the appropriate number of points will depend on your data.

keep(varlist) specifies the variables to be kept during the collapse. Variables not specified with the keep() option will be dropped. When keep() is specified, the keep variables are checked to ensure that all values of the variables are the same within id_var.

force forces the collapse, even when the values of the keep() variables are different within id_var.

nodots suppresses the display of dots during calculation.

**Remarks and examples**

pkcollapse generates all the summary pharmacokinetic measures.

**Example 1**

We demonstrate the use of pkcollapse with the data described in [R] pk. We have drug concentration data on 15 subjects. Each subject is measured at 13 time points over a 32-hour period. Some of the records are

```
use http://www.stata-press.com/data/r13/pkdata
list, sep(0)

The resulting dataset, which we will call `pkdata2`, contains 1 observation per subject. This dataset is in wide format. If we want to use `pkcross` or `pkequiv`, we must transform these data to long format, which we do in the last example of [R] `pkshape`.

### Methods and formulas

The statistics generated by `pkcollapse` are described in [R] `pkexamine`.

### Also see

[R] `pk` — Pharmacokinetic (biopharmaceutical) data
Title

pkcross — Analyze crossover experiments

Syntax

pkcross outcome [ if ] [ in ] [, options]

options Description

Model

sequence(varname) sequence variable; default is sequence(sequence)
treatment(varname) treatment variable; default is treatment(treat)
period(varname) period variable; default is period(period)
id(varname) ID variable
carryover(varname) name of carryover variable; default is carryover(carry)
carryover(none) omit carryover effects from model; default is carryover(carry)
model(string) specify the model to fit

sequential estimate sequential instead of partial sums of squares

Parameterization

param(3) estimate mean and the period, treatment, and sequence effects;

assure no carryover effects exist; the default

param(1) estimate mean and the period, treatment, and carryover effects;

assure no sequence effects exist

param(2) estimate mean, period and treatment effects, and period-by-treatment

interaction; assume no sequence or carryover effects exist

param(4) estimate mean, period and treatment effects, and period-by-treatment

interaction; assume no period or crossover effects exist

Menu

Statistics > Epidemiology and related > Other > Analyze crossover experiments

Description

pkcross analyzes data from a crossover design experiment. When analyzing pharmaceutical trial
data, if the treatment, carryover, and sequence variables are known, the omnibus test for separability
of the treatment and carryover effects is calculated.

pkcross is one of the pk commands. Please read [R] pk before reading this entry.
Options

Model

sequence(varname) specifies the variable that contains the sequence in which the treatment was administered. If this option is not specified, sequence(sequence) is assumed.

treatment(varname) specifies the variable that contains the treatment information. If this option is not specified, treatment(treat) is assumed.

period(varname) specifies the variable that contains the period information. If this option is not specified, period(period) is assumed.

id(varname) specifies the variable that contains the subject identifiers. If this option is not specified, id(id) is assumed.

carryover(varname|none) specifies the variable that contains the carryover information. If carry(none) is specified, the carryover effects are omitted from the model. If this option is not specified, carryover(carry) is assumed.

model(string) specifies the model to be fit. For higher-order crossover designs, this option can be useful if you want to fit a model other than the default. However, anova (see [R] anova) can also be used to fit a crossover model. The default model for higher-order crossover designs is outcome predicted by sequence, period, treatment, and carryover effects. By default, the model statement is model(sequence period treat carry).

sequential specifies that sequential sums of squares be estimated.

Parameterization

param(#) specifies which of the four parameterizations to use for the analysis of a 2 × 2 crossover experiment. This option is ignored with higher-order crossover designs. The default is param(3). See the technical note for 2 × 2 crossover designs for more details.

param(3) estimates the overall mean, the period effects, the treatment effects, and the sequence effects, assuming that no carryover effects exist. This is the default parameterization.

param(1) estimates the overall mean, the period effects, the treatment effects, and the carryover effects, assuming that no sequence effects exist.

param(2) estimates the overall mean, the period effects, the treatment effects, and the period-by-treatment interaction, assuming that no sequence or carryover effects exist.

param(4) estimates the overall mean, the sequence effects, the treatment effects, and the sequence-by-treatment interaction, assuming that no period or crossover effects exist. When the sequence by treatment is equivalent to the period effect, this reduces to the third parameterization.

Remarks and examples

pkcross is designed to analyze crossover experiments. Use pkshape first to reshape your data; see [R] pkshape. pkcross assumes that the data were reshaped by pkshape or are organized in the same manner as produced with pkshape. Washout periods are indicated by the number 0. See the technical note in this entry for more information on analyzing 2 × 2 crossover experiments.
The 2 × 2 crossover design cannot be used to estimate more than four parameters because there are only four pieces of information (the four cell means) collected. `pkcross` uses ANOVA models to analyze the data, so one of the four parameters must be the overall mean of the model, leaving just 3 degrees of freedom to estimate the remaining effects (period, sequence, treatment, and carryover). Thus the model is overparameterized. Estimation of treatment and carryover effects requires the assumption of either no period effects or no sequence effects. Some researchers maintain that estimating carryover effects at the expense of other effects is a bad idea. This is a limitation of this design. `pkcross` implements four parameterizations for this model. They are numbered sequentially from one to four and are described in `Options`.

### Example 1

Consider the example data published in Chow and Liu (2009, 71) and described in [R] `pkshape`. We have entered and reshaped the data with `pkshape` and have variables that identify the subjects, periods, treatments, sequence, and carryover treatment. To compute the ANOVA table, use `pkcross`:

```stata
use http://www.stata-press.com/data/r13/chowliu
pkshape id seq period1 period2, order(ab ba)
pkcross outcome
```

Omnibus measure of separability of treatment and carryover = 29.2893%

There is evidence of intersubject variability, but there are no other significant effects. The omnibus test for separability is a measure reflecting the degree to which the study design allows the treatment effects to be estimated independently of the carryover effects. The measure of separability of the treatment and carryover effects indicates approximately 29% separability, which can be interpreted as the degree to which the treatment and carryover effects are orthogonal. This is a characteristic of the design of the study. For a complete discussion, see Ratkowsky, Evans, and Alldredge (1993). Compared to the output in Chow and Liu (2009), the sequence effect is mislabeled as a carryover effect. See Ratkowsky, Evans, and Alldredge (1993, sec. 3.2) for a complete discussion of the mislabeling.
By specifying `param(1)`, we obtain parameterization 1 for this model.

Example 2

Consider the case of a two-treatment, four-sequence, two-period crossover design. This design is commonly referred to as Balaam’s design (Balaam 1968). Ratkowsky, Evans, and Alldredge (1993, 140) published the following data from an amantadine trial, originally published by Taka and Armitage (1983):

```
use http://www.stata-press.com/data/r13/balaam, clear
list, sep(0)
```

</tbody>
</table>

The sequence identifier must be a string with zeros to indicate washout or baseline periods, or a number. If the sequence identifier is numeric, the `order` option must be specified with `pkshape`. If the sequence identifier is a string, `pkshape` will create sequence, period, and treatment identifiers without the `order` option. In this example, the dash is used to indicate a baseline period, which is an invalid code for this purpose. As a result, the data must be encoded; see [D] `encode`.

Omnibus measure of separability of treatment and carryover = 64.6447%

In this example, the sequence specifier used dashes instead of zeros to indicate a baseline period during which no treatment was given. For pkcross to work, we need to encode the string sequence variable and then use the order option with pkshape. A word of caution: encode does not necessarily choose the first sequence to be sequence 1, as in this example. Always double-check the sequence numbering when using encode.
Example 3

Continuing with the example from [R] pkshape, we fit an ANOVA model.

</table>

When the model statement is used and the omnibus measure of separability is desired, specify the variables in the `treatment()`, `carryover()`, and `sequence()` options to `pkcross`.

### Methods and formulas

`pkcross` uses ANOVA to fit models for crossover experiments; see [R] `anova`.

The omnibus measure of separability is

\[
S = 100(1 - V)\%
\]

where \( V \) is Cramér’s \( V \) and is defined as

\[
V = \left\{ \frac{\chi^2}{\min(r-1, c-1)} \right\}^{1/2}
\]

The \( \chi^2 \) is calculated as

\[
\chi^2 = \sum_i \sum_j \left\{ \frac{(O_{ij} - E_{ij})^2}{E_{ij}} \right\}
\]

where \( O \) and \( E \) are the observed and expected counts in a table of the number of times each treatment is followed by the other treatments.

**Description**

`pkequiv` performs bioequivalence testing for two treatments. By default, `pkequiv` calculates a standard confidence interval symmetric about the difference between the two treatment means. `pkequiv` also calculates confidence intervals symmetric about zero and intervals based on Fieller’s theorem. Also, `pkequiv` can perform interval hypothesis tests for bioequivalence.

`pkequiv` is one of the pk commands. Please read [R] pk before reading this entry.

**Options**

- `compare()` specifies the two treatments to be tested for equivalence. Sometimes there may be more than two treatments, but the equivalence can be determined only between any two treatments.
- `limit(#)` specifies the equivalence limit. The default is 0.2. The equivalence limit can be changed only symmetrically; that is, it is not possible to have a 0.15 lower limit and a 0.2 upper limit in the same test.
- `level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(90)`. This setting is not controlled by the `set level` command.
fieller specifies that an equivalence interval based on Fieller’s theorem be calculated.
symmetric specifies that a symmetric equivalence interval be calculated.

anderson specifies that the Anderson and Hauck (1983) hypothesis test for bioequivalence be computed.
This option is ignored when calculating equivalence intervals based on Fieller’s theorem or when calculating a confidence interval that is symmetric about zero.
tost specifies that the two one-sided hypothesis tests for bioequivalence be computed. This option is ignored when calculating equivalence intervals based on Fieller’s theorem or when calculating a confidence interval that is symmetric about zero.
noboot prevents the estimation of the probability that the confidence interval lies within the confidence limits. If this option is not specified, this probability is estimated by resampling the data.

Remarks and examples

pkequiv is designed to conduct tests for bioequivalence based on data from a crossover experiment. pkequiv requires that the user specify the outcome, treatment, period, sequence, and id variables. The data must be in the same format as that produced by pkshape; see [R] pkshape.
Example 1

We have the following data on which we want to conduct a bioequivalence test between \( \text{treat} = A \) and \( \text{treat} = B \).

```
. use http://www.stata-press.com/data/r13/pkdata3
. list, sep(4)
```

Classic confidence interval for bioequivalence

<table>
<thead>
<tr>
<th>[equivalence limits]</th>
<th>[ test limits ]</th>
</tr>
</thead>
<tbody>
<tr>
<td>difference: -30.296</td>
<td>30.296</td>
</tr>
<tr>
<td>ratio: 80%</td>
<td>120%</td>
</tr>
<tr>
<td>probability test limits are within equivalence limits = 0.6410</td>
<td></td>
</tr>
<tr>
<td>note: reference treatment = 1</td>
<td></td>
</tr>
</tbody>
</table>
The default output for `pkequiv` shows a confidence interval for the difference of the means (test limits), the ratio of the means, and the federal equivalence limits. The classic confidence interval can be constructed around the difference between the average measure of effect for the two drugs or around the ratio of the average measure of effect for the two drugs. `pkequiv` reports both the difference measure and the ratio measure. For these data, U.S. federal government regulations state that the confidence interval for the difference must be entirely contained within the range \([-30.296, 30.296]\) and between 80% and 120% for the ratio. Here the test limits are within the equivalence limits. Although the test limits are inside the equivalence limits, there is only a 64% assurance that the observed confidence interval will be within the equivalence limits in the long run. This is an interesting case because, although this sample shows bioequivalence, the evaluation of the long-run performance indicates possible problems. These fictitious data were generated with high intersubject variability, which causes poor long-run performance.

If we conduct a bioequivalence test with the data published in Chow and Liu (2009, 71), which we introduced in [R] `pk` and fully described in [R] `pkshape`, we observe that the probability that the test limits are within the equivalence limits is high.

```stata
use http://www.stata-press.com/data/r13/chowliu2
data set seed 1
pkequiv outcome treat period seq id
```

**Classic confidence interval for bioequivalence**

<table>
<thead>
<tr>
<th>Equivalence limits</th>
<th>Test limits</th>
</tr>
</thead>
<tbody>
<tr>
<td>difference:</td>
<td></td>
</tr>
<tr>
<td>-16.512</td>
<td>16.512</td>
</tr>
<tr>
<td>-8.698</td>
<td>4.123</td>
</tr>
<tr>
<td>ratio:</td>
<td></td>
</tr>
<tr>
<td>80%</td>
<td>120%</td>
</tr>
<tr>
<td>89.464%</td>
<td>104.994%</td>
</tr>
</tbody>
</table>

Probability test limits are within equivalence limits = 0.9980
note: reference treatment = 1

For these data, the test limits are well within the equivalence limits, and the probability that the test limits are within the equivalence limits is 99.8%.

**Example 2**

We compute a confidence interval that is symmetric about zero:

```stata
pkequiv outcome treat period seq id, symmetric
```

**Westlake’s symmetric confidence interval for bioequivalence**

<table>
<thead>
<tr>
<th>Equivalence limits</th>
<th>Test mean</th>
</tr>
</thead>
<tbody>
<tr>
<td>Test formulation:</td>
<td></td>
</tr>
<tr>
<td>75.145</td>
<td>89.974</td>
</tr>
<tr>
<td>80.272</td>
<td></td>
</tr>
</tbody>
</table>

Note: reference treatment = 1

The reported equivalence limit is constructed symmetrically about the reference mean, which is equivalent to constructing a confidence interval symmetric about zero for the difference in the two drugs. In the output above, we see that the test formulation mean of 80.272 is within the equivalence limits, indicating that the test drug is bioequivalent to the reference drug.
pkequiv displays interval hypothesis tests of bioequivalence if you specify the tost or the anderson option, or both. For example,

```
pkequiv outcome treat period seq id, tost anderson
```

Classic confidence interval for bioequivalence

<table>
<thead>
<tr>
<th>[equivalence limits]</th>
<th>[ test limits ]</th>
</tr>
</thead>
<tbody>
<tr>
<td>difference:</td>
<td></td>
</tr>
<tr>
<td>-16.512</td>
<td>16.512</td>
</tr>
<tr>
<td>ratio:</td>
<td></td>
</tr>
<tr>
<td>80%</td>
<td>120%</td>
</tr>
<tr>
<td>-8.698</td>
<td>4.123</td>
</tr>
<tr>
<td>89.464%</td>
<td>104.994%</td>
</tr>
</tbody>
</table>

Probability test limits are within equivalence limits = 0.9990

Schuirmann's two one-sided tests

- upper test statistic = -5.036 p-value = 0.000
- lower test statistic = 3.810 p-value = 0.001

Anderson and Hauck's test

- noncentrality parameter = 4.423
- test statistic = -0.613 empirical p-value = 0.0005

Note: reference treatment = 1

Both of Schuirmann’s one-sided tests are highly significant, suggesting that the two drugs are bioequivalent. A similar conclusion is drawn from the Anderson and Hauck test of bioequivalence.

 Stored results

pkequiv stores the following in r():

Scalars

- r(stddev) pooled-sample standard deviation of period differences from both sequences
- r(uci) upper confidence interval for a classic interval
- r(lci) lower confidence interval for a classic interval
- r(delta) delta value used in calculating a symmetric confidence interval
- r(u3) upper confidence interval for Fieller’s confidence interval
- r(l3) lower confidence interval for Fieller’s confidence interval

Methods and formulas

The lower confidence interval for the difference in the two treatments for the classic shortest confidence interval is

\[ L_1 = (\bar{Y}_T - \bar{Y}_R) - t_{(\alpha, n_1 + n_2 - 2)} \hat{\sigma} \sqrt{\frac{1}{n_1} + \frac{1}{n_2}} \]

The upper limit is

\[ U_1 = (\bar{Y}_T - \bar{Y}_R) + t_{(\alpha, n_1 + n_2 - 2)} \hat{\sigma} \sqrt{\frac{1}{n_1} + \frac{1}{n_2}} \]
The limits for the ratio measure are

\[ L_2 = \left( \frac{L_1}{Y_R} + 1 \right) \times 100\% \]

and

\[ U_2 = \left( \frac{U_1}{Y_R} + 1 \right) \times 100\% \]

where \( \bar{Y}_T \) is the mean of the test formulation of the drug, \( \bar{Y}_R \) is the mean of the reference formulation of the drug, and \( t_{(\alpha,n_1+n_2-2)} \) is the \( t \) distribution with \( n_1 + n_2 - 2 \) degrees of freedom. \( \hat{\sigma}_d \) is the pooled sample variance of the period differences from both sequences, defined as

\[ \hat{\sigma}_d = \frac{1}{n_1 + n_2 - 2} \sum_{k=1}^{2} \sum_{i=1}^{n_k} (d_{ik} - \bar{d}_k)^2 \]

The upper and lower limits for the symmetric confidence interval are \( \bar{Y}_R + \Delta \) and \( \bar{Y}_R - \Delta \), where

\[ \Delta = k_1 \hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2} - (\bar{Y}_T - \bar{Y}_R)} \]

and (simultaneously)

\[ \Delta = -k_2 \hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2} + 2(\bar{Y}_T - \bar{Y}_R)} \]

and \( k_1 \) and \( k_2 \) are computed iteratively to satisfy the above equalities and the condition

\[ \int_{k_1}^{k_2} f(t)dt = 1 - 2\alpha \]

where \( f(t) \) is the probability density function of the \( t \) distribution with \( n_1 + n_2 - 2 \) degrees of freedom.

See Chow and Liu (2009, 88–92) for details about calculating the confidence interval based on Fieller’s theorem.

The two test statistics for the two one-sided tests of equivalence are

\[ T_L = \frac{(\bar{Y}_T - \bar{Y}_R) - \theta_L}{\hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \]

and

\[ T_U = \frac{(\bar{Y}_T - \bar{Y}_R) - \theta_U}{\hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \]

where \( -\theta_L = \theta_U \) and are the regulated confidence limits.
The logic of the Anderson and Hauck test is tricky; see Chow and Liu (2009) for a complete explanation. However, the test statistic is

$$T_{AH} = \frac{(\overline{Y}_T - \overline{Y}_R) - (\theta_L + \theta_U)}{\hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}$$

and the noncentrality parameter is estimated by

$$\hat{\delta} = \frac{\theta_U - \theta_L}{2\hat{\sigma}_d \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}$$

The empirical $p$-value is calculated as

$$p = F_t (|T_{AH}| - \hat{\delta}) - F_t (-|T_{AH}| - \hat{\delta})$$

where $F_t$ is the cumulative distribution function of the $t$ distribution with $n_1 + n_2 - 2$ degrees of freedom.

**Menu**

Statistics > Epidemiology and related > Other > Pharmacokinetic measures

**Description**

`pkexamine` calculates pharmacokinetic measures from time-and-concentration subject-level data. `pkexamine` computes and displays the maximum measured concentration, the time at the maximum measured concentration, the time of the last measurement, the elimination time, the half-life, and the area under the concentration-time curve ($AUC$). Three estimates of the area under the concentration-time curve from 0 to infinity ($AUC_{0,\infty}$) are also calculated.

`pkexamine` is one of the pk commands. Please read [R] `pk` before reading this entry.
Options

fit(#) specifies the number of points, counting back from the last measurement, to use in fitting the extension to estimate the $AUC_{0,\infty}$. The default is fit(3), or the last three points. This value should be viewed as a minimum; the appropriate number of points will depend on your data.

trapezoid specifies that the trapezoidal rule be used to calculate the AUC. The default is cubic splines, which give better results for most functions. When the curve is irregular, trapezoid may give better results.

graph tells pkexamine to graph the concentration-time curve.

line and log specify the estimates of the $AUC_{0,\infty}$ to display when graphing the $AUC_{0,\infty}$. These options are ignored, unless they are specified with the graph option.

exp(#) specifies that the exponential fit for the $AUC_{0,\infty}$ be plotted. You must specify the maximum time value to which you want to plot the curve, and this time value must be greater than the maximum time measurement in the data. If you specify 0, the curve will be plotted to the point at which the linear extension would cross the $x$ axis. This option is not valid with the line or log option and is ignored, unless the graph option is also specified.

cline_options affect the rendition of the plotted points connected by lines; see [G-3] cline_options.

d_marker_options specify the look of markers. This look includes the marker symbol, the marker size, and its color and outline; see [G-3] marker_options.

marker_label_options specify if and how the markers are to be labeled; see [G-3] marker_label_options.

addplot(plot) provides a way to add other plots to the generated graph. See [G-3] addplot_option.

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples

pkexamine computes summary statistics for a given patient in a pharmacokinetic trial. If by idvar: is specified, statistics will be displayed for each subject in the data.

Example 1

Chow and Liu (2009, 13) present data on a study examining primidone concentrations versus time for a subject over a 32-hour period after dosing.
We use `pkexamine` to produce the summary statistics:

```
pkexamine time conc, graph
```

<table>
<thead>
<tr>
<th></th>
<th>AUC [0, inf.)</th>
<th>AUC [0, inf.)</th>
<th>AUC [0, inf.)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Linear of log conc.</td>
<td>142.603</td>
<td>107.759</td>
<td>142.603</td>
</tr>
<tr>
<td>Linear fit</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Exponential fit</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

Fit based on last 3 points.
The maximum concentration of 4.7 occurs at time 3, and the time of the last observation (Tmax) is 32. In addition to the AUC, which is calculated from 0 to the maximum value of time, pkexamine also reports the area under the curve, computed by extending the curve with each of three methods: a linear fit to the log of the concentration, a linear regression line, and a decreasing exponential regression line. See Methods and formulas for details on these three methods.

By default, all extensions to the AUC are based on the last three points. Looking at the graph for these data, it seems more appropriate to use the last seven points to estimate the AUC_{0,\infty}:

```
   . pkexamine time conc, fit(7)
```

<table>
<thead>
<tr>
<th>AUC [0, Tmax]</th>
<th>AUC [0, inf.) Linear of log conc.</th>
<th>AUC [0, inf.) Linear fit</th>
<th>AUC [0, inf.) Exponential fit</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>85.24</td>
<td>131.027</td>
<td>96.805</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>129.181</td>
</tr>
</tbody>
</table>

Fit based on last 7 points.

This approach decreased the estimate of the AUC_{0,\infty} for all extensions. To see a graph of the AUC_{0,\infty} using a linear extension, specify the graph and line options.

```
   . pkexamine time conc, fit(7) graph line
```

<table>
<thead>
<tr>
<th>AUC [0, Tmax]</th>
<th>AUC [0, inf.) Linear of log conc.</th>
<th>AUC [0, inf.) Linear fit</th>
<th>AUC [0, inf.) Exponential fit</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>85.24</td>
<td>131.027</td>
<td>96.805</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>129.181</td>
</tr>
</tbody>
</table>

Fit based on last 7 points.
Stored results

`pkexamine` stores the following in `r()`:

**Scalars**
- `r(auc)` area under the concentration curve
- `r(half)` half-life of the drug
- `r(ke)` elimination rate
- `r(tmax)` time at last concentration measurement
- `r(cmax)` maximum concentration
- `r(tomc)` time of maximum concentration
- `r(auc_line)` $AUC_{0,\infty}$ estimated with a linear fit
- `r(auc_exp)` $AUC_{0,\infty}$ estimated with an exponential fit
- `r(auc_ln)` $AUC_{0,\infty}$ estimated with a linear fit of the natural log

**Methods and formulas**

Let $i$ index the observations sorted by time, let $k$ be the number of observations, and let $f$ be the number of points specified in the `fit(#)` option.

The $AUC_{0,t_{\text{max}}}$ is defined as

$$AUC_{0,t_{\text{max}}} = \int_0^{t_{\text{max}}} C_t dt$$

where $C_t$ is the concentration at time $t$. By default, the integral is calculated numerically using cubic splines. However, if the trapezoidal rule is used, the $AUC_{0,t_{\text{max}}}$ is given as

$$AUC_{0,t_{\text{max}}} = \sum_{i=2}^{k} \frac{C_{i-1} + C_i}{2} (t_i - t_{i-1})$$
The AUC$_{0,\infty}$ is the AUC$_{0,t_{\text{max}}}$ + AUC$_{t_{\text{max}},\infty}$, or

$$AUC_{0,\infty} = \int_0^{t_{\text{max}}} C_t dt + \int_{t_{\text{max}}}^{\infty} C_t dt$$

When using the linear extension to the AUC$_{0,t_{\text{max}}}$, the integration is cut off when the line crosses the $x$ axis. The log extension is a linear extension on the log concentration scale. The area for the exponential extension is

$$AUC_{0,\infty} = \int_{t_{\text{max}}}^{\infty} e^{-(\beta_0 + t\beta_1)} dt = -\frac{e^{-(\beta_0 + t_{\text{max}}\beta_1)}}{\beta_1}$$

The elimination rate $K_{eq}$ is the negative of the slope from a linear regression of log concentration on time fit to the number of points specified in the fit(#) option:

$$K_{eq} = -\frac{\sum_{i=k-f+1}^{k} (t_i - \bar{t}) (\ln C_i - \ln \bar{C})}{\sum_{i=k-f+1}^{k} (t_i - \bar{t})^2}$$

The half-life is

$$t_{\text{half}} = \frac{\ln 2}{K_{eq}}$$

Statistics > Epidemiology and related > Other > Reshape pharmacokinetic latin-square data

Description

`pkshape` reshapes the data for use with `anova`, `pkcross`, and `pkequiv`; see [R] _anova_, [R] _pkcross_, and [R] _pkequiv_. Latin-square and crossover data are often organized in a manner that cannot be analyzed easily with Stata. `pkshape` reorganizes the data in memory for use in Stata.

`pkshape` is one of the pk commands. Please read [R] _pk_ before reading this entry.

Options

`order(string)` specifies the order in which treatments were applied. If the `sequence()` specifier is a string variable that specifies the order, this option is not necessary. Otherwise, `order()` specifies how to generate the treatment and carryover variables. Any string variable can be used to specify the order. For crossover designs, any washout periods can be indicated with the number 0.

`outcome(newvar)` specifies the name for the outcome variable in the reorganized data. By default, `outcome(outcome)` is used.

`treatment(newvar)` specifies the name for the treatment variable in the reorganized data. By default, `treatment(treat)` is used.

`carryover(newvar)` specifies the name for the carryover variable in the reorganized data. By default, `carryover(carry)` is used.

`sequence(newvar)` specifies the name for the sequence variable in the reorganized data. By default, `sequence(sequence)` is used.

`period(newvar)` specifies the name for the period variable in the reorganized data. By default, `period(period)` is used.
Remarks and examples

Often data from a Latin-square experiment are naturally organized in a manner that Stata cannot manage easily. \texttt{pkshape} reorganizes Latin-square data so that they can be used with \texttt{anova} (see \texttt{[R] anova}) or any \texttt{pk} command. This includes the classic 2 × 2 crossover design commonly used in pharmaceutical research, as well as many other Latin-square designs.

Example 1

Consider the example data published in Chow and Liu (2009, 71). There are 24 patients, 12 in each sequence. Sequence 1 consists of the reference formulation followed by the test formulation; sequence 2 is the test formulation followed by the reference formulation. The measurements reported are the AUC$_{0-t_{\text{max}}}$ for each patient and for each period.

</table>

Because the outcome for one person is in two different variables, the treatment that was applied to an individual is a function of the period and the sequence. To analyze this treatment using \texttt{anova}, all the outcomes must be in one variable, and each covariate must be in its own variable. To reorganize these data, use \texttt{pkshape}:

. \texttt{pkshape id seq period1 period2, order(ab ba)}
. \texttt{sort seq id treat}
Now the data are organized into separate variables that indicate each factor level for each of the covariates, so the data may be used with `anova` or `pkcross`; see [R] `anova` and [R] `pkcross`.

</tbody>
</table>
Consider the study of background music on bank teller productivity published in Kutner et al. (2005). The data are

<table>
<thead>
<tr>
<th>Week</th>
<th>Monday</th>
<th>Tuesday</th>
<th>Wednesday</th>
<th>Thursday</th>
<th>Friday</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>18(D)</td>
<td>17(C)</td>
<td>14(A)</td>
<td>21(B)</td>
<td>17(E)</td>
</tr>
<tr>
<td>2</td>
<td>13(C)</td>
<td>34(B)</td>
<td>21(E)</td>
<td>16(A)</td>
<td>15(D)</td>
</tr>
<tr>
<td>3</td>
<td>7(A)</td>
<td>29(D)</td>
<td>32(B)</td>
<td>27(E)</td>
<td>13(C)</td>
</tr>
<tr>
<td>4</td>
<td>17(E)</td>
<td>13(A)</td>
<td>24(C)</td>
<td>31(D)</td>
<td>25(B)</td>
</tr>
<tr>
<td>5</td>
<td>21(B)</td>
<td>26(E)</td>
<td>26(D)</td>
<td>31(C)</td>
<td>7(A)</td>
</tr>
</tbody>
</table>

The numbers are the productivity scores, and the letters represent the treatment. We entered the data into Stata:

```
use http://www.stata-press.com/data/r13/music, clear
list
```

We reshape these data with `pkshape`:

```
pkshape id seq day1 day2 day3 day4 day5
list, sep(0)
```
Here the sequence variable is a string variable that specifies how the treatments were applied, so the order option is not used. When the sequence variable is a string and the order is specified, the arguments from the order option are used. We could now produce an ANOVA table:

```
. anova outcome seq period treat
```

```
Number of obs = 25   R-squared = 0.8666
Root MSE = 3.96232  Adj R-squared = 0.7331

Source       Partial SS     df       MS      F    Prob > F
-------------    --------     ----       ----    ----      ----
Model         1223.6         12  101.966667  6.49  0.0014
sequence      82             4   20.5      1.31  0.3226
period        477.2         4   119.3     7.60  0.0027
period        664.4         4   166.1    10.58  0.0007
Total         188.4         24   7.8333333 4.20  0.0126
```

**Example 3**

Consider the Latin-square crossover example published in Kutner et al. (2005). The example is about apple sales given different methods for displaying apples.

```
<table>
<thead>
<tr>
<th>Pattern</th>
<th>Store</th>
<th>Week 1</th>
<th>Week 2</th>
<th>Week 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>9(B)</td>
<td>12(C)</td>
<td>15(A)</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>4(B)</td>
<td>12(C)</td>
<td>9(A)</td>
</tr>
<tr>
<td></td>
<td>2</td>
<td>12(A)</td>
<td>14(B)</td>
<td>3(C)</td>
</tr>
<tr>
<td>3</td>
<td>2</td>
<td>13(A)</td>
<td>14(B)</td>
<td>3(C)</td>
</tr>
<tr>
<td>4</td>
<td>3</td>
<td>7(C)</td>
<td>18(A)</td>
<td>6(B)</td>
</tr>
<tr>
<td>5</td>
<td>4</td>
<td>5(C)</td>
<td>20(A)</td>
<td>4(B)</td>
</tr>
</tbody>
</table>
```

We entered the data into Stata:

```
. use http://www.stata-press.com/data/r13/applesales, clear
. list, sep(2)
```

```
id   seq  p1  p2  p3  square
 1.    1    1    9   12  15    1
 2.    2    1    4   12    9    2
 3.    3    2   12   14    3    1
 4.    4    2   13   14    3    2
 5.    5    3    7   18    6    1
 6.    6    3    5   20    4    2
```
Now the data can be reorganized using descriptive names for the outcome variables.

```
pkshape id seq p1 p2 p3, order(bca abc cab) seq(pattern) period(order) treat(displays)
anova outcome pattern order display id|pattern
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>

Menu

Statistics > Epidemiology and related > Other > Summarize pharmacokinetic data

Description

`pksumm` obtains summary measures based on the first four moments from the empirical distribution of each pharmacokinetic measurement and tests the null hypothesis that the distribution of that measurement is normally distributed.

`pksumm` is one of the pk commands. Please read [R] pk before reading this entry.
**Options**

**Main**

- **trapezoid** specifies that the trapezoidal rule be used to calculate the AUC. The default is cubic splines, which give better results for most situations. When the curve is irregular, the trapezoidal rule may give better results.

- **fit(#)** specifies the number of points, counting back from the last time measurement, to use in fitting the extension to estimate the \( \text{AUC}_{0,\infty} \). The default is \( \text{fit}(3) \), the last three points. This default should be viewed as a minimum; the appropriate number of points will depend on the data.

- **notimechk** suppresses the check that the follow-up time for all subjects is the same. By default, \text{pksumm} expects the maximum follow-up time to be equal for all subjects.

- **nodots** suppresses the progress dots during calculation. By default, a period is displayed for every call to calculate the pharmacokinetic measures.

- **graph** requests a graph of the distribution of the statistic specified with **stat()**.

- **stat(statistic)** specifies the statistic that **pksumm** should graph. The default is **stat(auc)**. If the **graph** option is not specified, this option is ignored.

**Histogram, Density plots, Y axis, X axis, Titles, Legend, Overall**

- **histogram_options** are any of the options documented in [R] **histogram**, excluding **by()**. For **pksumm**, fraction is the default, not density.

**Remarks and examples**

**pksumm** produces summary statistics for the distribution of nine common pharmacokinetic measurements. If there are more than eight subjects, **pksumm** also computes a test for normality on each measurement. The nine measurements summarized by **pksumm** are listed above and are described in **Methods and formulas** of [R] **pkexamine**.

**Example 1**

We demonstrate the use of **pksumm** on a variation of the data described in [R] **pk**. We have drug concentration data on 15 subjects, each measured at 13 time points over a 32-hour period. A few of the records are
We can use \texttt{pksumm} to view the summary statistics for all the pharmacokinetic parameters.

\begin{verbatim}
. pksumm id time conc

 tmax & 32.00 & 32.00 & 0.00 & . & . & . \\
\end{tabular}
\end{verbatim}

For the 15 subjects, the mean $\text{AUC}_{0,t_{\text{max}}}$ is 150.74, and $\sigma^2 = 123.07$. The skewness of $-0.26$ indicates that the distribution is slightly skewed left. The $p$-value of 0.69 for the $\chi^2$ test of normality indicates that we cannot reject the null hypothesis that the distribution is normal.

If we were to consider any of the three variants of the $\text{AUC}_{0,\infty}$, we would see that there is huge variability and that the distribution is heavily skewed. A skewness different from 0 and a kurtosis different from 3 are expected because the distribution of the $\text{AUC}_{0,\infty}$ is not normal.

We now graph the distribution of $\text{AUC}_{0,t_{\text{max}}}$ by specifying the \texttt{graph} option.

1629
Description

poisson fits a Poisson regression of depvar on indepvars, where depvar is a nonnegative count variable.

If you have panel data, see [XT] xtpoisson.

Options

Model

noconstant, exposure(varname_e), offset(varname_o), constraints(constraints), collinear;
see [R] estimation options.

SE/Robust

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting

level(#) ; see [R] estimation options.

irr reports estimated coefficients transformed to incidence-rate ratios, that is, $e^{\beta_i}$ rather than $\beta_i$. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. irr may be specified at estimation or when replaying previously estimated results.

cocnsreport; see [R] estimation options.

display_options: nomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following option is available with poisson but is not shown in the dialog box: coeflegend; see [R] estimation options.
Remarks and examples

The basic idea of Poisson regression was outlined by Coleman (1964, 378–379). See Cameron and Trivedi (2013; 2010, chap. 17) and Johnson, Kemp, and Kotz (2005, chap. 4) for information about the Poisson distribution. See Cameron and Trivedi (2013), Long (1997, chap. 8), Long and Freese (2014, chap. 9), McNeil (1996, chap. 6), and Selvin (2011, chap. 6) for an introduction to Poisson regression. Also see Selvin (2004, chap. 5) for a discussion of the analysis of spatial distributions, which includes a discussion of the Poisson distribution. An early example of Poisson regression was Cochran (1940).

Poisson regression fits models of the number of occurrences (counts) of an event. The Poisson distribution has been applied to diverse events, such as the number of soldiers kicked to death by horses in the Prussian army (von Bortkiewicz 1898); the pattern of hits by buzz bombs launched against London during World War II (Clarke 1946); telephone connections to a wrong number (Thorndike 1926); and disease incidence, typically with respect to time, but occasionally with respect to space. The basic assumptions are as follows:

1. There is a quantity called the incidence rate that is the rate at which events occur. Examples are 5 per second, 20 per 1,000 person-years, 17 per square meter, and 38 per cubic centimeter.
2. The incidence rate can be multiplied by exposure to obtain the expected number of observed events. For example, a rate of 5 per second multiplied by 30 seconds means that 150 events are expected; a rate of 20 per 1,000 person-years multiplied by 2,000 person-years means that 40 events are expected; and so on.
3. Over very small exposures $\epsilon$, the probability of finding more than one event is small compared with $\epsilon$.
4. Nonoverlapping exposures are mutually independent.

With these assumptions, to find the probability of $k$ events in an exposure of size $E$, you divide $E$ into $n$ subintervals $E_1, E_2, \ldots, E_n$, and approximate the answer as the binomial probability of observing $k$ successes in $n$ trials. If you let $n \to \infty$, you obtain the Poisson distribution.

In the Poisson regression model, the incidence rate for the $j$th observation is assumed to be given by

$$r_j = e^{\beta_0 + \beta_1 x_{1,j} + \cdots + \beta_k x_{k,j}}$$

If $E_j$ is the exposure, the expected number of events, $C_j$, will be

$$C_j = E_j e^{\beta_0 + \beta_1 x_{1,j} + \cdots + \beta_k x_{k,j}} = e^{\ln(E_j) + \beta_0 + \beta_1 x_{1,j} + \cdots + \beta_k x_{k,j}}$$

This model is fit by poisson. Without the exposure() or offset() options, $E_j$ is assumed to be 1 (equivalent to assuming that exposure is unknown), and controlling for exposure, if necessary, is your responsibility.

Comparing rates is most easily done by calculating incidence-rate ratios (IRRs). For instance, what is the relative incidence rate of chromosome interchanges in cells as the intensity of radiation increases; the relative incidence rate of telephone connections to a wrong number as load increases; or the relative incidence rate of deaths due to cancer for females relative to males? That is, you want to hold all the $x$’s in the model constant except one, say, the $i$th. The IRR for a one-unit change in $x_i$ is

$$e^{\ln(E) + \beta_1 x_{1,i} + \cdots + \beta_i (x_{i+1} + \cdots + \beta_k x_k)}$$

$$e^{\ln(E) + \beta_1 x_{1,i} + \cdots + \beta_i x_{i+1} + \cdots + \beta_k x_k} = e^{\beta_i}$$
More generally, the IRR for a $\Delta x_i$ change in $x_i$ is $e^{\beta_i \Delta x_i}$. The `lincom` command can be used after `poisson` to display incidence-rate ratios for any group relative to another; see [R] `lincom`.

### Example 1

Chatterjee and Hadi (2012, 174) give the number of injury incidents and the proportion of flights for each airline out of the total number of flights from New York for nine major U.S. airlines in one year:

```
use http://www.stata-press.com/data/r13/airline
list
airline injuries n XYZowned
1. 1 11 0.0950 1
2. 2 7 0.1920 0
3. 3 7 0.0750 0
4. 4 19 0.2078 0
5. 5 9 0.1382 0
6. 6 4 0.0540 1
7. 7 3 0.1292 0
8. 8 1 0.0503 0
9. 9 3 0.0629 1
```

To their data, we have added a fictional variable, `XYZowned`. We will imagine that an accusation is made that the airlines owned by XYZ Company have a higher injury rate.

```
. poisson injuries XYZowned, exposure(n) irr
Iteration 0: log likelihood = -23.027197
Iteration 1: log likelihood = -23.027177
Iteration 2: log likelihood = -23.027177
Poisson regression
Number of obs = 9
LR chi2(1) = 1.77
Prob > chi2 = 0.1836
Log likelihood = -23.027177
Pseudo R2 = 0.0370

injuries | IRR Std. Err.   z  P>|z| [95% Conf. Interval]
---------|-------------------+-----------------+-----------------------------+-------------------+-----------------------------+
 XYZowned| 1.463467  .406872  1.37  0.171  .8486578  2.523675
 _cons    | 58.04416  8.568145  27.54  0.000  43.47662  77.49281
 ln(n)    | 1  (exposure)
```

We specified `irr` to see the IRRs rather than the underlying coefficients. We estimate that XYZ Airlines’ injury rate is 1.46 times larger than that for other airlines, but the 95% confidence interval is 0.85 to 2.52; we cannot even reject the hypothesis that XYZ Airlines has a lower injury rate.

### Technical note

In example 1, we assumed that each airline’s exposure was proportional to its fraction of flights out of New York. What if “large” airlines, however, also used larger planes, and so had even more passengers than would be expected, given this measure of exposure? A better measure would be each airline’s fraction of passengers on flights out of New York, a number that we do not have. Even so, we suppose that $n$ represents this number to some extent, so a better estimate of the effect might be
. gen lnN=ln(n)
. poisson injuries XYZowned lnN
Iteration 0:  log likelihood =  -22.333875
Iteration 1:  log likelihood =  -22.332276
Iteration 2:  log likelihood =  -22.332276
Poisson regression

Log likelihood =  -22.332276

|        | Coef.       | Std. Err. | z      | P>|z|   | [95% Conf. Interval] |
|--------|-------------|-----------|--------|-------|---------------------|
| injuries |             |           |        |       |                     |
| XYZowned|  .6840667   | .3895877  | 1.76   | 0.079 | -.0795111 - 1.447645|
| lnN     |  1.424169   | .3725155  | 3.82   | 0.000 | .6940517 - 2.154285 |
| _cons  |  4.863891   | .7090501  | 6.86   | 0.000 | 3.474178 - 6.253603 |

Here rather than specifying the **exposure()** option, we explicitly included the variable that would normalize for exposure in the model. We did not specify the **irr** option, so we see coefficients rather than **IRRs**. We started with the model

\[
\text{rate} = e^{\beta_0 + \beta_1 \text{XYZowned}}
\]

The observed counts are therefore

\[
\text{count} = ne^{\beta_0 + \beta_1 \text{XYZowned}} = e^{\ln(n) + \beta_0 + \beta_1 \text{XYZowned}}
\]

which amounts to constraining the coefficient on \(\ln(n)\) to 1. This is what was estimated when we specified the **exposure(n)** option. In the above model, we included the normalizing exposure ourselves and, rather than constraining the coefficient to be 1, estimated the coefficient.

The estimated coefficient is 1.42, a respectable distance away from 1, and is consistent with our speculation that larger airlines also use larger airplanes. With this small amount of data, however, we also have a wide confidence interval that includes 1.

Our estimated **coefficient** on **XYZowned** is now 0.684, and the implied **IRR** is \(e^{0.684} \approx 1.98\) (which we could also see by typing **poisson, irr**). The 95% confidence interval for the coefficient still includes 0 (the interval for the **IRR** includes 1), so although the point estimate is now larger, we still cannot be certain of our results.

Our expert opinion would be that, although there is not enough evidence to support the charge, there is enough evidence to justify collecting more data.

---

**Example 2**

In a famous age-specific study of coronary disease deaths among male British doctors, Doll and Hill (1966) reported the following data (reprinted in Rothman, Greenland, and Lash [2008, 264]):

<table>
<thead>
<tr>
<th>Age</th>
<th>Smokers</th>
<th>Person-years</th>
<th>Nonsmokers</th>
<th>Person-years</th>
</tr>
</thead>
<tbody>
<tr>
<td>35–44</td>
<td>32</td>
<td>52,407</td>
<td>2</td>
<td>18,790</td>
</tr>
<tr>
<td>45–54</td>
<td>104</td>
<td>43,248</td>
<td>12</td>
<td>10,673</td>
</tr>
<tr>
<td>55–64</td>
<td>206</td>
<td>28,612</td>
<td>28</td>
<td>5,710</td>
</tr>
<tr>
<td>65–74</td>
<td>186</td>
<td>12,663</td>
<td>28</td>
<td>2,585</td>
</tr>
<tr>
<td>75–84</td>
<td>102</td>
<td>5,317</td>
<td>31</td>
<td>1,462</td>
</tr>
</tbody>
</table>
The first step is to enter these data into Stata, which we have done:

```
. use http://www.stata-press.com/data/r13/dollhill3, clear
. list
```

```
<table>
<thead>
<tr>
<th>agecat</th>
<th>smokes</th>
<th>deaths</th>
<th>pyears</th>
</tr>
</thead>
<tbody>
<tr>
<td>35-44</td>
<td>1</td>
<td>32</td>
<td>52,407</td>
</tr>
<tr>
<td>45-54</td>
<td>1</td>
<td>104</td>
<td>43,248</td>
</tr>
<tr>
<td>55-64</td>
<td>1</td>
<td>206</td>
<td>28,612</td>
</tr>
<tr>
<td>65-74</td>
<td>1</td>
<td>186</td>
<td>12,663</td>
</tr>
<tr>
<td>75-84</td>
<td>1</td>
<td>102</td>
<td>5,317</td>
</tr>
<tr>
<td>35-44</td>
<td>0</td>
<td>2</td>
<td>18,790</td>
</tr>
<tr>
<td>45-54</td>
<td>0</td>
<td>12</td>
<td>10,673</td>
</tr>
<tr>
<td>55-64</td>
<td>0</td>
<td>28</td>
<td>5,710</td>
</tr>
<tr>
<td>65-74</td>
<td>0</td>
<td>28</td>
<td>2,585</td>
</tr>
<tr>
<td>75-84</td>
<td>0</td>
<td>31</td>
<td>1,462</td>
</tr>
</tbody>
</table>
```

The most “natural” analysis of these data would begin by introducing indicator variables for each age category and one indicator for smoking:

```
. poisson deaths smokes i.agecat, exposure(pyears) irr
```

```
Iteration 0: log likelihood = -33.823284
Iteration 1: log likelihood = -33.600471
Iteration 2: log likelihood = -33.600153
Iteration 3: log likelihood = -33.600153

Poisson regression
Number of obs = 10
LR chi2(5)    = 922.93
Prob > chi2   = 0.0000
Log likelihood = -33.600153 Pseudo R2 = 0.9321
```

```
| deaths | IRR    | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|--------|--------|-----------|-------|------|----------------------|
| smokes | 1.425519 | .1530638  | 3.30  | 0.001| 1.154984 1.759421    |
| agecat | 45-54  | 4.410584  | .8605197 | 7.61 | 0.000 | 3.009011 6.464997   |
|        | 55-64  | 13.83920  | 2.542638 | 14.30| 0.000 | 9.654328 19.83809   |
|        | 65-74  | 28.51678  | 5.269878 | 18.13| 0.000 | 19.85177 40.96395   |
|        | 75-84  | 40.45121  | 7.775511 | 19.25| 0.000 | 27.75326 58.95885   |
| _cons | 0.0003636 | .0000697 | -41.30| 0.000| 0.0002497 0.0005296 |
| ln(pyyears) | 1 (exposure) |          |       |      |                      |
```

In the above, we specified `irr` to obtain IRRs. We estimate that smokers have 1.43 times the mortality rate of nonsmokers. See, however, example 1 in [R] poisson postestimation.
Stored results

poisson stores the following in e():

Scalars
- e(N) number of observations
- e(k) number of parameters
- e(k_eq) number of equations in e(b)
- e(k_eq_model) number of equations in overall model test
- e(k_dv) number of dependent variables
- e(df_m) model degrees of freedom
- e(r2_p) pseudo-$R^2$-squared
- e(ll) log likelihood
- e(ll_0) log likelihood, constant-only model
- e(N_clust) number of clusters
- e(chi2) $\chi^2$
- e(p) significance
- e(rank) rank of e(V)
- e(ic) number of iterations
- e(rc) return code
- e(converged) 1 if converged, 0 otherwise

Macros
- e(cmd) poisson
- e(cmdline) command as typed
- e(depvar) name of dependent variable
- e(wtype) weight type
- e(wexp) weight expression
- e(title) title in estimation output
- e(clustvar) name of cluster variable
- e(offset) linear offset variable
- e(chi2type) Wald or LR; type of model $\chi^2$ test
- e(vce) vcetype specified in vce()
- e(vcetype) title used to label Std. Err.
- e(opt) type of optimization
- e(which) max or min; whether optimizer is to perform maximization or minimization
- e(ml_method) type of ml method
- e(user) name of likelihood-evaluator program
- e(technique) maximization technique

Methods and formulas

The log likelihood (with weights $w_j$ and offsets) is given by

$$
\Pr(Y = y) = \frac{e^{-\lambda} \lambda^y}{y!}
$$

$$
\xi_j = x_j \beta + \text{offset}_j
$$

$$
f(y_j) = \frac{e^{-\exp(\xi_j)} e^{\xi_j y_j}}{y_j!}
$$

$$
\ln L = \sum_{j=1}^{n} w_j \left\{ -e^{\xi_j} + \xi_j y_j - \ln(y_j!) \right\}
$$

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \cite{poisson:robust}, particularly \textit{Maximum likelihood estimators} and \textit{Methods and formulas}.

\texttt{poisson} also supports estimation with survey data. For details on VCEs with survey data, see \cite{svy:variance}.

Siméon-Denis Poisson (1781–1840) was a French mathematician and physicist who contributed to several fields: his name is perpetuated in Poisson brackets, Poisson’s constant, Poisson’s differential equation, Poisson’s integral, and Poisson’s ratio. Among many other results, he produced a version of the law of large numbers. His rather misleadingly titled \textit{Recherches sur la probabilité des jugements} embraces a complete treatise on probability, as the subtitle indicates, including what is now known as the Poisson distribution. That, however, was discovered earlier by the Huguenot–British mathematician Abraham de Moivre (1667–1754).

## poisson postestimation — Postestimation tools for poisson

### Description

The following postestimation command is of special interest after `poisson`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat gof</code></td>
<td>goodness-of-fit test</td>
</tr>
</tbody>
</table>

`estat gof` is not appropriate after the `svy` prefix.

The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>contrast</code></td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td><code>estat ic</code></td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td><code>estat summarize</code></td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>forecast</code></td>
<td>dynamic forecasts and simulations</td>
</tr>
<tr>
<td><code>lincom</code></td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td><code>linktest</code></td>
<td>link test for model specification</td>
</tr>
<tr>
<td><code>lrtest</code></td>
<td>likelihood-ratio test</td>
</tr>
<tr>
<td><code>margins</code></td>
<td>marginal means, predictive margins, marginal effects, and average marginal effects</td>
</tr>
<tr>
<td><code>marginsplot</code></td>
<td>graph the results from margins (profile plots, interaction plots, etc.)</td>
</tr>
<tr>
<td><code>nlcom</code></td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td><code>predict</code></td>
<td>predictions, residuals, influence statistics, and other diagnostic measures</td>
</tr>
<tr>
<td><code>predictnl</code></td>
<td>point estimates, standard errors, testing, and inference for generalized predictions</td>
</tr>
<tr>
<td><code>pwcompare</code></td>
<td>pairwise comparisons of estimates</td>
</tr>
<tr>
<td><code>suest</code></td>
<td>seemingly unrelated estimation</td>
</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

1 `forecast` is not appropriate with `mi` or `svy` estimation results.
2 `lrtest` is not appropriate with `svy` estimation results.
Special-interest postestimation command

`estat gof` performs a goodness-of-fit test of the model. Both the deviance statistic and the Pearson statistic are reported. If the tests are significant, the Poisson regression model is inappropriate. Then you could try a negative binomial model; see [R] `nbreg`.

**Syntax for predict**

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>n</code></td>
<td>number of events; the default</td>
</tr>
<tr>
<td><code>ir</code></td>
<td>incidence rate</td>
</tr>
<tr>
<td><code>pr(n)</code></td>
<td>probability $\Pr(y_j = n)$</td>
</tr>
<tr>
<td><code>pr(a,b)</code></td>
<td>probability $\Pr(a \leq y_j \leq b)$</td>
</tr>
<tr>
<td><code>xb</code></td>
<td>linear prediction</td>
</tr>
<tr>
<td><code>stdp</code></td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td><code>score</code></td>
<td>first derivative of the log likelihood with respect to $x_j \beta$</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

**Menu for predict**

Statistics > Postestimation > Predictions, residuals, etc.

**Options for predict**

- `n`, the default, calculates the predicted number of events, which is $\exp(x_j \beta)$ if neither `offset()` nor `exposure()` was specified when the model was fit; $\exp(x_j \beta + \text{offset}_j)$ if `offset()` was specified; or $\exp(x_j \beta) \times \text{exposure}_j$ if `exposure()` was specified.

- `ir` calculates the incidence rate $\exp(x_j \beta)$, which is the predicted number of events when exposure is 1. Specifying `ir` is equivalent to specifying `n` when neither `offset()` nor `exposure()` was specified when the model was fit.

- `pr(n)` calculates the probability $\Pr(y_j = n)$, where $n$ is a nonnegative integer that may be specified as a number or a variable.

- `pr(a,b)` calculates the probability $\Pr(a \leq y_j \leq b)$, where $a$ and $b$ are nonnegative integers that may be specified as numbers or variables;

  - `b` missing ($b \geq .$) means $+\infty$;

  - `pr(20,. )` calculates $\Pr(y_j \geq 20)$;

  - `pr(20,b)` calculates $\Pr(y_j \geq 20)$ in observations for which $b \geq .$ and calculates $\Pr(20 \leq y_j \leq b)$ elsewhere.

- `pr(.,b)` produces a syntax error. A missing value in an observation of the variable $a$ causes a missing value in that observation for `pr(a,b)`.
xb calculates the linear prediction, which is $x_j \beta$ if neither offset() nor exposure() was specified; $x_j \beta + \text{offset}_j$ if offset() was specified; or $x_j \beta + \ln(\text{exposure}_j)$ if exposure() was specified; see nooffset below.

stdp calculates the standard error of the linear prediction.

score calculates the equation-level score, $\partial \ln L / \partial (x_j \beta)$.

nooffset is relevant only if you specified offset() or exposure() when you fit the model. It modifies the calculations made by predict so that they ignore the offset or exposure variable; the linear prediction is treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_j$ or $x_j \beta + \ln(\text{exposure}_j)$. Specifying predict ..., nooffset is equivalent to specifying predict ..., ir.

Syntax for estat gof

estat gof

Menu for estat

Statistics > Postestimation > Reports and statistics

Remarks and examples

Example 1

Continuing with example 2 of [R] poisson, we use estat gof to determine whether the model fits the data well.

. use http://www.stata-press.com/data/r13/dollhill3
. poisson deaths smokes i.agecat, exp(pyears) irr
  (output omitted)
. estat gof

Deviance goodness-of-fit = 12.13244
Prob > chi2(4) = 0.0164
Pearson goodness-of-fit = 11.15533
Prob > chi2(4) = 0.0249

The deviance goodness-of-fit test tells us that, given the model, we can reject the hypothesis that these data are Poisson distributed at the 1.64% significance level. The Pearson goodness-of-fit test tells us that we can reject the hypothesis at the 2.49% significance level.

So let us now back up and be more careful. We can most easily obtain the incidence-rate ratios within age categories by using ir; see [ST] epitab:

. ir deaths smokes pyears, by(agecat) nohet

<table>

</tbody>
</table>
We find that the mortality incidence ratios are greatly different within age category, being highest for the youngest categories and actually dropping below 1 for the oldest. (In the last case, we might argue that those who smoke and who have not died by age 75 are self-selected to be particularly robust.)

Seeing this, we will now parameterize the smoking effects separately for each category, although we will begin by constraining the smoking effects on third and fourth age categories to be equivalent:

```
constraint 1 smokes#3.agecat = smokes#4.agecat
poisson deaths c.smokes#agecat i.agecat, exposure(pyears) irr constraints(1)
```

```
Iteration 0: log likelihood = -31.95424
Iteration 1: log likelihood = -27.796801
Iteration 2: log likelihood = -27.574177
Iteration 3: log likelihood = -27.572645
Iteration 4: log likelihood = -27.572645
Poisson regression

| 45-54    | 10.5631 | 8.067701 | 3.09  | 0.002   | 2.364153  47.19623   |
| 55-64    | 47.671 | 34.37409 | 5.36  | 0.000   | 11.60056  195.8978   |
| 65-74    | 98.22765 | 70.85012 | 6.36  | 0.000   | 23.89324  403.8244   |
| 75-84    | 199.2099 | 145.3356 | 7.26  | 0.000   | 47.67693  832.3648   |
| _cons    | .0001064 | .0000753 | -12.94 | 0.000 | .0000266  .0004256  |
| ln(pyears) |     |           |       |         |                      |

```
estat gof
```

Deviance goodness-of-fit = .0774185
Prob > chi2(1) = 0.7808
Pearson goodness-of-fit = .0773882
Prob > chi2(1) = 0.7809

The goodness-of-fit is now small; we are no longer running roughshod over the data. Let us now consider simplifying the model. The point estimate of the incidence-rate ratio for smoking in age category 1 is much larger than that for smoking in age category 2, but the confidence interval for smokes#1.agecat is similarly wide. Is the difference real?

```
constraint 1 smokes#1.agecat = smokes#2.agecat
```

```
( 1) [deaths]1b.agecat#c.smokes - [deaths]2.agecat#c.smokes = 0

chi2( 1) =  1.56
Prob > chi2 = 0.2117
```

The point estimates of the incidence-rate ratio for smoking in the 35–44 age category is much larger than that for smoking in the 45–54 age category, but there is insufficient data, and we may be observing random differences. With that success, might we also combine the smokers in the third and fourth categories with those in the first and second categories?
Combining the first four categories may be overdoing it—the 9.38% significance level is enough to stop us, although others may disagree.

Thus we now fit our final model:

```
constraint 2 smokes#1.agecat = smokes#2.agecat
poisson deaths c.smokes#agecat i.agecat, exposure(pyears) irr constraints(1/2)
```

```
Iteration 0: log likelihood = -31.550722
Iteration 1: log likelihood = -28.525057
Iteration 2: log likelihood = -28.514535
Iteration 3: log likelihood = -28.514535
Poisson regression
Number of obs = 10
Wald chi2(7) = 642.25
Log likelihood = -28.514535 Prob > chi2 = 0.0000
( 1) [deaths]3.agecat#c.smokes - [deaths]4.agecat#c.smokes = 0
( 2) [deaths]1b.agecat#c.smokes - [deaths]2.agecat#c.smokes = 0
```

| deaths | IRR   | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|--------|-------|-----------|------|-----|----------------------|
| agecat#c.smokes
| 35-44  | 2.636259 | .7408403 | 3.45 | 0.001 | 1.519791 4.572907 |
| 45-54  | 2.636259 | .7408403 | 3.45 | 0.001 | 1.519791 4.572907 |
| 55-64  | 1.412229 | .2017485 | 2.42 | 0.016 | 1.067343 1.868557 |
| 65-74  | 1.412229 | .2017485 | 2.42 | 0.016 | 1.067343 1.868557 |
| 75-84  | .9047304 | .1855513 | -0.49| 0.625 | .6052658 1.35236  |
| agecat
| 45-54  | 4.294559 | .8385329 | 7.46 | 0.000 | 2.928987 6.296797 |
| 55-64  | 23.42263 | 7.787716 | 9.49 | 0.000 | 12.20738 44.94164 |
| 65-74  | 48.26309 | 16.06939 | 11.64| 0.000 | 25.13068 92.68856 |
| 75-84  | 97.87965 | 34.30881 | 13.08| 0.000 | 49.24123 194.561 |
| _cons  | .0002166 | .0000652 | -28.03| 0.000 | .0001201 .0003908 |
| ln(pyears) | 1 (exposure) |
The above strikes us as a fair representation of the data. The probabilities of observing the deaths seen in these data are estimated using the following `predict` command:

```
 . predict p, pr(0, deaths)
 . list deaths p
```

<table>
<thead>
<tr>
<th>deaths</th>
<th>p</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. 32</td>
<td>0.6891766</td>
</tr>
<tr>
<td>2. 104</td>
<td>0.4456625</td>
</tr>
<tr>
<td>3. 206</td>
<td>0.5455328</td>
</tr>
<tr>
<td>4. 186</td>
<td>0.4910622</td>
</tr>
<tr>

<td>0.5475718</td>
</tr>
</tbody>
</table>

The probability \( \Pr(y \leq \text{deaths}) \) ranges from 0.23 to 0.80.

**Methods and formulas**

In the following, we use the same notation as in \[R\] `poisson`.

The equation-level scores are given by

\[
\text{score}(\mathbf{x}/\beta)_j = y_j - e^{\xi_j}
\]

The deviance (D) and Pearson (P) goodness-of-fit statistics are given by

\[
\ln L_{\text{max}} = \sum_{j=1}^{n} w_j \left[-y_j \left\{ \ln(y_j) - 1 \right\} - \ln(y_j!) \right] \\
\chi^2_D = -2 \left\{ \ln L - \ln L_{\text{max}} \right\} \\
\chi^2_P = \sum_{j=1}^{n} w_j \frac{(y_j - e^{\xi_j})^2}{e^{\xi_j}}
\]

### Menu for predict

Statistics  >  Postestimation  >  Predictions, residuals, etc.
**Description**

`predict` calculates predictions, residuals, influence statistics, and the like after estimation. Exactly what `predict` can do is determined by the previous estimation command; command-specific options are documented with each estimation command. Regardless of command-specific options, the actions of `predict` share certain similarities across estimation commands:

1. `predict newvar` creates `newvar` containing “predicted values”—numbers related to the $E(y_j|x_j)$. For instance, after linear regression, `predict newvar` creates $x_j \mathbf{b}$ and, after probit, creates the probability $\Phi(x_j \mathbf{b})$.

2. `predict newvar, xb` creates `newvar` containing $x_j \mathbf{b}$. This may be the same result as option 1 (for example, linear regression) or different (for example, probit), but regardless, option `xb` is allowed.

3. `predict newvar, stdp` creates `newvar` containing the standard error of the linear prediction $x_j \mathbf{b}$.

4. `predict newvar, other_options` may create `newvar` containing other useful quantities; see help or the reference manual entry for the particular estimation command to find out about other available options.

5. `nooffset` added to any of the above commands requests that the calculation ignore any offset or exposure variable specified by including the `offset(varname_o)` or `exposure(varname_e)` option when you fit the model.

`predict` can be used to make in-sample or out-of-sample predictions:

6. `predict` calculates the requested statistic for all possible observations, whether they were used in fitting the model or not. `predict` does this for standard options 1–3 and generally does this for estimator-specific options 4.

7. `predict newvar if e(sample), ...` restricts the prediction to the estimation subsample.

8. Some statistics make sense only with respect to the estimation subsample. In such cases, the calculation is automatically restricted to the estimation subsample, and the documentation for the specific option states this. Even so, you can still specify `if e(sample)` if you are uncertain.

9. `predict` can make out-of-sample predictions even using other datasets. In particular, you can

   ```
   . use ds1
   . (fit a model)
   . use two                    /* another dataset          */
   . predict yhat, ...         /* fill in the predictions */
   ```

**Options**

`xb` calculates the linear prediction from the fitted model. That is, all models can be thought of as estimating a set of parameters $b_1, b_2, \ldots, b_k$, and the linear prediction is $\hat{y}_j = b_1 x_{1j} + b_2 x_{2j} + \cdots + b_k x_{kj}$, often written in matrix notation as $\hat{y}_j = x_j \mathbf{b}$. For linear regression, the values $\hat{y}_j$ are called the predicted values or, for out-of-sample predictions, the forecast. For logit and probit, for example, $\hat{y}_j$ is called the logit or probit index.

$x_{1j}, x_{2j}, \ldots, x_{kj}$ are obtained from the data currently in memory and do not necessarily correspond to the data on the independent variables used to fit the model (obtaining $b_1, b_2, \ldots, b_k$).
stdp calculates the standard error of the linear prediction. Here the prediction means the same thing as the “index”, namely, $x_j b$. The statistic produced by stdp can be thought of as the standard error of the predicted expected value, or mean index, for the observation’s covariate pattern. The standard error of the prediction is also commonly referred to as the standard error of the fitted value. The calculation can be made in or out of sample.

stddp is allowed only after you have previously fit a multiple-equation model. The standard error of the difference in linear predictions $(x_{1j} b - x_{2j} b)$ between equations 1 and 2 is calculated. This option requires that equation(eqno1,eqno2) be specified.

score calculates the equation-level score, $\partial \ln L / \partial (x_j \beta)$. Here $\ln L$ refers to the log-likelihood function.

scores is the ME model equivalent of the score option, resulting in multiple equation-level score variables. An equation-level score variable is created for each equation in the model; ancillary parameters—such as $\ln \sigma$ and atanh$\rho$—make up separate equations.

equation(eqno[1,eqno]) — synonym outcome() — is relevant only when you have previously fit a multiple-equation model. It specifies the equation to which you are referring.

equation() is typically filled in with one eqno—it would be filled in that way with options xb and stdp, for instance. equation(#1) would mean the calculation is to be made for the first equation, equation(#2) would mean the second, and so on. You could also refer to the equations by their names. equation(income) would refer to the equation named income and equation(hours) to the equation named hours.

If you do not specify equation(), results are the same as if you specified equation(#1).

Other statistics, such as stddp, refer to between-equation concepts. In those cases, you might specify equation(#1,#2) or equation(income,hours). When two equations must be specified, equation() is required.

Options

nooffset may be combined with most statistics and specifies that the calculation should be made, ignoring any offset or exposure variable specified when the model was fit.

This option is available, even if it is not documented for predict after a specific command. If neither the offset(varnameo) option nor the exposure(varnameo) option was specified when the model was fit, specifying nooffset does nothing.

other_options refers to command-specific options that are documented with each command.

Remarks and examples

Remarks are presented under the following headings:

Estimation-sample predictions
Out-of-sample predictions
Residuals
Single-equation (SE) models
SE model scores
Multiple-equation (ME) models
ME model scores

Most of the examples are presented using linear regression, but the general syntax is applicable to all estimators.
You can think of any estimation command as estimating a set of coefficients $b_1$, $b_2$, ..., $b_k$ corresponding to the variables $x_1$, $x_2$, ..., $x_k$, along with a (possibly empty) set of ancillary statistics $\gamma_1$, $\gamma_2$, ..., $\gamma_m$. All estimation commands store the $b_i$s and $\gamma_i$s. `predict` accesses that stored information and combines it with the data currently in memory to make various calculations. For instance, `predict` can calculate the linear prediction, $\hat{y}_j = b_1x_{1j} + b_2x_{2j} + \cdots + b_kx_{kj}$. The data on which predict makes the calculation can be the same data used to fit the model or a different dataset—it does not matter. `predict` uses the stored parameter estimates from the model, obtains the corresponding values of $x$ for each observation in the data, and then combines them to produce the desired result.

### Estimation-sample predictions

> **Example 1**

We have a 74-observation dataset on automobiles, including the mileage rating (mpg), the car’s weight (weight), and whether the car is foreign (foreign). We fit the model

```
.use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
.regress mpg weight if foreign
```

```
Source |        SS       df       MS  Number of obs = 22
--------+--------------------------------------------------
Model   | 427.990298    1  427.990298 Prob > F = 0.0005
Residual| 489.873338    20  24.4936669 R-squared = 0.4663
         |                   Adj R-squared = 0.4396
         |                   Root MSE = 4.9491
Total   | 917.863636    21  43.7077922
         |--------------------------------------------------
mpg     |     Coef.  Std. Err.     t    P>|t|     [95% Conf. Interval]
--------+--------------------------------------------------
weight  |  -0.010426   .0024942  -4.18  0.000     -.0156287   -.0052232
_cons   |    48.9183    5.871851   8.33  0.000     36.66983     61.16676
```

If we were to type `predict pmpg` now, we would obtain the linear predictions for all 74 observations. To obtain the predictions just for the sample on which we fit the model, we could type

```
.predict pmpg if e(sample)
(option xb assumed; fitted values)
(52 missing values generated)
```

Here `e(sample)` is true only for foreign cars because we typed `if foreign` when we fit the model and because there are no missing values among the relevant variables. If there had been missing values, `e(sample)` would also account for those.

By the way, the `if e(sample)` restriction can be used with any Stata command, so we could obtain summary statistics on the estimation sample by typing

```
.summarize if e(sample)
(output omitted)
```

Out-of-sample predictions

By out-of-sample predictions, we mean predictions extending beyond the estimation sample. In the example above, typing `predict pmpg` would generate linear predictions using all 74 observations.

`predict` will work on other datasets, too. You can use a new dataset and type `predict` to obtain results for that sample.

Example 2

Using the same auto dataset, assume that we wish to fit the model

$$mpg = \beta_1 weight + \beta_2 \ln(weight) + \beta_3 foreign + \beta_4$$

We first create the $\ln(weight)$ variable, and then type the `regress` command:

```plaintext
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. generate lnweight = ln(weight)
. regress mpg weight lnweight foreign
```

If we typed `predict pmpg` now, we would obtain predictions for all 74 cars in the current data. Instead, we are going to use a new dataset.

The dataset `newautos.dta` contains the make, weight, and place of manufacture of two cars, the Pontiac Sunbird and the Volvo 260. Let’s use the dataset and create the predictions:

```plaintext
. use http://www.stata-press.com/data/r13/newautos, clear
(New Automobile Models)
. list
   make weight foreign
1. Pont. Sunbird 2690 Domestic
2. Volvo 260 3170 Foreign
. predict mpg
(option xb assumed; fitted values)
variable lnweight not found
r(111);
```

Things did not work. We typed `predict mpg`, and Stata responded with the message “variable lnweight not found”. `predict` can calculate predicted values on a different dataset only if that dataset contains the variables that went into the model. Here our dataset does not contain a variable called `lnweight`. `lnweight` is just the log of weight, so we can create it and try again:
. generate lnweight = ln(weight)
. predict mpg
   (option xb assumed; fitted values)
. list

<p>| | | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>make</td>
<td>weight</td>
<td>foreign</td>
<td>lnweight</td>
<td>mpg</td>
</tr>
<tr>
<td>-------</td>
<td>-------</td>
<td>--------</td>
<td>---------</td>
<td>------</td>
</tr>
<tr>
<td>1.</td>
<td>Pont. Sunbird</td>
<td>2690</td>
<td>Domestic</td>
<td>7.897296</td>
</tr>
<tr>
<td>2.</td>
<td>Volvo 260</td>
<td>3170</td>
<td>Foreign</td>
<td>8.061487</td>
</tr>
</tbody>
</table>

We obtained our predicted values. The Pontiac Sunbird has a predicted mileage rating of 23.3 mpg, whereas the Volvo 260 has a predicted rating of 17.9 mpg.

Residuals

Example 3

With many estimators, predict can calculate more than predicted values. With most regression-type estimators, we can, for instance, obtain residuals. Using our regression example, we return to our original data and obtain residuals by typing

. use http://www.stata-press.com/data/r13/auto, clear
   (1978 Automobile Data)
. generate lnweight = ln(weight)
. regress mpg weight lnweight foreign
   (output omitted)
. predict double resid, residuals
. summarize resid

<p>| | | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Variable</td>
<td>Obs</td>
<td>Mean</td>
<td>Std. Dev.</td>
<td>Min</td>
</tr>
<tr>
<td>resid</td>
<td>74</td>
<td>-1.51e-15</td>
<td>3.212091</td>
<td>-5.453078</td>
</tr>
</tbody>
</table>

We could do this without refitting the model. Stata always remembers the last set of estimates, even as we use new datasets.

It was not necessary to type the double in predict double resid, residuals, but we wanted to remind you that you can specify the type of a variable in front of the variable’s name; see [U] 11.4.2 Lists of new variables. We made the new variable resid a double rather than the default float.

If you want your residuals to have a mean as close to zero as possible, remember to request the extra precision of double. If we had not specified double, the mean of resid would have been roughly $10^{-9}$ rather than $10^{-14}$. Although $10^{-14}$ sounds more precise than $10^{-9}$, the difference really does not matter.

For linear regression, predict can also calculate standardized residuals and Studentized residuals with the options rstandard and rstudent; for examples, see [R] regress postestimation.
Single-equation (SE) models

If you have not read the discussion above on using `predict` after linear regression, please do so. And `predict`'s default calculation almost always produces a statistic in the same metric as the dependent variable of the fitted model—for example, predicted counts for Poisson regression. In any case, `xb` can always be specified to obtain the linear prediction.

`predict` can calculate the standard error of the prediction, which is obtained by using the covariance matrix of the estimators.

» Example 4

After most binary outcome models (for example, logistic, logit, probit, cloglog, scobit), `predict` calculates the probability of a positive outcome if we do not tell it otherwise. We can specify the `xb` option if we want the linear prediction (also known as the logit or probit index). The odd abbreviation `xb` is meant to suggest `xβ`. In logit and probit models, for example, the predicted probability is $p = F(xβ)$, where $F(\cdot)$ is the logistic or normal cumulative distribution function, respectively.

```
. logistic foreign mpg weight
(output omitted)
. predict phat
(option pr assumed; Pr(foreign))
. predict idxhat, xb
. summarize foreign phat idxhat

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>74</td>
<td>.2972973</td>
<td>.4601885</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>phat</td>
<td>74</td>
<td>.2972973</td>
<td>.3052979</td>
<td>.000729</td>
<td>.8980594</td>
</tr>
<tr>
<td>idxhat</td>
<td>74</td>
<td>-1.678202</td>
<td>2.321509</td>
<td>-7.223107</td>
<td>2.175845</td>
</tr>
</tbody>
</table>
```

Because this is a logit model, we could obtain the predicted probabilities ourselves from the predicted index

```
. generate phat2 = exp(idxhat)/(1+exp(idxhat))
```

but using `predict` without options is easier.

» Example 5

For all models, `predict` attempts to produce a predicted value in the same metric as the dependent variable of the model. We have seen that for dichotomous outcome models, the default statistic produced by `predict` is the probability of a success. Similarly, for Poisson regression, the default statistic produced by `predict` is the predicted count for the dependent variable. You can always specify the `xb` option to obtain the linear combination of the coefficients with an observation’s $x$ values (the inner product of the coefficients and $x$ values). For `poisson` (without an explicit exposure), this is the natural log of the count.

```
. use http://www.stata-press.com/data/r13/airline, clear
. poisson injuries XYZowned
(output omitted)
```
predict injhat
(option n assumed; predicted number of events)
predict idx, xb
generate exp_idx = exp(idx)
summarize injuries injhat exp_idx idx

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
</table>
injuries  | 9   | 7.111111| 5.487359  | 1    | 19   |
injhat    | 9   | 7.111111| 0.833333  | 6    | 7.666667|
exp_idx   | 9   | 7.111111| 0.833333  | 6    | 7.666667|
idx       | 9   | 1.955174| 0.1225612 | 1.791759| 2.036882|

We note that our “hand-computed” prediction of the count (exp_idx) matches what was produced by the default operation of predict.

If our model has an exposure-time variable, we can use predict to obtain the linear prediction with or without the exposure. Let’s verify what we are getting by obtaining the linear prediction with and without exposure, transforming these predictions to count predictions and comparing them with the default count prediction from predict. We must remember to multiply by the exposure time when using predict ..., nooffset.

use http://www.stata-press.com/data/r13/airline, clear
poisson injuries XYZowned, exposure(n)
(output omitted)
predict double injhat
(option n assumed; predicted number of events)
predict double idx, xb
gen double exp_idx = exp(idx)
predict double idxn, xb nooffset
gen double exp_idxn = exp(idxn)*n
summarize injuries injhat exp_idx exp_idxn idx idxn

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
</table>
injuries  | 9   | 7.111111 | 5.487359    | 1     | 19    |
injhat    | 9   | 7.111111 | 3.10936     | 2.919621 | 12.06158 |
exp_idx   | 9   | 7.111111 | 3.10936     | 2.919621 | 12.06158 |
exp_idxn  | 9   | 7.111111 | 3.10936     | 2.919621 | 12.06158 |
idx       | 9   | 1.869722 | 0.4671044   | 1.071454 | 2.490025 |
idxn      | 9   | 4.18814  | 0.1904042   | 4.061204 | 4.442013 |

Looking at the identical means and standard deviations for injhat, exp_idx, and exp_idxn, we see that we can reproduce the default computations of predict for poisson estimations. We have also demonstrated the relationship between the count predictions and the linear predictions with and without exposure.

SE model scores

Example 6

With most maximum likelihood estimators, predict can calculate equation-level scores. The first derivative of the log likelihood with respect to $x_j \beta$ is the equation-level score.
predict — Obtain predictions, residuals, etc., after estimation

(1978 Automobile Data)

. use http://www.stata-press.com/data/r13/auto, clear
. logistic foreign mpg weight
(output omitted)
. predict double sc, score
. summarize sc

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>sc</td>
<td>74</td>
<td>-1.37e-12</td>
<td>.3533133</td>
<td>-.8760856</td>
<td>.8821309</td>
</tr>
</tbody>
</table>

See [P] _robust and [SVY] variance estimation for details regarding the role equation-level scores play in linearization-based variance estimators.

Technical note

predict after some estimation commands, such as regress and cnsreg, allows the score option as a synonym for the residuals option.

Multiple-equation (ME) models

If you have not read the above discussion on using predict after SE models, please do so. With the exception of the ability to select specific equations to predict from, the use of predict after ME models follows almost the same form that it does for SE models.

Example 7

The details of prediction statistics that are specific to particular ME models are documented with the estimation command. If you are using ME commands that do not have separate discussions on obtaining predictions, read Obtaining predicted values in [R] mlogit postestimation, even if your interest is not in multinomial logistic regression. As a general introduction to the ME models, we will demonstrate predict after sureg:

. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. sureg (price foreign displ) (weight foreign length)

Seemingly unrelated regression

<table>

`predict` — Obtain predictions, residuals, etc., after estimation

`sureg` estimated two equations, one called `price` and the other `weight`; see [R] `sureg`.

. predict pred_p, equation(price)
   (option xb assumed; fitted values)
. predict pred_w, equation(weight)
   (option xb assumed; fitted values)
. summarize price pred_p weight pred_w

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>price</td>
<td>74</td>
<td>6165.257</td>
<td>2949.496</td>
<td>3291</td>
<td>15906</td>
</tr>
<tr>
<td>pred_p</td>
<td>74</td>
<td>6165.257</td>
<td>1678.805</td>
<td>2664.81</td>
<td>10485.33</td>
</tr>
<tr>
<td>weight</td>
<td>74</td>
<td>3019.459</td>
<td>777.1936</td>
<td>1760</td>
<td>4840</td>
</tr>
<tr>
<td>pred_w</td>
<td>74</td>
<td>3019.459</td>
<td>726.0468</td>
<td>1501.602</td>
<td>4447.996</td>
</tr>
</tbody>
</table>

You may specify the equation by name, as we did above, or by number: `equation(#1)` means the same thing as `equation(price)` in this case.

### ME model scores

#### Example 8

For ME models, `predict` allows you to specify a stub when generating equation-level score variables. `predict` generates new variables using this stub by appending an equation index. Depending upon the command, the index will start with 0 or 1. Here is an example where `predict` starts indexing the score variables with 0.

. ologit rep78 mpg weight
   (output omitted)
. predict double sc*, scores
. summarize sc*

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>sc0</td>
<td>69</td>
<td>-1.33e-11</td>
<td>.5337363</td>
<td>-.9854088</td>
<td>.921433</td>
</tr>
<tr>
<td>sc1</td>
<td>69</td>
<td>-7.69e-13</td>
<td>.186919</td>
<td>-.2738537</td>
<td>.9854088</td>
</tr>
<tr>
<td>sc2</td>
<td>69</td>
<td>-2.87e-11</td>
<td>.4061637</td>
<td>-.5188487</td>
<td>1.130178</td>
</tr>
<tr>
<td>sc3</td>
<td>69</td>
<td>-1.04e-10</td>
<td>.5315368</td>
<td>-1.067351</td>
<td>.8194842</td>
</tr>
<tr>
<td>sc4</td>
<td>69</td>
<td>1.47e-10</td>
<td>.360525</td>
<td>-.921433</td>
<td>.6140182</td>
</tr>
</tbody>
</table>

Although it involves much more typing, we could also specify the new variable names individually.

. predict double (sc_xb sc_1 sc_2 sc_3 sc_4), scores
. summarize sc_*

<table>

</tr>
</tbody>
</table>
Methods and formulas

Denote the previously estimated coefficient vector as \( \mathbf{b} \) and its estimated variance matrix as \( \mathbf{V} \). \texttt{predict} works by recalling various aspects of the model, such as \( \mathbf{b} \), and combining that information with the data currently in memory. Let’s write \( \mathbf{x}_j \) for the \( j \)th observation currently in memory.

The \emph{predicted value} (xb option) is defined as \( \hat{y}_j = \mathbf{x}_j \mathbf{b} + \text{offset}_j \)

The \emph{standard error of the prediction} (the stdp option) is defined as \( s_{p_j} = \sqrt{\mathbf{x}_j \mathbf{V} \mathbf{x}_j'} \)

The \emph{standard error of the difference in linear predictions} between equations 1 and 2 is defined as

\[
s_{dp_j} = \left\{ (\mathbf{x}_{1j}, -\mathbf{x}_{2j}, 0, \ldots, 0) \mathbf{V} (\mathbf{x}_{1j}, -\mathbf{x}_{2j}, 0, \ldots, 0)' \right\}^{1/2}
\]

See the individual estimation commands for information about calculating command-specific \texttt{predict} statistics.

Menu

Statistics > Postestimation > Nonlinear predictions

Description

`predictnl` calculates (possibly) nonlinear predictions after any Stata estimation command and optionally calculates the variances, standard errors, Wald test statistics, significance levels, and confidence limits for these predictions. Unlike its companion nonlinear postestimation commands `testnl` and `nlcom`, `predictnl` generates functions of the data (that is, predictions), not scalars. The quantities generated by `predictnl` are thus vectorized over the observations in the data.

Consider some general prediction, \( g(\theta, x_i) \), for \( i = 1, \ldots, n \), where \( \theta \) are the model parameters and \( x_i \) are some data for the \( i \)th observation; \( x_i \) is assumed fixed. Typically, \( g(\theta, x_i) \) is estimated by \( g(\hat{\theta}, x_i) \), where \( \hat{\theta} \) are the estimated model parameters, which are stored in `e(b)` following any Stata estimation command.
predictnl — Obtain nonlinear predictions, standard errors, etc., after estimation

In its most common use, predictnl generates two variables: one containing the estimated prediction, \( g(\hat{\theta}, x_i) \), the other containing the estimated standard error of \( g(\hat{\theta}, x_i) \). The calculation of standard errors (and other obtainable quantities that are based on the standard errors, such as test statistics) is based on the delta method, an approximation appropriate in large samples; see Methods and formulas.

predictnl can be used with svy estimation results (assuming that predict is also allowed), see \[SVY]\ svy postestimation.

The specification of \( g(\hat{\theta}, x_i) \) is handled by specifying \( pnl\_exp \), and the values of \( g(\hat{\theta}, x_i) \) are stored in the new variable \( newvar \) of storage type \( type \).

1. \texttt{predict([predict_options])}: When you are evaluating \( pnl\_exp \), \texttt{predict()} is a convenience function that replicates the calculation performed by the command
   \begin{verbatim}
   predict ..., predict_options
   \end{verbatim}
   As such, the \texttt{predict()} function may be used either as a shorthand for the formula used to make this prediction or when the formula is not readily available. When used without arguments, \texttt{predict()} replicates the default prediction for that particular estimation command.

2. \texttt{xb([eqno])}: The \texttt{xb()} function replicates the calculation of the linear predictor \( x_i b \) for equation \( eqno \). If \texttt{xb()} is specified without \( eqno \), the linear predictor for the first equation (or the only equation in single-equation estimation) is obtained.
   For example, \texttt{xb(#1)} (or equivalently, \texttt{xb()} with no arguments) translates to the linear predictor for the first equation, \texttt{xb(#2)} for the second, and so on. You could also refer to the equations by their names, such as \texttt{xb(income)}.
   When specifying \( pnl\_exp \), both of these functions may be used repeatedly, in combination, and in combination with other Stata functions and expressions. See Remarks and examples for examples that use both of these functions.

Options

\begin{verbatim}
Main
\end{verbatim}

\( \texttt{se(newvar)} \) adds \( newvar \) of storage type \( type \), where for each \( i \) in the prediction sample, \( newvar[i] \) contains the estimated standard error of \( g(\hat{\theta}, x_i) \).

\( \texttt{variance(newvar)} \) adds \( newvar \) of storage type \( type \), where for each \( i \) in the prediction sample, \( newvar[i] \) contains the estimated variance of \( g(\hat{\theta}, x_i) \).

\( \texttt{wald(newvar)} \) adds \( newvar \) of storage type \( type \), where for each \( i \) in the prediction sample, \( newvar[i] \) contains the Wald test statistic for the test of the hypothesis \( H_0: g(\theta, x_i) = 0 \).

\( \texttt{p(newvar)} \) adds \( newvar \) of storage type \( type \), where \( newvar[i] \) contains the significance level (\( p \)-value) of the Wald test of \( H_0: g(\theta, x_i) = 0 \) versus the two-sided alternative.

\( \texttt{ci(newvars)} \) requires the specification of two \( newvars \), such that the \( i \)th observation of each will contain the left and right endpoints (respectively) of a confidence interval for \( g(\theta, x_i) \). The level of the confidence intervals is determined by \( \texttt{level(#)} \).

\( \texttt{level(#)} \) specifies the confidence level, as a percentage, for confidence intervals. The default is \( \texttt{level(95)} \) or as set by \texttt{set level}; see [U] 20.7 Specifying the width of confidence intervals.
g(stub) specifies that new variables, stub1, stub2, ..., stubk be created, where k is the dimension of \( \theta \). stub1 will contain the observation-specific derivatives of \( g(\theta, x_i) \) with respect to the first element, \( \theta_1 \), of \( \theta \); stub2 will contain the derivatives of \( g(\theta, x_i) \) with respect to \( \theta_2 \), etc.; If the derivative of \( g(\theta, x_i) \) with respect to a particular coefficient in \( \theta \) equals zero for all observations in the prediction sample, the stub variable for that coefficient is not created. The ordering of the parameters in \( \theta \) is precisely that of the stored vector of parameter estimates \( \hat{\theta} \).

iterate(#) specifies the maximum number of iterations used to find the optimal step size in the calculation of numerical derivatives of \( g(\theta, x_i) \) with respect to \( \theta \). By default, the maximum number of iterations is 100, but convergence is usually achieved after only a few iterations. You should rarely have to use this option.

force forces the calculation of standard errors and other inference-related quantities in situations where predictnl would otherwise refuse to do so. The calculation of standard errors takes place by evaluating (at \( \hat{\theta} \)) the numerical derivative of \( g(\theta, x_i) \) with respect to \( \theta \). If predictnl detects that \( g() \) is possibly a function of random quantities other than \( \hat{\theta} \), it will refuse to calculate standard errors or any other quantity derived from them. The force option forces the calculation to take place anyway. If you use the force option, there is no guarantee that any inference quantities (for example, standard errors) will be correct or that the values obtained can be interpreted.

The following option is available with predictnl but is not shown in the dialog box:

\[
df(#) \quad \text{specifies that the } F \text{ distribution with } # \text{ denominator degrees of freedom be used for the reference distribution of the test statistic.}
\]

Remarks and examples

Remarks are presented under the following headings:

- Introduction
- Nonlinear transformations and standard errors
- Using xb() and predict()
- Multiple-equation (ME) estimators
- Test statistics and significance levels
- Manipulability
- Confidence intervals

Introduction

predictnl and nlcom both use the delta method. They take a nonlinear transformation of the estimated parameter vector from some fitted model and apply the delta method to calculate the variance, standard error, Wald test statistic, etc., of this transformation. nlcom is designed for scalar functions of the parameters, and predictnl is designed for functions of the parameters and of the data, that is, for predictions.

Nonlinear transformations and standard errors

We begin by fitting a probit model to the low-birthweight data of Hosmer, Lemeshow, and Sturdivant (2013, 24). The data are described in detail in example 1 of [R] logistic.

\[
\text{. use http://www.stata-press.com/data/r13/lbw}
\]
predictnl — Obtain nonlinear predictions, standard errors, etc., after estimation

(Hosmer & Lemeshow data)

. probit low lwt smoke ptl ht

Iteration 0: log likelihood = -117.336
Iteration 1: log likelihood = -106.75886
Iteration 2: log likelihood = -106.67852
Iteration 3: log likelihood = -106.67851

Probit regression

| Coef.  | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|--------|-----------|-------|------|----------------------|
| lwt    | -.0095164 | .0036875 | -2.58 | 0.010 | -.0167438 to -.0022891 |
| smoke  | .3487004  | .2041772 | 1.71  | 0.088 | -.0514794 to .7488803  |
| ptl    | .365667   | .1921201 | 1.90  | 0.057 | -.0108815 to .7422154  |
| ht     | 1.082355  | .410673 | 2.64  | 0.008 | .2774503 to 1.887259   |
| _cons  | .4238985  | .4823224 | 0.88  | 0.379 | -.5214361 to 1.369233  |

Log likelihood = -106.67851

Thus subject 180 in our data has an estimated probability of low birthweight of 23.6% with standard error 4.3%.

After we fit such a model, we first would want to generate the predicted probabilities of a low birthweight, given the covariate values in the estimation sample. This is easily done using predict after probit, but it doesn’t answer the question, “What are the standard errors of those predictions?”

For the time being, we will consider ourselves ignorant of any automated way to obtain the predicted probabilities after probit. The formula for the prediction is

\[ \Pr(y \neq 0|x_i) = \Phi(x_i\beta) \]

where \( \Phi \) is the standard cumulative normal. Thus for this example, \( g(\theta, x_i) = \Phi(x_i\beta) \). Armed with the formula, we can use predictn1 to generate the predictions and their standard errors:

. predictnl phat = normal(_b[_cons] + _b[ht]*ht + _b[ptl]*ptl + _b[smoke]*smoke + _b[lwt]*lwt), se(phat_se)

. list phat phat_se lwt smoke ptl ht in -10/l

</tbody>
</table>

Thus subject 180 in our data has an estimated probability of low birthweight of 23.6% with standard error 4.3%.

Used without options, predictn1 is not much different from generate. By specifying the se(phat_se) option, we were able to obtain a variable containing the standard errors of the predictions; therein lies the utility of predictn1.
Using \texttt{xb()} and \texttt{predict()}

As was the case above, a prediction is often not a function of a few isolated parameters and their corresponding variables but instead is some (possibly elaborate) function of the entire linear predictor. For models with many predictors, the brute-force expression for the linear predictor can be cumbersome to type. An alternative is to use the inline function \texttt{xb()}. \texttt{xb()} is a shortcut for having to type \texttt{\_b[_cons] + \_b[ht]*ht + \_b[ptl]*ptl + ...},

\begin{verbatim}
  . drop phat phat_se
  . predictnl phat = norm(xb()), se(phat_se)
  . list phat phat_se lwt smoke ptl ht in -10/l

    phat    phat_se  lwt  smoke  ptl  ht
  -------------  -------------  -------------  -------------  -------------  -------------  -------------  -------------  -------------  -------------  -------------  -------------
   180.  0.2363556  0.042707  120  0  0  0
   181.  0.657712  0.1580714  154  0  1  1
   182.  0.2793261  0.0519958  106  0  0  0
   183.  0.1502118  0.067339  190  1  0  0
   184.  0.5702871  0.0819911  101  1  1  0
   185.  0.4477045  0.079889  95  1  0  0
   186.  0.2988379  0.0576306  100  0  0  0
   187.  0.4514706  0.080815  94  1  0  0
   188.  0.5615571  0.1551051  142  0  0  1
   189.  0.7316517  0.1361469  130  1  0  1
\end{verbatim}

which yields the same results. This approach is easier, produces more readable code, and is less prone to error, such as forgetting to include a term in the sum.

Here we used \texttt{xb()} without arguments because we have only one equation in our model. In multiple-equation (ME) settings, \texttt{xb()} (or equivalently \texttt{xb(#1)}) yields the linear predictor from the first equation, \texttt{xb(#2)} from the second, etc. You can also refer to equations by their names, for example, \texttt{xb(income)}.

\section*{Technical note}

Most estimation commands in Stata allow the postestimation calculation of linear predictors and their standard errors via \texttt{predict}. For example, to obtain these for the first (or only) equation in the model, you could type

\begin{verbatim}
predict \texttt{xbvar}, xb
predict \texttt{stdpvar}, stdp
\end{verbatim}

Equivalently, you could type

\begin{verbatim}
predictnl \texttt{xbvar = xb()}, se(\texttt{stdpvar})
\end{verbatim}

but we recommend the first method, as it is faster. As we demonstrated above, however, \texttt{predictnl} is more general.

Returning to our probit example, we can further simplify the calculation by using the inline function \texttt{predict()}. \texttt{predict(pred_options)} works by substituting, within our \texttt{predictnl} expression, the calculation performed by

\begin{verbatim}
predict ..., pred_options
\end{verbatim}
In our example, we are interested in the predicted probabilities after a probit regression, normally obtained via

```
predict ..., p
```

We can obtain these predictions (and standard errors) by using

```
. drop phat phat_se
. predictnl phat = predict(p), se(phat_se)
. list phat phat_se lwt smoke ptl ht in -10/l
```

<table>

<td>1</td>
</tr>
</tbody>
</table>

which again replicates what we have already done by other means. However, this version did not require knowledge of the formula for the predicted probabilities after a probit regression—`predict(p)` took care of that for us.

Because the predicted probability is the default prediction after `probit`, we could have just used `predict()` without arguments, namely,

```
. predictnl phat = predict(), se(phat_se)
```

Also, the expression `pnl_exp` can be inordinately complicated, with multiple calls to `predict()` and `xb()`. For example,

```
. predictnl phat = normal(invnormal(predict()) + predict(xb)/xb() - 1),
> se(phat_se)
```

is perfectly valid and will give the same result as before, albeit a bit inefficiently.

---

## Technical note

When using `predict()` and `xb()`, the _formula_ for the calculation is substituted within `pnl_exp`, not the values that result from the application of that formula. To see this, note the subtle difference between

```
. predict xbeta, xb
. predictnl phat = normal(xbeta), se(phat_se)
```

and

```
. predictnl phat = normal(xb()), se(phat_se)
```
Both sequences will yield the same \( \text{phat} \), yet for the first sequence, \( \text{phat}_\text{se} \) will equal zero for all observations. The reason is that, once evaluated, \( \text{xbeta} \) will contain the values of the linear predictor, yet these values are treated as fixed and nonstochastic as far as \text{predictnl} \ is concerned. By contrast, because \( \text{xb()} \) is shorthand for the formula used to calculate the linear predictor, it contains not values, but references to the estimated regression coefficients and corresponding variables. Thus the second method produces the desired result.

**Multiple-equation (ME) estimators**

In \[ \text{R} \] \text{mlogit}, data on insurance choice (Tarlov et al. 1989; Wells et al. 1989) were examined, and a multinomial logit was used to assess the effects of age, gender, race, and site of study (one of three sites) on the type of insurance:

```stata
use http://www.stata-press.com/data/r13/sysdsn1, clear
(Health insurance data)
mlogit insure age male nonwhite i.site, nolog
```

Multinomial logistic regression

Of particular interest is the estimation of the relative risk, which, for a given selection, is the ratio of the probability of making that selection to the probability of selecting the base category (Indemnity here), given a set of covariate values. In a multinomial logit model, the relative risk (when comparing to the base category) simplifies to the exponentiated linear predictor for that selection.

Using this example, we can estimate the observation-specific relative risks of selecting a prepaid plan over the base category (with standard errors) by either referring to the Prepaid equation by name or number,

```
predictnl RRppaid = exp(xb(Prepaid)), se(SERRppaid)
```
or

predictnl RRppaid = exp(xb(#1)), se(SERRppaid)

because Prepaid is the first equation in the model.

Those of us for whom the simplified formula for the relative risk does not immediately come to mind may prefer to calculate the relative risk directly from its definition, that is, as a ratio of two predicted probabilities. After \texttt{mlogit}, the predicted probability for a category may be obtained using \texttt{predict}, but we must specify the category as the outcome:

predictnl RRppaid = predict(outcome(Prepaid))/predict(outcome(Indemnity)),
> se(SERRppaid)
(1 missing value generated)

. list RRppaid SERRppaid age male nonwhite site in 1/10

</table>

The “(1 missing value generated)” message is not an error; further examination of the data would reveal that \texttt{age} is missing in one observation and that the offending observation (among others) is not in the estimation sample. Just as with \texttt{predict}, \texttt{predictnl} can generate predictions in or out of the estimation sample.

Thus we estimate (among other things) that a white, female, 73-year-old from site 2 is less likely to choose a prepaid plan over an indemnity plan—her relative risk is about 62% with standard error 15%.

**Test statistics and significance levels**

Often a standard error calculation is just a means to an end, and what is really desired is a test of the hypothesis,

\[
H_0 : g(\theta, x_i) = 0
\]

versus the two-sided alternative.

We can use \texttt{predictnl} to obtain the Wald test statistics or significance levels (or both) for the above tests, whether or not we want standard errors. To obtain the Wald test statistics, we use the \texttt{wald()} option; for significance levels, we use \texttt{p()}.

Returning to our \texttt{mlogit} example, suppose that we wanted for each observation a test of whether the relative risk of choosing a prepaid plan over an indemnity plan is different from one. One way to do this would be to define \( g() \) to be the relative risk minus one and then test whether \( g() \) is different from zero.

predictnl RRm1 = exp(xb(Prepaid))) - 1, wald(W_RRm1) p(sig_RRm1)
(1 missing value generated)
The newly created variable \( W_{RRm1} \) contains the Wald test statistic for each observation, and \( \text{sig}_{RRm1} \) contains the level of significance. Thus our 73-year-old white female represented by the first observation would have a relative risk of choosing prepaid over indemnity that is significantly different from 1, at least at the 5% level. For this test, it was not necessary to generate a variable containing the standard error of the relative risk minus 1, but we could have done so had we wanted. We could have also omitted specifying \( \text{wald}(W_{RRm1}) \) if all we cared about were, say, the significance levels of the tests.

In this regard, \texttt{predictnl} acts as an observation-specific version of \texttt{testnl}, with the test results vectorized over the observations in the data. The significance levels are pointwise—they are not adjusted to reflect any simultaneous testing over the observations in the data.

**Manipulability**

There are many ways to specify \( g(\theta, x_i) \) to yield tests such that, for multiple specifications of \( g() \), the theoretical conditions for which

\[
H_0: g(\theta, x_i) = 0
\]

is true will be equivalent. However, this does not mean that the tests themselves will be equivalent. This is known as the manipulability of the Wald test for nonlinear hypotheses; also see [R] \texttt{boxcox}.

As an example, consider the previous section where we defined \( g() \) to be the relative risk between choosing a prepaid plan over an indemnity plan, minus 1. We could also have defined \( g() \) to be the risk difference—the probability of choosing a prepaid plan minus the probability of choosing an indemnity plan. Either specification of \( g() \) yields a mathematically equivalent specification of \( H_0: g() = 0 \); that is, the risk difference will equal zero when the relative risk equals one. However, the tests themselves do not give the same results:
In certain cases (such as subject 8), the difference can be severe enough to potentially change the conclusion. The reason for this inconsistency is that the nonlinear Wald test is actually a standard Wald test of a first-order Taylor approximation of \( g() \), and this approximation can differ according to how \( g() \) is specified.

As such, keep in mind the manipulability of nonlinear Wald tests when drawing scientific conclusions.

### Confidence intervals

We can also use `predictnl` to obtain confidence intervals for the observation-specific \( g(\theta, x_i) \) by using the `ci()` option to specify two new variables to contain the left and right endpoints of the confidence interval, respectively. For example, we could generate confidence intervals for the risk differences calculated previously:

```
. predictnl RD = predict(outcome(Prepaid)) - predict(outcome(Indemnity)),
    > ci(RD_lcl RD_rcl)
(1 missing value generated)
```

The confidence level, here, 95%, is either set using the `level()` option or obtained from the current default level, `c(level)`. see \([U\text{ } 20.7\) Specifying the width of confidence intervals.\]
From the above output, we can see that, for subjects 1, 8, and 10, a 95% confidence interval for the risk difference does not contain zero, meaning that, for these subjects, there is some evidence of a significant difference in risks.

The confidence intervals calculated by `predictnl` are pointwise; there is no adjustment (such as a Bonferroni correction) made so that these confidence intervals may be considered jointly at the specified level.

**Methods and formulas**

For the $i$th observation, consider the transformation $g(\theta, x_i)$, estimated by $g(\hat{\theta}, x_i)$, for the $1 \times k$ parameter vector $\theta$ and data $x_i$ ($x_i$ is assumed fixed). The variance of $g(\hat{\theta}, x_i)$ is estimated by

$$\hat{\text{Var}}\left\{g(\hat{\theta}, x_i)\right\} = GVG'$$

where $G$ is the vector of derivatives

$$G = \left\{ \frac{\partial g(\theta, x_i)}{\partial \theta} \right\}_{\theta=\hat{\theta}}^{(1 \times k)}$$

and $V$ is the estimated variance–covariance matrix of $\hat{\theta}$. Standard errors, $\hat{\text{se}}\{g(\hat{\theta}, x_i)\}$, are obtained as the square roots of the variances.

The Wald test statistic for testing $H_0: g(\theta, x_i) = 0$ versus the two-sided alternative is given by

$$W_i = \frac{\left\{g(\hat{\theta}, x_i)\right\}^2}{\hat{\text{Var}}\left\{g(\hat{\theta}, x_i)\right\}}$$

When the variance–covariance matrix of $\hat{\theta}$ is an asymptotic covariance matrix, $W_i$ is approximately distributed as $\chi^2$ with 1 degree of freedom. For linear regression, $W_i$ is taken to be approximately distributed as $F_{1,r}$, where $r$ is the residual degrees of freedom from the original model fit. The levels of significance of the observation-by-observation tests of $H_0$ versus the two-sided alternative are given by

$$p_i = \Pr(T > W_i)$$

where $T$ is either a $\chi^2$- or $F$-distributed random variable, as described above.

A $(1 - \alpha) \times 100\%$ confidence interval for $g(\theta, x_i)$ is given by

$$g(\hat{\theta}, x_i) \pm z_{\alpha/2} \left[ \hat{\text{se}} \left\{g(\hat{\theta}, x_i)\right\} \right]$$

when $W_i$ is $\chi^2$-distributed, and

$$g(\hat{\theta}, x_i) \pm t_{\alpha/2,r} \left[ \hat{\text{se}} \left\{g(\hat{\theta}, x_i)\right\} \right]$$

when $W_i$ is $F$-distributed.
when $W_i$ is $F$-distributed. $z_p$ is the $1 - p$ quantile of the standard normal distribution, and $t_{p,r}$ is the $1 - p$ quantile of the $t$ distribution with $r$ degrees of freedom.

Syntax

```
probit depvar [indepvars] [if] [in] [weight] [, options]
```

```
options
```

Model

- `noconstant` suppress constant term
- `offset(varname)` include varname in model with coefficient constrained to 1
- `asis` retain perfect predictor variables
- `constraints(constraints)` apply specified linear constraints
- `collinear` keep collinear variables

SE/Robust

- `vce(vcetype)` vcetype may be `oim`, `robust`, `cluster clustvar`, `bootstrap`, or `jackknife`

Reporting

- `level(#)` set confidence level; default is `level(95)`
- `nocnsreport` do not display constraints
- `display_options` control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

Maximization

- `maximize_options` control the maximization process; seldom used
- `nocoef` do not display the coefficient table; seldom used
- `coeflegend` display legend instead of statistics

Options

- `indepvars` may contain factor variables; see [U] 11.4.3 Factor variables.
- `depvar` and `indepvars` may contain time-series operators; see [U] 11.4.4 Time-series varlists.
- `bootstrap`, `by`, `fp`, `jackknife`, `mfp`, `mi estimate`, `nestreg`, `rolling`, `statsby`, `stepwise`, and `svy` are allowed; see [U] 11.1.10 Prefix commands.
- `vce(bootstrap)` and `vce(jackknife)` are not allowed with the `mi estimate` prefix; see [MI] mi estimate.
- Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
- `vce()`, `nocoef`, and weights are not allowed with the `svy` prefix; see [SVY] svy.
- `fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 weight.
- nocoef and coeflegend do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
probit — Probit regression

Menu

Statistics > Binary outcomes > Probit regression

Description

probit fits a maximum-likelihood probit model.

If estimating on grouped data, see the bprobit command described in [R] glogit.

Several auxiliary commands may be run after probit, logit, or logistic; see [R] logistic postestimation for a description of these commands.

See [R] logistic for a list of related estimation commands.

Options

- **Model**: noconstant, offset(varname), constraints(constraints), collinear; see [R] estimation options.

- **asis** specifies that all specified variables and observations be retained in the maximization process. This option is typically not specified and may introduce numerical instability. Normally probit drops variables that perfectly predict success or failure in the dependent variable along with their associated observations. In those cases, the effective coefficient on the dropped variables is infinity (negative infinity) for variables that completely determine a success (failure). Dropping the variable and perfectly predicted observations has no effect on the likelihood or estimates of the remaining coefficients and increases the numerical stability of the optimization process. Specifying this option forces retention of perfect predictor variables and their associated observations.

- **SE/Robust**: vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

- **Reporting**: level(#); see [R] estimation options.

- **nocnsreport**: see [R] estimation options.

- **display_options**: nomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

- **Maximization**: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.
The following options are available with `probit` but are not shown in the dialog box:

- `nocoef` specifies that the coefficient table not be displayed. This option is sometimes used by programmers but is of no use interactively.
- `coeflegend`; see `[R] estimation options`.

## Remarks and examples

Remarks are presented under the following headings:

- **Robust standard errors**
- **Model identification**

`probit` fits maximum likelihood models with dichotomous dependent (left-hand-side) variables coded as 0/1 (more precisely, coded as 0 and not 0).

### Example 1

We have data on the make, weight, and mileage rating of 22 foreign and 52 domestic automobiles. We wish to fit a probit model explaining whether a car is foreign based on its weight and mileage. Here is an overview of our data:

```
. use http://www.stata-press.com/data/r13/auto  
(1978 Automobile Data)
. keep make mpg weight foreign
. describe
Contains data from http://www.stata-press.com/data/r13/auto.dta
    obs:  74  1978 Automobile Data
    vars:  4  13 Apr 2013 17:45
    size: 1,702  (_dta has notes)

    storage  display  value
    +-----------------+-----------------+-----------------+
    | variable name   | type | format | label          |
    +-----------------+-----------------+-----------------+
    | make        | str18 | %-18s | Make and Model |
    | mpg         | int   | %8.0g | Mileage (mpg)  |
    | weight      | int   | %8.0gc| Weight (lbs.)  |
    | foreign     | byte  | %8.0g | origin Car type|
    +-----------------+-----------------+-----------------+
```

Sorted by:  foreign

Note: dataset has changed since last saved

```
. inspect foreign
foreign:  Car type
<table>
<thead>
<tr>
<th>Number of Observations</th>
</tr>
</thead>
<tbody>
<tr>
<td>Total</td>
</tr>
<tr>
<td>-------+----------+-------------</td>
</tr>
<tr>
<td>#</td>
</tr>
<tr>
<td>#</td>
</tr>
<tr>
<td>#</td>
</tr>
<tr>
<td># #</td>
</tr>
<tr>
<td># #</td>
</tr>
</tbody>
</table>
```

(2 unique values)

foreign is labeled and all values are documented in the label.
The `foreign` variable takes on two unique values, 0 and 1. The value 0 denotes a domestic car, and 1 denotes a foreign car.

The model that we wish to fit is

\[ \Pr(\text{foreign} = 1) = \Phi(\beta_0 + \beta_1 \text{weight} + \beta_2 \text{mpg}) \]

where \( \Phi \) is the cumulative normal distribution.

To fit this model, we type

```
.probit foreign weight mpg
```

Iteration 0:  log likelihood = -45.03321
Iteration 1:  log likelihood = -27.914626
(output omitted)
Iteration 5:  log likelihood = -26.844189

Probit regression

|                | Coef.  | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|----------------|--------|-----------|-------|------|---------------------|
| foreign        |        |           |       |      |                     |
| weight         | -.0023355 | .0005661  | -4.13 | 0.000 | -.003445 to -.0012261 |
| mpg            | -.1039503 | .0515689  | -2.02 | 0.044 | -.2050235 to -.0028772 |
| _cons          | 8.275464  | 2.554142  | 3.24  | 0.001 | 3.269437 to 13.28149 |

We find that heavier cars are less likely to be foreign and that cars yielding better gas mileage are also less likely to be foreign, at least holding the weight of the car constant.

See `[R] maximize` for an explanation of the output.

⚠️ Technical note

Stata interprets a value of 0 as a negative outcome (failure) and treats all other values (except missing) as positive outcomes (successes). Thus if your dependent variable takes on the values 0 and 1, then 0 is interpreted as failure and 1 as success. If your dependent variable takes on the values 0, 1, and 2, then 0 is still interpreted as failure, but both 1 and 2 are treated as successes.

If you prefer a more formal mathematical statement, when you type `probit y x`, Stata fits the model

\[ \Pr(y_j \neq 0 \mid x_j) = \Phi(x_j \beta) \]

where \( \Phi \) is the standard cumulative normal.

⚠️ Robust standard errors

If you specify the `vce(robust)` option, `probit` reports robust standard errors; see `[U] 20.21 Obtaining robust variance estimates`.

➤ Example 2

For the model from example 1, the robust calculation increases the standard error of the coefficient on `mpg` by almost 15%:
. probit foreign weight mpg, vce(robust) nolog

Probit regression
Number of obs = 74
Wald chi2(2) = 30.26
Prob > chi2 = 0.0000
Log pseudolikelihood = -26.844189 Pseudo R2 = 0.4039

Robust

|     | Coef. | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|-----|-------|-----------|-------|------|----------------------|
|     | weight| -.0023355 | .0004934 | -4.73 | 0.000 | -.0033025 -.0013686 |
|     | mpg   | -.1039503 | .0593548 | -1.75 | 0.080 | -.2202836 .0123829  |
|     | _cons | 8.275464  | 2.539177  | 3.26  | 0.001 | 3.298769  13.25216  |

Without vce(robust), the standard error for the coefficient on mpg was reported to be 0.052 with a resulting confidence interval of $[-0.21, -0.00]$.  

Example 3

The vce(cluster clustvar) option can relax the independence assumption required by the probit estimator to independence between clusters. To demonstrate, we will switch to a different dataset.

We are studying unionization of women in the United States and have a dataset with 26,200 observations on 4,434 women between 1970 and 1988. We will use the variables age (the women were 14–26 in 1968, and our data span the age range of 16–46), grade (years of schooling completed, ranging from 0 to 18), not_smsa (28% of the person-time was spent living outside an SMSA—standard metropolitan statistical area), south (41% of the person-time was in the South), and year. Each of these variables is included in the regression as a covariate along with the interaction between south and year. This interaction, along with the south and year variables, is specified in the probit command using factor-variables notation, south##c.year. We also have variable union, indicating union membership. Overall, 22% of the person-time is marked as time under union membership, and 44% of these women have belonged to a union.
We fit the following model, ignoring that the women are observed an average of 5.9 times each in these data:

```
. use http://www.stata-press.com/data/r13/union, clear
(NLS Women 14-24 in 1968)
. probit union age grade not_smsa south##c.year
Iteration 0: log likelihood = -13864.23
Iteration 1: log likelihood = -13545.541
Iteration 2: log likelihood = -13544.385
Iteration 3: log likelihood = -13544.385
Probit regression Number of obs = 26200
LR chi2(6) = 639.69
Prob > chi2 = 0.0000
Log likelihood = -13544.385 Pseudo R2 = 0.0231

|       | Coef. | Std. Err. |     z  |   P>|z| |    [95% Conf. Interval] |
|-------|-------|-----------|--------|-------|-------------------------|
| age   | 0.0118481 | 0.0029072  | 4.08   | 0.000 | 0.0061502 0.017546 |
| grade | 0.0267365 | 0.0036689  | 7.29   | 0.000 | 0.0195457 0.0339273 |
| not_smsa | -0.1293525 | 0.0202595   | -6.38  | 0.000 | -0.1690604 -0.0896445 |
| 1.south | -0.8281077 | 0.2472219   | -3.35  | 0.001 | -1.312654 -0.3435618 |
| year  | -0.0080931 | 0.0033469   | -2.42  | 0.016 | -0.0146529 -0.0015333 |
| south#c.year | 0.0057369 | 0.0030917   | 1.86   | 0.064 | -0.0003226 0.0117965 |
| _cons | -0.6542487 | 0.2007777 | -3.26  | 0.001 | -1.047766 -0.2607316 |

The reported standard errors in this model are probably meaningless. Women are observed repeatedly, and so the observations are not independent. Looking at the coefficients, we find a large southern effect against unionization and a time trend for the south that is almost significantly different from the overall downward trend. The `vce(cluster clustvar)` option provides a way to fit this model and obtains correct standard errors:
. probit union age grade not_smsa south##c.year, vce(cluster id)

Iteration 0:  log pseudolikelihood =  -13864.23
Iteration 1:  log pseudolikelihood =  -13545.541
Iteration 2:  log pseudolikelihood =  -13544.385
Iteration 3:  log pseudolikelihood =  -13544.385

Probit regression
Number of obs =  26200
Wald chi2(6) =  166.53
Prob > chi2 =  0.0000
Log pseudolikelihood =  -13544.385
Pseudo R2 =  0.0231

(Std. Err. adjusted for 4434 clusters in idcode)
Robust

|         | Coef.  | Std. Err. |   z   | P>|z|   | [95% Conf. Interval] |
|---------|--------|-----------|-------|-------|---------------------|
| union   | age    | 0.0118481 | 0.0056625 | 2.09 | 0.036  | 0.0007499 - 0.0229463 |
|         | grade  | 0.0267365 | 0.0078124 | 3.42 | 0.001  | 0.0114244 - 0.0420486 |
|         | not_smsa | -0.1293525 | 0.0403885 | -3.20 | 0.001  | -0.2085125 - 0.0501925 |
|         | 1.south | -0.8281077 | 0.3201584 | -2.59 | 0.010  | -1.4556070 - 0.0260899 |
|         | year   | -0.0080931 | 0.0060829 | -1.33 | 0.183  | -0.0200153 - 0.0038292 |
|         | south#c.year | 1 | 0.0057369 | 0.0040133 | 1.43 | 0.153  | -0.0021290 - 0.0136029 |
|         | _cons  | -0.6542487 | 0.3485976 | -1.88 | 0.061  | -1.3374870 - 0.028995 |

These standard errors are larger than those reported by the inappropriate conventional calculation. By comparison, another model we could fit is an equal-correlation population-averaged probit model:

. xtprobit union age grade not_smsa south##c.year, pa

Iteration 1:  tolerance =  0.12544249
Iteration 2:  tolerance =  0.0034686
Iteration 3:  tolerance =  0.00017448
Iteration 4:  tolerance =  8.382e-06
Iteration 5:  tolerance =  3.997e-07

GEE population-averaged model
Number of obs =  26200
Group variable:  idcode Number of groups =  4434
Link:  probit Obs per group:  min =  1
Family:  binomial avg =  5.9
Correlation:  exchangeable max =  12
Wald chi2(6) =  242.57
Scale parameter:  1 Prob > chi2 =  0.0000

|         | Coef.  | Std. Err. |   z   | P>|z|   | [95% Conf. Interval] |
|---------|--------|-----------|-------|-------|---------------------|
| union   | age    | 0.0089699 | 0.0053208 | 1.69 | 0.092  | -0.0014586 - 0.0193985 |
|         | grade  | 0.0333174 | 0.0062352 | 5.34 | 0.000  | 0.0210966 - 0.0455382 |
|         | not_smsa | -0.0715717 | 0.0275430 | -2.60 | 0.009  | -0.1255551 - 0.0175884 |
|         | 1.south | -1.0173688 | 0.2079311 | -4.89 | 0.000  | -1.4249050 - 0.6098308 |
|         | year   | -0.0062708 | 0.0055314 | -1.13 | 0.257  | -0.0171122 - 0.0045706 |
|         | south#c.year | 1 | 0.0086294 | 0.00258  | 3.34 | 0.001  | 0.0035727 - 0.013686 |
|         | _cons  | -0.8670997 | 0.2947711 | -2.94 | 0.003  | -1.44484 - 0.2893592 |
The coefficient estimates are similar, but these standard errors are smaller than those produced by `probit, vce(cluster clustvar)`, as we would expect. If the equal-correlation assumption is valid, the population-averaged probit estimator above should be more efficient.

Is the assumption valid? That is a difficult question to answer. The default population-averaged estimates correspond to an assumption of exchangeable correlation within person. It would not be unreasonable to assume an AR(1) correlation within person or to assume that the observations are correlated but that we do not wish to impose any structure. See [XT] `xtprobit` and [XT] `xtgee` for full details.

`probit, vce(cluster clustvar)` is robust to assumptions about within-cluster correlation. That is, it inefficiently sums within cluster for the standard error calculation rather than attempting to exploit what might be assumed about the within-cluster correlation.

**Model identification**

The `probit` command has one more feature that is probably the most useful. It will automatically check the model for identification and, if the model is underidentified, drop whatever variables and observations are necessary for estimation to proceed.

#### Example 4

Have you ever fit a probit model where one or more of your independent variables perfectly predicted one or the other outcome?

For instance, consider the following data:

<table>
<thead>
<tr>
<th>Outcome y</th>
<th>Independent variable x</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
</tr>
</tbody>
</table>

Say that we wish to predict the outcome on the basis of the independent variable. The outcome is always zero when the independent variable is one. In our data, \( \Pr(y = 0 \mid x = 1) = 1 \), which means that the probit coefficient on \( x \) must be minus infinity with a corresponding infinite standard error. At this point, you may suspect that we have a problem.

Unfortunately, not all such problems are so easily detected, especially if you have many independent variables in your model. If you have ever had such difficulties, then you have experienced one of the more unpleasant aspects of computer optimization. The computer has no idea that it is trying to solve for an infinite coefficient as it begins its iterative process. All it knows is that, at each step, making the coefficient a little bigger, or a little smaller, works wonders. It continues on its merry way until either 1) the whole thing comes crashing to the ground when a numerical overflow error occurs or 2) it reaches some predetermined cutoff that stops the process. Meanwhile, you have been waiting. And the estimates that you finally receive, if any, may be nothing more than numerical roundoff.

Stata watches for these sorts of problems, alerts you, fixes them, and then properly fits the model.

Let’s return to our automobile data. Among the variables we have in the data is one called `repair` that takes on three values. A value of 1 indicates that the car has a poor repair record, 2 indicates an average record, and 3 indicates a better-than-average record. Here is a tabulation of our data:
All the cars with poor repair records (repair = 1) are domestic. If we were to attempt to predict foreign on the basis of the repair records, the predicted probability for the repair = 1 category would have to be zero. This in turn means that the probit coefficient must be minus infinity, and that would set most computer programs buzzing.

Let’s try using Stata on this problem.

```
. probit foreign b3.repair
    note: 1.repair != 0 predicts failure perfectly
    1.repair dropped and 10 obs not used
```

Iteration 0: log likelihood = -26.992087
Iteration 1: log likelihood = -22.276479
Iteration 2: log likelihood = -22.229184
Iteration 3: log likelihood = -22.229138
Iteration 4: log likelihood = -22.229138
Probit regression Number of obs = 48
LR chi2(1) = 9.53
Prob > chi2 = 0.0020
Log likelihood = -22.229138 Pseudo R2 = 0.1765

```
| foreign | Coef.  | Std. Err. | z     | P>|z|    | [95% Conf. Interval] |
|---------|--------|-----------|-------|-------|---------------------|
| repair  |        |           |       |       |                     |
| 1       | 0 (empty) |           |       |       |                     |
| 2       | -1.281552 | .4297326  | -2.98 | 0.003 | -2.123812 -.4392911 |
| _cons   | 9.89e-17 | .295409   | 0.00  | 1.000 | -.578991 .578991    |
```

Remember that all the cars with poor repair records (repair = 1) are domestic, so the model cannot be fit, or at least it cannot be fit if we restrict ourselves to finite coefficients. Stata noted that fact “note: 1.repair != 0 predicts failure perfectly”. This is Stata’s mathematically precise way of saying what we said in English. When repair is 1, the car is domestic.

Stata then went on to say, “1.repair dropped and 10 obs not used”. This is Stata eliminating the problem. First, 1.repair had to be removed from the model because it would have an infinite coefficient. Then the 10 observations that led to the problem had to be eliminated, as well, so as not to bias the remaining coefficients in the model. The 10 observations that are not used are the 10 domestic cars that have poor repair records.

Stata then fit what was left of the model, using the remaining observations. Because no observations remained for cars with poor repair records, Stata reports “(empty)” in the row for repair = 1.
Technical note

Stata is pretty smart about catching these problems. It will catch “one-way causation by a dummy variable”, as we demonstrated above.

Stata also watches for “two-way causation”, that is, a variable that perfectly determines the outcome, both successes and failures. Here Stata says that the variable “predicts outcome perfectly” and stops. Statistics dictate that no model can be fit.

Stata also checks your data for collinear variables; it will say “so-and-so omitted because of collinearity”. No observations need to be eliminated here and model fitting will proceed without the offending variable.

It will also catch a subtle problem that can arise with continuous data. For instance, if we were estimating the chances of surviving the first year after an operation, and if we included in our model age, and if all the persons over 65 died within the year, Stata will say, “age > 65 predicts failure perfectly”. It will then inform us about how it resolves the issue and fit what can be fit of our model.

`probit` (and `logit`, `logistic`, and `ivprobit`) will also occasionally fail to converge and then display messages such as

```
Note: 4 failures and 0 successes completely determined.
```

The cause of this message and what to do if you see it are described in [R] `logit`.

Stored results

`probit` stores the following in `e()`:  

Scalars

- `e(N)` number of observations
- `e(N_cds)` number of completely determined successes
- `e(N_cdf)` number of completely determined failures
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(r2_p)` pseudo-$R^2$-squared
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(p)` significance of model test
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise
Probit analysis originated in connection with bioassay, and the word probit, a contraction of “probability unit”, was suggested by Bliss (1934a, 1934b). For an introduction to probit and logit, see, for example, Aldrich and Nelson (1984), Cameron and Trivedi (2010), Greene (2012), Long (1997), Pampel (2000), or Powers and Xie (2008). Long and Freese (2014, chap. 5 and 6) and Jones (2007, chap. 3) provide introductions to probit and logit, along with Stata examples.

The log-likelihood function for probit is

$$\ln L = \sum_{j \in S} w_j \ln \Phi(x_j \beta) + \sum_{j \notin S} w_j \ln \left\{ 1 - \Phi(x_j \beta) \right\}$$

where $\Phi$ is the cumulative normal and $w_j$ denotes the optional weights. $\ln L$ is maximized, as described in [R] maximize.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using vce(robust) and vce(cluster clustvar), respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas. The scores are calculated as $u_j = \{\phi(x_j \beta) / \Phi(x_j \beta)\}x_j$ for the positive outcomes and $-[\phi(x_j \beta) / \{1 - \Phi(x_j \beta)\}]x_j$ for the negative outcomes, where $\phi$ is the normal density.

probit also supports estimation with survey data. For details on VCEs with survey data, see [SVY] variance estimation.
Chester Ittner Bliss (1899–1979) was born in Ohio. He was educated as an entomologist, earning degrees from Ohio State and Columbia, and was employed by the United States Department of Agriculture until 1933. When he lost his job because of the Depression, Bliss then worked with R. A. Fisher in London and at the Institute of Plant Protection in Leningrad before returning to a post at the Connecticut Agricultural Experiment Station in 1938. He was also a lecturer at Yale for 25 years. Among many contributions to biostatistics, his development and application of probit methods to biological problems are outstanding.

The following postestimation commands are of special interest after `probit`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat classification</code></td>
<td>report various summary statistics, including the classification table</td>
</tr>
<tr>
<td><code>estat gof</code></td>
<td>Pearson or Hosmer–Lemeshow goodness-of-fit test</td>
</tr>
<tr>
<td><code>lroc</code></td>
<td>compute area under ROC curve and graph the curve</td>
</tr>
<tr>
<td><code>lsens</code></td>
<td>graph sensitivity and specificity versus probability cutoff</td>
</tr>
</tbody>
</table>

These commands are not appropriate after the `svy` prefix.

The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>contrast</code></td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td><code>estat ic</code></td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td><code>estat summarize</code></td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>

<tr>
<td><code>stdp</code></td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td><code>*deviance</code></td>
<td>deviance residual</td>
</tr>
<tr>
<td><code>score</code></td>
<td>first derivative of the log likelihood with respect to $x_j \beta$</td>
</tr>
</tbody>
</table>

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when `if e(sample)` is not specified.

**Menu for predict**

Statistics > Postestimation > Predictions, residuals, etc.

**Options for predict**

- `pr`, the default, calculates the probability of a positive outcome.
- `xb` calculates the linear prediction.
- `stdp` calculates the standard error of the linear prediction.
- `deviance` calculates the deviance residual.
- `score` calculates the equation-level score, $\partial \ln L / \partial (x_j \beta)$.
- `nooffset` is relevant only if you specified `offset(varname)` for `probit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $x_j b$ rather than as $x_j b + offset_j$.
- `rules` requests that Stata use any rules that were used to identify the model when making the prediction. By default, Stata calculates missing for excluded observations.
- `asif` requests that Stata ignore the rules and exclusion criteria and calculate predictions for all observations possible using the estimated parameter from the model.

**Remarks and examples**

Remarks are presented under the following headings:

- Obtaining predicted values
- Performing hypothesis tests
Obtaining predicted values

Once you have fit a probit model, you can obtain the predicted probabilities by using the predict command for both the estimation sample and other samples; see [U] 20 Estimation and postestimation commands and [R] predict. Here we will make only a few additional comments.

predict without arguments calculates the predicted probability of a positive outcome. With the xb option, predict calculates the linear combination $x_j b$, where $x_j$ are the independent variables in the $j$th observation and $b$ is the estimated parameter vector. This is known as the index function because the cumulative density indexed at this value is the probability of a positive outcome.

In both cases, Stata remembers any rules used to identify the model and calculates missing for excluded observations unless rules or asif is specified. This is covered in the following example.

With the stdp option, predict calculates the standard error of the prediction, which is not adjusted for replicated covariate patterns in the data.

You can calculate the unadjusted-for-replicated-covariate-patterns diagonal elements of the hat matrix, or leverage, by typing

```
. predict pred
. predict stdp, stdp
. generate hat = stdp^2*pred*(1-pred)
```

Example 1

In example 4 of [R] probit, we fit the probit model `probit foreign b3.repair`. To obtain predicted probabilities, we type

```
. predict p
(option pr assumed; Pr(foreign))
(10 missing values generated)
. summarize foreign p
```

```
Variable |    Obs   Mean    Std. Dev.   Min   Max
---------|---------|------------|--------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|---
. predict p3, asif
(option pr assumed; Pr(foreign))
. summarize for p p2 p3

</tbody>
</table>

Which is right? By default, predict uses the most conservative approach. If many observations had been excluded due to a simple rule, we could be reasonably certain that the rules prediction is correct. The asif prediction is correct only if the exclusion is a fluke and we would be willing to exclude the variable from the analysis, anyway. Then, however, we should refit the model to include the excluded observations.

Performing hypothesis tests

After estimation with probit, you can perform hypothesis tests by using the test or testnl command; see [U] 20 Estimation and postestimation commands.

Methods and formulas

Let index $j$ be used to index observations. Define $M_j$ for each observation as the total number of observations sharing $j$’s covariate pattern. Define $Y_j$ as the total number of positive responses among observations sharing $j$’s covariate pattern. Define $p_j$ as the predicted probability of a positive outcome for observation $j$.

For $M_j > 1$, the deviance residual $d_j$ is defined as

$$d_j = \pm \left( 2 \left[ Y_j \ln \left( \frac{Y_j}{M_j p_j} \right) + (M_j - Y_j) \ln \left( \frac{M_j - Y_j}{M_j (1 - p_j)} \right) \right] \right)^{1/2}$$

where the sign is the same as the sign of $(Y_j - M_j p_j)$. In the limiting cases, the deviance residual is given by

$$d_j = \begin{cases} 
-\sqrt{2M_j \ln(1 - p_j)} & \text{if } Y_j = 0 \\
\sqrt{2M_j \ln p_j} & \text{if } Y_j = M_j 
\end{cases}$$

### Remarks and examples

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

vce() and weights are not allowed with the svy prefix; see [SVY] svy.

fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.

coeflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
Menu

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Proportions

Description

proportion produces estimates of proportions, along with standard errors, for the categories identified by the values in each variable of `varlist`.

Options

`stdize(varname)` specifies that the point estimates be adjusted by direct standardization across the strata identified by `varname`. This option requires the `stdweight()` option.

`stdweight(varname)` specifies the weight variable associated with the standard strata identified in the `stdize()` option. The standardization weights must be constant within the standard strata.

`nostdrescale` prevents the standardization weights from being rescaled within the `over()` groups. This option requires `stdize()` but is ignored if the `over()` option is not specified.

`nolabel` specifies that value labels attached to the variables in `varlist` be ignored.

`missing` specifies that missing values in `varlist` be treated as valid categories, rather than omitted from the analysis (the default).

`over(varlist [, nolabel])` specifies that estimates be computed for multiple subpopulations, which are identified by the different values of the variables in `varlist`.

When this option is supplied with one variable name, such as `over(varname)`, the value labels of `varname` are used to identify the subpopulations. If `varname` does not have labeled values (or there are unlabeled values), the values themselves are used, provided that they are nonnegative integers. Noninteger values, negative values, and labels that are not valid Stata names are substituted with a default identifier.

When `over()` is supplied with multiple variable names, each subpopulation is assigned a unique default identifier.

`nolabel` requests that value labels attached to the variables identifying the subpopulations be ignored.

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`analytic`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap, jackknife`); see [R] `vce_option`.

`vce(analytic)`, the default, uses the analytically derived variance estimator associated with the sample proportion.

`level(#)`; see [R] `estimation options`. 
citytype(logit) specifies how to compute the limits of confidence intervals.

citytype(logit), the default, uses the logit transformation to compute the limits of confidence intervals.

citytype(normal) uses the normal approximation to compute the limits of confidence intervals.

noheader prevents the table header from being displayed. This option implies nolegend.

nolegend prevents the table legend identifying the subpopulations from being displayed.

display_options: cformat(%,fmt) and nolstretch; see [R] estimation options.

The following option is available with proportion but is not shown in the dialog box: coeflegend; see [R] estimation options.

Remarks and examples

Example 1

We can estimate the proportion of each repair rating in auto2.dta:

```
. use http://www.stata-press.com/data/r13/auto2
(1978 Automobile Data)
. proportion rep78
```

<table>
<thead>
<tr>
<th>Proportion estimation</th>
<th>Number of obs = 69</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Proportion</td>
</tr>
<tr>
<td>rep78</td>
<td></td>
</tr>
<tr>
<td>Poor</td>
<td>.0289855</td>
</tr>
<tr>
<td>Fair</td>
<td>.115942</td>
</tr>
<tr>
<td>Average</td>
<td>.4347826</td>
</tr>
<tr>
<td>Good</td>
<td>.2608696</td>
</tr>
<tr>
<td>Excellent</td>
<td>.1594203</td>
</tr>
</tbody>
</table>

Here we use the missing option to include missing values as a category of rep78:

```
. proportion rep78, missing
```

<table>
<thead>
<tr>
<th>Proportion estimation</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>_prop_6: rep78 = .</td>
<td></td>
</tr>
<tr>
<td>rep78</td>
<td></td>
</tr>
<tr>
<td>Poor</td>
<td>.027027</td>
</tr>
<tr>
<td>Fair</td>
<td>.1081081</td>
</tr>
<tr>
<td>Average</td>
<td>.4054054</td>
</tr>
<tr>
<td>Good</td>
<td>.2432432</td>
</tr>
<tr>
<td>Excellent</td>
<td>.1486486</td>
</tr>
<tr>
<td>_prop_6</td>
<td>.0675676</td>
</tr>
</tbody>
</table>
Example 2

We can also estimate proportions over groups:

```stata
. proportion rep78, over(foreign)
```

<table>
<thead>
<tr>
<th>Over</th>
<th>Proportion</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Poor</td>
<td>Domestic</td>
<td>.0416667</td>
<td>.0291477</td>
</tr>
<tr>
<td></td>
<td>Foreign</td>
<td>. (no observations)</td>
<td></td>
</tr>
<tr>
<td>Fair</td>
<td>Domestic</td>
<td>.1666667</td>
<td>.0543607</td>
</tr>
<tr>
<td></td>
<td>Foreign</td>
<td>. (no observations)</td>
<td></td>
</tr>
<tr>
<td>Average</td>
<td>Domestic</td>
<td>.5625</td>
<td>.0723605</td>
</tr>
<tr>
<td></td>
<td>Foreign</td>
<td>.1428571</td>
<td>.0782461</td>
</tr>
<tr>
<td>Good</td>
<td>Domestic</td>
<td>.1875</td>
<td>.0569329</td>
</tr>
<tr>
<td></td>
<td>Foreign</td>
<td>.4285714</td>
<td>.1106567</td>
</tr>
<tr>
<td>Excellent</td>
<td>Domestic</td>
<td>.0416667</td>
<td>.0291477</td>
</tr>
<tr>
<td></td>
<td>Foreign</td>
<td>.4285714</td>
<td>.1106567</td>
</tr>
</tbody>
</table>
**Stored results**

The *proportion* command stores the following in `e()`:

**Scalars**
- `e(N)` number of observations
- `e(N_over)` number of subpopulations
- `e(N_stdize)` number of standard strata
- `e(N_clust)` number of clusters
- `e(k_eq)` number of equations in `e(b)`
- `e(df_r)` sample degrees of freedom
- `e(rank)` rank of `e(V)`

**Macros**
- `e(cmd)` `proportion`
- `e(cmdline)` command as typed
- `e(varlist)` `varlist`
- `e(stdize)` `varname` from `stdize()`
- `e(stdweight)` `varname` from `stdweight()`
- `e(vtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(cluster)` name of cluster variable
- `e(over)` `varlist` from `over()`
- `e(over_labels)` labels from `over()` variables
- `e(over_namelist)` names from `e(over_labels)`
- `e(namelist)` proportion identifiers
- `e(label#)` labels from #th variable in `varlist`
- `e(vcetype)` `vcetype` specified in `vce()`
- `e(properties)` `b V`
- `e(estat_cmd)` program used to implement `estat`
- `e(marginsnotok)` predictions disallowed by `margins`

**Matrices**
- `e(b)` vector of proportion estimates
- `e(V)` (co)variance estimates
- `e(_N)` vector of numbers of nonmissing observations
- `e(_N_stdsum)` number of nonmissing observations within the standard strata
- `e(_p_stdize)` standardizing proportions
- `e(error)` error code corresponding to `e(b)`

**Functions**
- `e(sample)` marks estimation sample

**Methods and formulas**

Proportions are means of indicator variables; see [R] `mean`.

**Confidence intervals**

Confidence intervals for proportions are calculated using a logit transform so that the endpoints lie between 0 and 1. Let \( \hat{p} \) be an estimated proportion and \( \hat{s} \) be an estimate of its standard error. Let

\[
f(\hat{p}) = \ln \left( \frac{\hat{p}}{1 - \hat{p}} \right)
\]

be the logit transform of the proportion. In this metric, an estimate of the standard error is

\[
\hat{SE}\{f(\hat{p})\} = f'(\hat{p})\hat{s} = \frac{\hat{s}}{\hat{p}(1 - \hat{p})}
\]
Thus a $100(1 - \alpha)\%$ confidence interval in this metric is

$$\ln \left( \frac{\hat{p}}{1 - \hat{p}} \right) \pm \frac{t_{1-\alpha/2,\nu} \hat{s}}{\hat{p}(1 - \hat{p})}$$

where $t_{1-\alpha/2,\nu}$ is the $(1 - \alpha/2)$th quantile of Student’s $t$ distribution with $\nu$ degrees of freedom. The endpoints of this confidence interval are transformed back to the proportion metric by using the inverse of the logit transform

$$f^{-1}(y) = \frac{e^y}{1 + e^y}$$

Hence, the displayed confidence intervals for proportions are

$$f^{-1} \left\{ \ln \left( \frac{\hat{p}}{1 - \hat{p}} \right) \pm \frac{t_{1-\alpha/2,\nu} \hat{s}}{\hat{p}(1 - \hat{p})} \right\}$$

</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

Remarks and examples

Example 1

In example 2 of [R] proportion, we computed the proportions of cars with different repair records for each group, foreign or domestic. We use `test` to test whether the proportion of cars with repair record equal to 4 is the same for domestic and foreign cars.

```stata
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. proportion rep78, over(foreign)
   (output omitted)
. test [prop_4]:Domestic=[prop_4]:Foreign
   (1) [prop_4]Domestic - [prop_4]Foreign = 0
       F( 1, 68) = 3.75
       Prob > F = 0.0569
```

There is not a significant difference between those proportions at the 5% level.

Example 2

Continuing with `auto.dta` from example 1, we generate a new variable, `highprice`, that indicates if the price is larger than $5,000 and then use `proportion` to see the proportion of cars with high price among domestic and foreign cars separately.
. generate highprice = price>5000
. proportion highprice, over(foreign)

Proportion estimation

<table>
<thead>
<tr>
<th>Over</th>
<th>Proportion</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>_prop_1</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Domestic</td>
<td>.5576923</td>
<td>.0695464</td>
<td>.4182157 .6886264</td>
</tr>
<tr>
<td>Foreign</td>
<td>.3636364</td>
<td>.1049728</td>
<td>.1879015 .5852765</td>
</tr>
<tr>
<td>_prop_2</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Domestic</td>
<td>.4423077</td>
<td>.0695464</td>
<td>.3113736 .5817843</td>
</tr>
<tr>
<td>Foreign</td>
<td>.6363636</td>
<td>.1049728</td>
<td>.4147235 .8120985</td>
</tr>
</tbody>
</table>

We will compute the odds ratio of having a high price in group Foreign to having a high price in group Domestic. Usually, odds ratios are computed by using the logistic command, but here we will perform the computation by using nlcom after proportion.

. nlcom OR: ([_prop_2]_b[Foreign]/[_prop_1]_b[Foreign])/([_prop_2]_b[Domestic]/
> [_prop_1]_b[Domestic])

| Proportion | Coef.     | Std. Err. | z     | P>|z|   | [95% Conf. Interval] |
|------------|-----------|-----------|-------|-------|----------------------|
| OR         | 2.206522  | 1.178522  | 1.87  | 0.061 | -.1033393 .4516383   |

This is the same odds ratio that we would obtain from

. logistic highprice foreign

The odds ratio is slightly larger than 2, which means that the odds of having a high price among foreign cars are more than twice that of having a high price among domestic cars.

[U] 20 Estimation and postestimation commands
prtest — Tests of proportions

Syntax

One-sample test of proportion

\texttt{prtest varname == \# \[] \[if\]\[in\] \[, level(\#)\]}

Two-sample test of proportions using groups

\texttt{prtest varname \[if\] \[in\], by(groupvar) \[level(\#)\]}

Two-sample test of proportions using variables

\texttt{prtest varname_1 == varname_2 \[if\] \[in\], \[, level(\#)\]}

Immediate form of one-sample test of proportion

\texttt{prtesti \#obs1 \#p1 \#p2 \[, level(\#) count\]}

Immediate form of two-sample test of proportions

\texttt{prtesti \#obs1 \#p1 \#obs2 \#p2 \[, level(\#) count\]}

by is allowed with \texttt{prtest}; see [D] by.

Menu

\texttt{prtest}

Statistics > Summaries, tables, and tests > Classical tests of hypotheses > Proportion test

\texttt{prtesti}

Statistics > Summaries, tables, and tests > Classical tests of hypotheses > Proportion test calculator

Description

\texttt{prtest} performs tests on the equality of proportions using large-sample statistics.

In the first form, \texttt{prtest} tests that \texttt{varname} has a proportion of \#p. In the second form, \texttt{prtest} tests that \texttt{varname} has the same proportion within the two groups defined by \texttt{groupvar}. In the third form, \texttt{prtest} tests that \texttt{varname}_1 and \texttt{varname}_2 have the same proportion.

\texttt{prtesti} is the immediate form of \texttt{prtest}; see [U] 19 Immediate commands.
The `bitest` command is a better version of the first form of `prtest` in that it gives exact \( p \)-values. Researchers should use `bitest` when possible, especially for small samples; see [R] `bitest`.

**Options**

- **by** (`groupvar`) specifies a numeric variable that contains the group information for a given observation. This variable must have only two values. Do not confuse the by() option with the by prefix; both may be specified.

- **level(#)** specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [U] 20.7 Specifying the width of confidence intervals.

- **count** specifies that integer counts instead of proportions be used in the immediate forms of `prtest`.

  In the first syntax, `prtesti` expects that \( \#obs1 \) and \( \#p1 \) are counts—\( \#p1 \leq \#obs1 \)—and \( \#p2 \) is a proportion. In the second syntax, `prtesti` expects that all four numbers are integer counts, that \( \#obs1 \geq \#p1 \), and that \( \#obs2 \geq \#p2 \).

**Remarks and examples**

The `prtest` output follows the output of `ttest` in providing a lot of information. Each proportion is presented along with a confidence interval. The appropriate one- or two-sample test is performed, and the two-sided and both one-sided results are included at the bottom of the output. For a two-sample test, the calculated difference is also presented with its confidence interval. This command may be used for both large-sample testing and large-sample interval estimation.

➤ **Example 1: One-sample test of proportion**

In the first form, `prtest` tests whether the mean of the sample is equal to a known constant. Assume that we have a sample of 74 automobiles. We wish to test whether the proportion of automobiles that are foreign is different from 40%.

```
. use http://www.stata-press.com/data/r13/auto
    (1978 Automobile Data)
. prtest foreign == .4
```

One-sample test of proportion

<table>
<thead>
<tr>
<th>Variable</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>0.2972973</td>
<td>0.0531331</td>
<td>0.1931583 to 0.4014363</td>
</tr>
</tbody>
</table>

\( p = \text{proportion(foreign)} \)

Ho: \( p = 0.4 \)

- Ha: \( p < 0.4 \)
  \( Pr(Z < z) = 0.0357 \)

- Ha: \( p > 0.4 \)
  \( Pr(Z > z) = 0.9643 \)

The test indicates that we cannot reject the hypothesis that the proportion of foreign automobiles is 0.40 at the 5% significance level.
Example 2: Two-sample test of proportions

We have two headache remedies that we give to patients. Each remedy’s effect is recorded as 0 for failing to relieve the headache and 1 for relieving the headache. We wish to test the equality of the proportion of people relieved by the two treatments.

```
use http://www.stata-press.com/data/r13/cure
.prtest cure1 == cure2
```

| Variable | Mean  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|----------|-------|-----------|-------|------|---------------------|
| cure1    | 0.52  | 0.0706541 | 0.3815205 | 0.6584795 |
| cure2    | 0.7118644 | 0.0589618 | 0.5963013 | 0.8274275 |
| diff     | -0.1918644 | 0.0920245 | -3.72229 | -0.114998 |

```
derf = prop(cure1) - prop(cure2) z = -2.0605
Ho: diff = 0
Ha: diff < 0 Ha: diff != 0 Ha: diff > 0
Pr(Z < z) = 0.0197 Pr(|Z| < |z|) = 0.0394 Pr(Z > z) = 0.9803
```

We find that the proportions are statistically different from each other at any level greater than 3.9%.

Example 3: Immediate form of one-sample test of proportion

prtesti is like prtest, except that you specify summary statistics rather than variables as arguments. For instance, we are reading an article that reports the proportion of registered voters among 50 randomly selected eligible voters as 0.52. We wish to test whether the proportion is 0.7:

```
.prtesti 50 .52 .70
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>0.52</td>
<td>0.0706541</td>
<td>0.3815205</td>
</tr>
</tbody>
</table>

```
p = proportion(x) z = -2.7775
Ho: p = 0.7
Ha: p < 0.7 Ha: p != 0.7 Ha: p > 0.7
Pr(Z < z) = 0.0027 Pr(|Z| > |z|) = 0.0055 Pr(Z > z) = 0.9973
```

Example 4: Immediate form of two-sample test of proportions

To judge teacher effectiveness, we wish to test whether the same proportion of people from two classes will answer an advanced question correctly. In the first classroom of 30 students, 40% answered the question correctly, whereas in the second classroom of 45 students, 67% answered the question correctly.
Two-sample test of proportions

| Variable | Mean | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|----------|------|-----------|-----|-----|----------------------|
| x        | .4   | .0894427  | .2246955 | .5753045 |
| y        | .67  | .0700952  | .532616  | .807384   |
| diff     | -.27 | .1136368  | -.4927241 | -.0472759 |
| under Ho: | .1169416 | -2.31  | .0210     | .9895    |

\[ \text{diff} = \text{prop}(x) - \text{prop}(y) \]
\[ z = -2.3088 \]

Ho: \( \text{diff} = 0 \)

Ha: \( \text{diff} < 0 \)
Ha: \( \text{diff} \neq 0 \)
Ha: \( \text{diff} > 0 \)

\[ \Pr(Z < z) = 0.0105 \]
\[ \Pr(|Z| < |z|) = 0.0210 \]
\[ \Pr(Z > z) = 0.9895 \]

### Stored results

`prtest` and `prtesti` store the following in `r()`:

Scalars
- \( r(z) \) z statistic
- \( r(P_{-#}) \) proportion for variable #
- \( r(N_{-#}) \) number of observations for variable #

### Methods and formulas

See Acock (2014, 155–161) for additional examples of tests of proportions using Stata.

A large-sample 100\((1 - \alpha)\)% confidence interval for a proportion \( p \) is

\[ \hat{p} \pm z_{1-\alpha/2} \sqrt{\frac{\hat{p} \hat{q}}{n}} \]

and a 100\((1 - \alpha)\)% confidence interval for the difference of two proportions is given by

\[ (\hat{p}_1 - \hat{p}_2) \pm z_{1-\alpha/2} \sqrt{\frac{\hat{p}_1 \hat{q}_1}{n_1} + \frac{\hat{p}_2 \hat{q}_2}{n_2}} \]

where \( \hat{q} = 1 - \hat{p} \) and \( z \) is calculated from the inverse cumulative standard normal distribution.

The one-tailed and two-tailed tests of a population proportion use a normally distributed test statistic calculated as

\[ z = \frac{\hat{p} - p_0}{\sqrt{p_0 q_0 / n}} \]

where \( p_0 \) is the hypothesized proportion. A test of the difference of two proportions also uses a normally distributed test statistic calculated as
\[
    z = \frac{\hat{p}_1 - \hat{p}_2}{\sqrt{\hat{p}_p q_p \left( \frac{1}{n_1} + \frac{1}{n_2} \right)}}
\]

where

\[
    \hat{p}_p = \frac{x_1 + x_2}{n_1 + n_2}
\]

and \(x_1\) and \(x_2\) are the total number of successes in the two populations.

Time-series operators are allowed if they were used in the estimation.

### Menu

Statistics > Postestimation > Pairwise comparisons

### Description

`pwcompare` performs pairwise comparisons across the levels of factor variables from the most recently fit model. `pwcompare` can compare estimated cell means, marginal means, intercepts, marginal intercepts, slopes, or marginal slopes—collectively called margins. `pwcompare` reports the comparisons as contrasts (differences) of margins along with significance tests or confidence intervals for the contrasts. The tests and confidence intervals can be adjusted for multiple comparisons.

`pwcompare` can be used with `svy` estimation results; see [SVY] `svy postestimation`.

See [R] `margins`, `pwcompare` for performing pairwise comparisons of margins of linear and nonlinear predictions.

### Options

- `mcompare(method)` specifies the method for computing p-values and confidence intervals that account for multiple comparisons within a factor-variable term.

Most methods adjust the comparisonwise error rate, $\alpha_c$, to achieve a prespecified experimentwise error rate, $\alpha_e$.

- `mcompare(noadjust)` is the default; it specifies no adjustment.

$$\alpha_c = \alpha_e$$

- `mcompare(bonferroni)` adjusts the comparisonwise error rate based on the upper limit of the Bonferroni inequality:

$$\alpha_e \leq m\alpha_c$$

where $m$ is the number of comparisons within the term.

The adjusted comparisonwise error rate is

$$\alpha_c = \frac{\alpha_e}{m}$$
mcompare(sidak) adjusts the comparisonwise error rate based on the upper limit of the probability inequality

\[ \alpha_e \leq 1 - (1 - \alpha_c)^m \]

where \( m \) is the number of comparisons within the term.

The adjusted comparisonwise error rate is

\[ \alpha_c = 1 - (1 - \alpha_e)^{1/m} \]

This adjustment is exact when the \( m \) comparisons are independent.

mcompare(scheffe) controls the experimentwise error rate using the \( F \) (or \( \chi^2 \)) distribution with degrees of freedom equal to the rank of the term.

For results from \texttt{anova}, \texttt{regress}, \texttt{manova}, and \texttt{mvreg} (see \texttt{[R] anova}, \texttt{[R] regress}, \texttt{[MV] manova}, and \texttt{[MV] mvreg}), \texttt{pwcompare} allows the following additional methods. These methods are not allowed with results that used \texttt{vce(robust)} or \texttt{vce(cluster clustvar)}.

mcompare(tukey) uses what is commonly referred to as Tukey’s honestly significant difference. This method uses the Studentized range distribution instead of the \( t \) distribution.

mcompare(snk) is a variation on mcompare(tukey) that counts only the number of margins in the range for a given comparison instead of the full number of margins.

mcompare(duncan) is a variation on mcompare(snk) with additional adjustment to the significance probabilities.

mcompare(dunnett) uses Dunnett’s method for making comparisons with a reference category.

mcompare(method adjustall) specifies that the multiple-comparison adjustments count all comparisons across all terms rather than performing multiple comparisons term by term. This leads to more conservative adjustments when multiple variables or terms are specified in \texttt{marginlist}. This option is compatible only with the \texttt{bonferroni} and \texttt{sidak} methods.

asobserved specifies that factor covariates be evaluated using the cell frequencies observed when the model was fit. The default is to treat all factor covariates as though there were an equal number of observations at each level.

\texttt{equation(eqspec)} specifies the equation from which margins are to be computed. The default is to compute margins from the first equation.

\texttt{atequations} specifies that the margins be computed within each equation.

\texttt{emptycells(empspec)} specifies how empty cells are handled in interactions involving factor variables that are being treated as balanced.

\texttt{emptycells(strict)} is the default; it specifies that margins involving empty cells be treated as not estimable.

\texttt{emptycells(reweight)} specifies that the effects of the observed cells be increased to accommodate any missing cells. This makes the margins estimable but changes their interpretation.

\texttt{noestimcheck} specifies that \texttt{pwcompare} not check for estimability. By default, the requested margins are checked and those found not estimable are reported as such. Nonestimability is usually caused by empty cells. If \texttt{noestimcheck} is specified, estimates are computed in the usual way and reported even though the resulting estimates are manipulable, which is to say they can differ across equivalent models having different parameterizations.
level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see[U] 20.7 Specifying the width of confidence intervals. The significance level used by the groups option is 100 − #, expressed as a percentage.

cieffects specifies that a table of the pairwise comparisons with their standard errors and confidence intervals be reported. This is the default.

cieffects specifies that a table of the pairwise comparisons with their standard errors and confidence intervals be reported. This is the default.

pveffects specifies that a table of the pairwise comparisons with their standard errors, test statistics, and p-values be reported.

effects specifies that a table of the pairwise comparisons with their standard errors, test statistics, p-values, and confidence intervals be reported.

cimargins specifies that a table of the margins with their standard errors and confidence intervals be reported.

groups specifies that a table of the margins with their standard errors and group codes be reported. Margins with the same letter in the group code are not significantly different at the specified significance level.

sort specifies that the reported tables be sorted on the margins or differences in each term.

post causes pwcompare to behave like a Stata estimation (e-class) command. pwcompare posts the vector of estimated margins along with the estimated variance–covariance matrix to e(), so you can treat the estimated margins just as you would results from any other estimation command. For example, you could use test to perform simultaneous tests of hypotheses on the margins, or you could use lincom to create linear combinations.

display_options: vsquish, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch.

vsquish specifies that the blank space separating factor-variable terms or time-series–operated variables from other variables in the model be suppressed.

nofvlabel displays factor-variable level values rather than attached value labels. This option overrides the fvlabel setting; see [R] set showbaselevels.

fvwrap(#) specifies how many lines to allow when long value labels must be wrapped. Labels requiring more than # lines are truncated. This option overrides the fvwrap setting; see [R] set showbaselevels.

fvwrapon(style) specifies whether value labels that wrap will break at word boundaries or break based on available space.

fvwrapon(word), the default, specifies that value labels break at word boundaries.

fvwrapon(width) specifies that value labels break based on available space.

This option overrides the fvwrapon setting; see [R] set showbaselevels.

cformat(%fmt) specifies how to format contrasts or margins, standard errors, and confidence limits in the table of pairwise comparisons.

pformat(%fmt) specifies how to format p-values in the table of pairwise comparisons.

sformat(%fmt) specifies how to format test statistics in the table of pairwise comparisons.

nolstretch specifies that the width of the table of pairwise comparisons not be automatically widened to accommodate longer variable names. The default, lstretch, is to automatically widen the table of pairwise comparisons up to the width of the Results window. To change the default, use set lstretch off. nolstretch is not shown in the dialog box.
**eform\_option** specifies that the contrasts table be displayed in exponentiated form. \(e^{\text{contrast}}\) is displayed rather than contrast. Standard errors and confidence intervals are also transformed. See \[R\] **eform\_option** for the list of available options.

The following option is available with **pwcompare** but is not shown in the dialog box:

\(\text{df}(#)\) specifies that the \(t\) distribution with \# degrees of freedom be used for computing \(p\)-values and confidence intervals. The default is to use \(e(\text{df}\_r)\) degrees of freedom or the standard normal distribution if \(e(\text{df}\_r)\) is missing.

### Remarks and examples

**pwcompare** performs pairwise comparisons of margins across the levels of factor variables from the most recently fit model. The margins can be estimated cell means, marginal means, intercepts, marginal intercepts, slopes, or marginal slopes. With the exception of slopes, we can also consider these margins to be marginal linear predictions.

The margins are calculated as linear combinations of the coefficients. Let \(k\) be the number of levels for a factor term in our model; then there are \(k\) margins for that term, and

\[
m = \binom{k}{2} = \frac{k(k-1)}{2}
\]

unique pairwise comparisons of those margins.

The confidence intervals and \(p\)-values for these pairwise comparisons can be adjusted to account for multiple comparisons. Bonferroni’s, Šidák’s, and Scheffé’s adjustments can be made for multiple comparisons after fitting any type of model. In addition, Tukey’s, Student–Newman–Keuls’, Duncan’s, and Dunnett’s adjustments are available when fitting ANOVA, linear regression, MANOVA, or multivariate regression models.

Remarks are presented under the following headings:

- **Pairwise comparisons of means**
  - Marginal means
  - All pairwise comparisons
- **Overview of multiple-comparison methods**
  - Fisher’s protected least-significant difference (LSD)
  - Bonferroni’s adjustment
  - Šidák’s adjustment
  - Scheffé’s adjustment
  - Tukey’s HSD adjustment
  - Student–Newman–Keuls’ adjustment
  - Duncan’s adjustment
  - Dunnett’s adjustment
- **Example adjustments using one-way models**
  - Fisher’s protected LSD
  - Tukey’s HSD
  - Dunnett’s method for comparisons to a control
- **Two-way models**
  - Pairwise comparisons of slopes
  - Nonlinear models
  - Multiple-equation models
  - Unbalanced data
  - Empty cells
Pairwise comparisons of means

Suppose we are interested in the effects of five different fertilizers on wheat yield. We could estimate the following linear regression model to determine the effect of each type of fertilizer on the yield.

```
. use http://www.stata-press.com/data/r13/yield
(Artificial wheat yield dataset)
. regress yield i.fertilizer
```

In this simple case, the coefficients for fertilizers 10-08-22, 16-04-08, 18-24-06, and 29-03-04 indicate the difference in the mean yield for that fertilizer versus the mean yield for fertilizer 10-10-10. That the standard errors of all four coefficients are identical results from having perfectly balanced data.

Marginal means

We can use `pwcompare` with the `cimargins` option to compute the mean yield for each of the fertilizers.

```
. pwcompare fertilizer, cimargins
```

```

```

Looking at the confidence intervals for fertilizers 10-10-10 and 10-08-22 in the table above, we might be tempted to conclude that these means are not significantly different because the intervals overlap. However, as discussed in *Interaction plots of [R] marginsplot*, we cannot draw conclusions about the differences in means by looking at confidence intervals for the means themselves. Instead, we would need to look at confidence intervals for the difference in means.
All pairwise comparisons

By default, *pwcompare* calculates all pairwise differences of the margins, in this case pairwise differences of the mean yields.

```

If a confidence interval does not include zero, the means for the compared fertilizers are significantly different. Therefore, at the 5% significance level, we would reject the hypothesis that the means for fertilizers 10-10-10 and 10-08-22 are equivalent—as we would do for 18-24-06 vs 10-10-10, 29-03-04 vs 10-08-22, 18-24-06 vs 16-04-08, and 29-03-04 vs 18-24-06.

We may prefer to see the *p*-values instead of looking at confidence intervals to determine whether the pairwise differences are significantly different from zero. We could use the *pveffects* option to see the differences with standard errors and *p*-values, or we could use the *effects* option to see both *p*-values and confidence intervals in the same table. Here we specify *effects* as well as the *sort* option so that the differences are sorted from smallest to largest.
```

Note: Margins sharing a letter in the group label are not significantly different at the 5% level.

The letter A that is assigned to fertilizers 29-03-04, 10-10-10, and 16-04-08 designates that the mean yields for these fertilizers are not different at the 5% level.

Overview of multiple-comparison methods

For a single test, if we choose a 5% significance level, we would have a 5% chance of concluding that two margins are different when the population values are actually equal. This is known as making a type I error. When we perform \( m = k(k - 1)/2 \) pairwise comparisons of the \( k \) margins, we have \( m \) opportunities to make a type I error.

\texttt{pwcompare} with the \texttt{mcompare()} option allows us to adjust the confidence intervals and \( p \)-values for each comparison to account for the increased probability of making a type I error when making multiple comparisons. Bonferroni’s adjustment, Šidák’s adjustment, and Scheffé’s adjustment can be used when making pairwise comparisons of the margins after any estimation command. Tukey’s honestly significant difference, Student–Newman–Keuls’ method, Duncan’s method, and Dunnett’s method are only available when fitting linear models after \texttt{anova}, \texttt{manova}, \texttt{regress}, or \texttt{mvreg}.

Fisher’s protected least-significant difference (LSD)

\texttt{pwcompare} does not offer an \texttt{mcompare()} option specifically for Fisher’s protected least-significant difference (LSD). In this methodology, no adjustment is made to the confidence intervals or \( p \)-values. However, it is protected in the sense that no pairwise comparisons are tested unless the joint test for the corresponding term in the model is significant. Therefore, the default \texttt{mcompare(noadjust)} corresponds to Fisher’s protected LSD assuming that the corresponding joint test was performed before using \texttt{pwcompare}.

\textit{Milliken and Johnson (2009)} recommend using this methodology for planned comparisons, assuming the corresponding joint test is significant.

Bonferroni’s adjustment

\texttt{mcompare(bonferroni)} adjusts significance levels based on the Bonferroni inequality, which, in the case of multiple testing, tells us that the maximum error rate for all comparisons is the sum of the error rates for the individual comparisons. Assuming that we are using the same significance level for all tests, the experimentwise error rate is the error rate for a single test multiplied by the
number of comparisons. Therefore, a $p$-value for each comparison can be computed by multiplying the unadjusted $p$-value by the total number of comparisons. If the adjusted $p$-value is greater than 1, then `pwcompare` will report a $p$-value of 1.

Bonferroni’s adjustment is popular because it is easy to compute manually and because it can be applied to any set of tests, not only the pairwise comparisons available in `pwcompare`. In addition, this method does not require equal sample sizes.

Because Bonferroni’s adjustment is so general, it is more conservative than many of the other adjustments. It is especially conservative when a large number of tests is being performed.

**Šík’s adjustment**

`mcompare(sidak)` performs an adjustment using Šík’s method. This adjustment, like Bonferroni’s adjustment, is derived from an inequality. However, in this case, the inequality is based on the probability of not making a type I error. For a single test, the probability that we do not make a type I error is $1 - \alpha$. For two independent tests, both using $\alpha$ as a significance level, the probability is $(1 - \alpha)(1 - \alpha)$. Likewise, for $m$ independent tests, the probability of not making a type I error is $(1 - \alpha)^m$. Therefore, the probability of making one or more type I errors is $1 - (1 - \alpha)^m$. When tests are not independent, the probability of making at least one error is less than $1 - (1 - \alpha)^m$. Therefore, we can compute an adjusted $p$-value as $1 - (1 - u_p)^m$, where $u_p$ is the unadjusted $p$-value for a single comparison.

Šík’s method is also conservative although slightly less so than Bonferroni’s method. Like Bonferroni’s method, this method does not require equal sample sizes.

**Scheffé’s adjustment**

Scheffé’s adjustment is used when `mcompare(scheffe)` is specified. This adjustment is derived from the joint $F$ test and its correspondence to the maximum normalized comparison. To adjust for multiple comparisons, the absolute value of the $t$ statistic for a particular comparison can be compared with a critical value of $\sqrt{(k-1)F_{k-1,\nu}}$, where $\nu$ is the residual degrees of freedom. $F_{k-1,\nu}$ is the distribution of the joint $F$ test for the corresponding term in a one-way ANOVA model. Winer, Brown, and Michels (1991, 191–195) discuss this in detail. For estimation commands that report $z$ statistics instead of $t$ statistics for the tests on coefficients, a $\chi^2$ distribution is used instead of an $F$ distribution.

Scheffé’s method allows for making all possible comparisons of the $k$ margins, not just the pairwise comparisons. Unlike the methods described above, it does not take into account the number of comparisons that are currently being made. Therefore, this method is even more conservative than the others. Because this method adjusts for all possible comparisons of the levels of the term, Milliken and Johnson (2009) recommend using this procedure when making unplanned contrasts that are suggested by the data. As Winer, Brown, and Michels (1991, 191) put it, this method is often used to adjust for “unfettered data snooping”. When using this adjustment, a contrast will never be significant if the joint $F$ or $\chi^2$ test for the term is not also significant.

This is another method that does not require equal sample sizes.
Tukey’s HSD adjustment

Tukey’s adjustment is also referred to as Tukey’s honestly significant difference (HSD) and is used when `mcompare(tukey)` is specified. It is often applied to all pairwise comparisons of means. Tukey’s HSD is commonly used as a post hoc test although this is not a requirement.

To adjust for multiple comparisons, Tukey’s method compares the absolute value of the $t$ statistic from the individual comparison with a critical value based on a Studentized range distribution with parameter equal to the number of levels in the term. When applied to pairwise comparisons of means,

$$q = \frac{\text{mean}_{\text{max}} - \text{mean}_{\text{min}}}{s}$$

follows a Studentized range distribution with parameter $k$ and $\nu$ degrees of freedom. Here $\text{mean}_{\text{max}}$ and $\text{mean}_{\text{min}}$ are the largest and smallest marginal means, and $s$ is an estimate of the standard error of the means.

Now for the comparison of the smallest and largest means, we can say that the probability of not making a type I error is

$$\Pr\left(\frac{\text{mean}_{\text{max}} - \text{mean}_{\text{min}}}{s} \leq q_{k,\nu}\right) = 1 - \alpha$$

Then the following inequality holds for all pairs of means simultaneously:

$$\Pr\left(\left|\frac{\text{mean}_i - \text{mean}_j}{s}\right| \leq q_{k,\nu}\right) \geq 1 - \alpha$$

Based on this procedure, Tukey’s HSD computes the $p$-value for each of the individual comparisons using the Studentized range distribution. However, because the equality holds only for the difference in the largest and smallest means, this procedure produces conservative tests for the remaining comparisons. Winer, Brown, and Michels (1991, 172–182) discuss this in further detail.

With unequal sample sizes, `mcompare(tukey)` produces the Tukey–Kramer adjustment (Tukey 1953; Kramer 1956).

Student–Newman–Keuls’ adjustment

The Student–Newman–Keuls (SNK) method is used when `mcompare(snk)` is specified. It is a modification to Tukey’s method and is less conservative. In this procedure, we first order the means. We then test the difference in the smallest and largest means using a critical value from the Studentized range distribution with parameter $k$, where $k$ is the number of levels in the term. This step uses the same methodology as in Tukey’s procedure. However, in the next step, we will then test for differences in the two sets of means that are the endpoints of the two ranges including $k - 1$ means. Specifically, we test the difference in the smallest mean and the second-largest mean using a critical value from the Studentized range distribution with parameter $k - 1$. We would also test the difference in the second-smallest mean and the largest mean using this critical value. Likewise, the means that are the endpoints of ranges including $k - 2$ means when ordered are tested using the Studentized range distribution with parameter $k - 2$, and so on.

Equal sample sizes are required for this method.
Duncan’s adjustment

When \texttt{mcompare(duncan)} is specified, tests are adjusted for multiple comparisons using Duncan’s method, which is sometimes referred to as Duncan’s new multiple range method. This adjustment produces tests that are less conservative than both Tukey’s HSD and SNK. This procedure is performed in the same manner as SNK except that the \( p \)-values for the individual comparisons are adjusted as \( 1 - (1 - \text{snk}p_i)^{1/(r+1)} \), where \( \text{snk}p \) is the \( p \)-value computed using the SNK method and \( r \) represents the number of means that, when ordered, fall between the two that are being compared.

Again equal sample sizes are required for this adjustment.

Dunnett’s adjustment

Dunnett’s adjustment is obtained by specifying \texttt{mcompare(dunnett)}. It is used when one of the levels of a factor can be considered a control or reference level with which each of the other levels is being compared. When Dunnett’s adjustment is requested, \( k - 1 \) instead of \( k(k-1)/2 \) pairwise comparisons are made. Dunnett (1955, 1964) developed tables of critical values for what Miller (1981, 76) refers to as the “many-one \( t \) statistic”. The \( t \) statistics for individual comparisons are compared with these critical values when making many comparisons to a single reference level.

This method also requires equal sample sizes.

Example adjustments using one-way models

Fisher’s protected LSD

Fisher’s protected LSD requires that we first verify that the joint test for a term in our model is significant before proceeding with pairwise comparisons. Using our previous example, we could have first used the \texttt{contrast} command to obtain a joint test for the effects of fertilizer.

\begin{verbatim}
. contrast fertilizer
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>fertilizer</td>
<td>4</td>
<td>5.33</td>
<td>0.0004</td>
</tr>
<tr>
<td>Denominator</td>
<td>195</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
\end{verbatim}

This test for the effects of fertilizer is highly significant. Now we can say we are using Fisher’s protected LSD when looking at the unadjusted \( p \)-values that were obtained from our previous command,

\begin{verbatim}
. pwcompare fertilizer, effects sort
\end{verbatim}
Tukey’s HSD

Because we fit a linear regression model and are interested in all pairwise comparisons of the marginal means, we may instead choose to use Tukey’s HSD.

```
pwcompare fertilizer, effects sort mcompare(tukey)
```

Pairwise comparisons of marginal linear predictions

This time, our \( p \)-values have been modified, and we find that only four of the pairwise differences are considered significantly different from zero at the 5% level.

If we only are interested in performing pairwise comparisons of a subset of our means, we can use factor-variable operators to select the levels of the factor that we want to compare. Here we exclude all comparisons involving fertilizer 10-10-10.

The adjusted p-values and confidence intervals differ from those in the previous output because Tukey’s adjustment takes into account the total number of comparisons being made when determining the appropriate degrees of freedom to use for the Studentized range distribution.

**Dunnett’s method for comparisons to a control**

If one of our five fertilizer groups represents fields where no fertilizer was applied, we may want to use Dunnett’s method to compare each of the four fertilizers with the control group. In this case, we make only $k - 1$ comparisons for $k$ groups.
```
. pwcompare fertilizer, effects mcompare(dunnett)
Pairwise comparisons of marginal linear predictions

```

In our previous `regress` command, fertilizer 10-10-10 was treated as the base. Therefore, by default, it was treated as the control when using Dunnett’s adjustment, and the pairwise comparisons are equivalent to the coefficients reported by `regress`. Based on our `regress` output, we would conclude that fertilizers 10-08-22 and 18-24-06 are different from fertilizer 10-10-10 at the 5% level. However, using Dunnett’s adjustment, we find only fertilizer 18-24-06 to be different from fertilizer 10-10-10 at this same significance level.

If the model is fit without a base level for a factor variable, then `pwcompare` will choose the first level as the reference level. If we want to make comparisons with a different level than the one `mcompare(dunnett)` chooses by default, we can use the `b.` operator to override the default. Here we use fertilizer 5 (29-03-04) as the reference level.

Note: Margins sharing a letter in the group label are not significantly different at the 5% level.

Based on Tukey’s HSD and a 5% significance level, we would conclude that the mean yield for fertilizer 29-03-04 without irrigation is not significantly different from the mean yields for fertilizers 10-10-10, 10-08-22, and 16-04-08 when used without irrigation but is significantly different from the remaining means.

Up to this point, most of the pairwise comparisons that we have performed could have also been obtained with `pwmean` (see [R] `pwmean`) if we had not been interested in examining the results from the estimation command before making pairwise comparisons of the means. For instance, we could reproduce the results from the above `pwcompare` command by typing

```
. pwmean yield, over(fertilizer irrigation) sort group mcompare(tukey)
```

However, `pwcompare` extends the capabilities of `pwmean` in many ways. For instance, `pwmean` only allows for pairwise comparisons of the cell means determined by the highest level interaction of the variables specified in the `over()` option. However, `pwcompare` allows us to fit a single model, such as the two-way model that we fit above,

```
. regress yield fertilizer##irrigation
```
and compute pairwise comparisons of the marginal means for only one of the variables in the model:

```
pwcompare fertilizer, sort effects mcompare(tukey)
Pairwise comparisons of marginal linear predictions
Margins : asbalanced

```

Here the standard errors for the differences in marginal means and the residual degrees of freedom are based on the full model. Therefore, the results will differ from those obtained from `pwcompare` after fitting the one-way model with only `fertilizer` (or equivalently using `pwmean`).

**Pairwise comparisons of slopes**

If we fit a model with a factor variable that is interacted with a continuous variable, `pwcompare` will even allow us to make pairwise comparisons of the slopes of the continuous variable for the levels of the factor variable.

In this case, we have a continuous variable, `NO3_N`, indicating the amount of nitrate nitrogen already existing in the soil, based on a sample taken from each field.

| 29-03-04 vs 18-24-06 | -.2996772 | .4900939 | -0.61   | 0.984 |
| 16-04-08 vs 10-08-22 | .276328   | .5844405 | 0.47    | 0.994 |

Using Scheffé’s adjustment, we find that five of the pairs have significantly different slopes at the 5% level.
Nonlinear models

`pwcompare` can also perform pairwise comparisons of the marginal linear predictions after fitting a nonlinear model. For instance, we can use the dataset from *Beyond linear models* in `[R] contrast* and fit the following logistic regression model of patient satisfaction on hospital:

```
use http://www.stata-press.com/data/r13/hospital
(Artificial hospital satisfaction data)

.logit satisfied i.hospital
```

Iteration 0: log likelihood = -393.72216
Iteration 1: log likelihood = -387.55736
Iteration 2: log likelihood = -387.4768
Iteration 3: log likelihood = -387.47679

Logistic regression  Number of obs = 802
LR chi2(2) = 12.49
Prob > chi2 = 0.0019
Log likelihood = -387.47679  Pseudo R2 = 0.0159

|         | Coef. Std. Err. z   P>|z| [95% Conf. Interval] |
|---------|-------------------|--|-----------|------------------|
| hospital|                   |   |           |                  |
| 2       | 0.5348129  0.2136021| 2.50 | 0.012   | 0.1161604 - 0.9534654 |
| 3       | 0.7354519  0.2221929| 3.31 | 0.001   | 0.2999618 - 1.170942  |
| _cons  | 1.034708  0.1391469| 7.44 | 0.000   | 0.7619855 - 1.307431  |

For this model, the marginal linear predictions are the predicted log odds for each hospital and can be obtained with the `cimargins` option:

```
.pwcompare hospital, cimargins
```

Pairwise comparisons of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>Margin Std. Err. [95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>hospital</td>
<td></td>
</tr>
<tr>
<td>1</td>
<td>1.034708  0.1391469 0.7619855 1.307431</td>
</tr>
<tr>
<td>2</td>
<td>1.569521  0.1620618 1.251886 1.887157</td>
</tr>
<tr>
<td>3</td>
<td>1.77016   0.1732277 1.43064  2.10968</td>
</tr>
</tbody>
</table>

The pairwise comparisons are, therefore, differences in the log odds. We can specify `mcompare(bonferroni)` and `effects` to request Bonferroni-adjusted $p$-values and confidence intervals.

```
.pwcompare hospital, effects mcompare(bonferroni)
```

Pairwise comparisons of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>Number of Comparisons</th>
</tr>
</thead>
<tbody>
<tr>
<td>satisfied hospital</td>
<td>3</td>
</tr>
</tbody>
</table>
### Pairwise comparisons

| Contrast | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|----------|-----------|-------|------|---------------------|
| satisfied hospital 2 vs 1 | .5348129 | .2136021 | 2.50 | 0.037 | .0234537 1.046172 |
| 3 vs 1 | .7354519 | .2221929 | 3.31 | 0.003 | .2035265 1.267377 |
| 3 vs 2 | .200639 | .2372169 | 0.85 | 1.000 | -.3672535 .7685314 |

For nonlinear models, only Bonferroni’s adjustment, Šidák’s adjustment, and Scheffé’s adjustment are available.

If we want pairwise comparisons reported as odds ratios, we can specify the `or` option.

```
. pwcompare hospital, effects mcompare(bonferroni) or
```

Pairwise comparisons of marginal linear predictions

<table>
<thead>
<tr>
<th>Number of Comparisons</th>
</tr>
</thead>
<tbody>
<tr>
<td>satisfied hospital</td>
</tr>
<tr>
<td>3</td>
</tr>
</tbody>
</table>

| Odds Ratio | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|------------|-----------|-------|------|---------------------|
| satisfied hospital 2 vs 1 | 1.707129 | .3646464 | 2.50 | 0.037 | 1.023731 2.846733 |
| 3 vs 1 | 2.086425 | .4635888 | 3.31 | 0.003 | 1.225718 3.551525 |
| 3 vs 2 | 1.222183 | .2899226 | 0.85 | 1.000 | .6926341 2.156597 |

Notice that these tests are still performed on the marginal linear predictions. The odds ratios reported here are the exponentiated versions of the pairwise differences of log odds in the previous output. For further discussion, see [R] `contrast`.

### Multiple-equation models

`pwcompare` works with models containing multiple equations. Commands such as `intreg` and `gnbreg` allow their ancillary parameters to be modeled as a function of independent variables, and `pwcompare` can compare the margins within these equations. The `equation()` option can be used to specify the equation for which pairwise comparisons of the margins should be made. The `atequations` option specifies that pairwise comparisons be computed for each equation. In addition, `pwcompare` allows a special pseudofactor for equation—called `_eqns`—when working with results from `manova`, `mvreg`, `mlogit`, and `mprobit`.

Here we use the jaw fracture dataset described in example 4 of [MV] `manova`. We fit a multivariate regression model including one independent factor variable, `fracture`.
. use http://www.stata-press.com/data/r13/jaw
(Table 4.6 Two-Way Unbalanced Data for Fractures of the Jaw -- Rencher (1998))
. mvreg y1 y2 y3 = i.fracture

<table>

|                      | _cons   | 38.42857  | 2.390776 | 16.07 | 0.000 | 33.49425                        | 43.36289 |
| y3                   | fracture two compo.. | 4.261905  | 2.842618 | 1.50  | 0.147 | -1.60497                        | 10.12878 |
|                      | one simpl.. | .9285714  | 3.093377 | 0.30  | 0.767 | -5.455846                       | 7.312989 |
|                      | _cons   | 58.57143  | 2.259083 | 25.93 | 0.000 | 53.90891                        | 63.23395 |
`pwcompare` performs pairwise comparisons of the margins using the coefficients from the first equation by default:

```
. pwcompare fracture, mcompare(bonferroni)
Pairwise comparisons of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>y1 fracture</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>two compound fractures vs one compound fracture</td>
<td>-8.833333</td>
<td>4.957441</td>
<td>-21.59201 3.925341</td>
</tr>
<tr>
<td>one simple fracture vs one compound fracture</td>
<td>6</td>
<td>5.394759</td>
<td>-7.884173 19.88417</td>
</tr>
<tr>
<td>two compound fractures vs one simple fracture</td>
<td>14.83333</td>
<td>4.75773</td>
<td>2.588644 27.07802</td>
</tr>
</tbody>
</table>
```

We can use the `equation()` option to get `pwcompare` to perform comparisons in the `y2` equation:

```
. pwcompare fracture, equation(y2) mcompare(bonferroni)
Pairwise comparisons of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>y2 fracture</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>two compound fractures vs one compound fracture</td>
<td>-5.761905</td>
<td>3.008327</td>
<td>-13.50426 1.980449</td>
</tr>
<tr>
<td>one simple fracture vs one compound fracture</td>
<td>-3.053571</td>
<td>3.273705</td>
<td>-11.47891 5.371769</td>
</tr>
<tr>
<td>two compound fractures vs one simple fracture</td>
<td>2.708333</td>
<td>2.887136</td>
<td>-4.722119 10.13879</td>
</tr>
</tbody>
</table>
```
Because we are working with `mvreg` results, we can use the `_eqns` pseudofactor to compare the margins between the three dependent variables. The levels of `_eqns` index the equations: 1 for the first equation, 2 for the second, and 3 for the third.

```
. pwcompare _eqns, mcompare(bonferroni)
Pairwise comparisons of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th>Number of Comparisons</th>
</tr>
</thead>
<tbody>
<tr>
<td>_eqns</td>
</tr>
<tr>
<td>3</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>_eqns</th>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>2 vs 1</td>
<td>-.5654762</td>
<td>2.545923</td>
<td>-7.117768 5.986815</td>
</tr>
<tr>
<td>3 vs 1</td>
<td>24.24603</td>
<td>2.320677</td>
<td>18.27344 30.21862</td>
</tr>
<tr>
<td>3 vs 2</td>
<td>24.81151</td>
<td>2.368188</td>
<td>18.71664 30.90637</td>
</tr>
</tbody>
</table>
```

For the previous command, the only methods available are `mcompare(bonferroni)`, `mcompare(sidak)`, or `mcompare(scheffe)`. Methods that use the Studentized range are not appropriate for making comparisons across equations.

**Unbalanced data**

`pwcompare` treats all factors as balanced when it computes the marginal means. By “balanced”, we mean that the number of observations in each combination of factor levels (in each cell mean) is equal. We can alternatively specify the `asobserved` option when we have unbalanced data to obtain marginal means that are based on the observed cell frequencies from the model fit. For more details on the difference in these two types of marginal means and a discussion of when each may be appropriate, see `[R] margins` and `[R] contrast`.

In addition, when our data are not balanced, some of the multiple-comparison adjustments are no longer appropriate. Student–Newman–Keuls’ method, Duncan’s method, and Dunnett’s method assume equal numbers of observations per group.

Here we use an unbalanced dataset and fit a two-way ANOVA model for cholesterol levels on race and age group. Then we perform pairwise comparisons of the mean cholesterol levels for each race, requesting Šidák’s adjustment as well as marginal means that are computed using the observed cell frequencies.

Empty cells

An empty cell is a combination of the levels of factor variables that is not observed in the estimation sample. When we have empty cells in our data, the marginal means involving those empty cells are not estimable as described in [R] margins. In addition, all pairwise comparisons involving a marginal mean that is not estimable are themselves not estimable. Here we use a dataset where we do not have any observations for white individuals in the 20–29 age group. We can use the emptycells(reweight) option to reweight the nonempty cells so that we can estimate the marginal mean for whites and compute pairwise comparisons involving that marginal mean.

For further details on the emptycells(reweight) option, see [R] margins and [R] contrast.
 Stored results

pwcompare stores the following in r():

Scalars
r(df_r) variance degrees of freedom
r(k_terms) number of terms in marginlist
r(level) confidence level of confidence intervals
r(balanced) 1 if fully balanced data; 0 otherwise

Macros
r(cmd) pwcompare
r(cmdline) command as typed
r(est_cmd) e(cmd) from original estimation results
r(est_cmdline) e(cmdline) from original estimation results
r(title) title in output
r(emptycells) empspec from emptycells()

r(groups#) group codes for the #th margin in r(b)

r(mcmethod_vs) method from mcompare()

r(mctitle_vs) title for method from mcompare()

r(mcadjustall_vs) adjustall or empty

r(margin_method) asbalanced or asobserved

r(vce) vcetype specified in vce() in original estimation command

Matrices
r(b) margin estimates
r(V) variance–covariance matrix of the margin estimates
r(error) margin estimability codes;
0 means estimable,
8 means not estimable
r(table) matrix containing the margins with their standard errors, test statistics, p-values,
and confidence intervals
r(M) matrix that produces the margins from the model coefficients
r(b_vs) margin difference estimates
r(V_vs) variance–covariance matrix of the margin difference estimates
r(error_vs) margin difference estimability codes;
0 means estimable,
8 means not estimable
r(table_vs) matrix containing the margin differences with their standard errors, test statistics,
p-values, and confidence intervals
r(L) matrix that produces the margin differences from the model coefficients
r(k_groups) number of significance groups for each term
pwcompare with the post option also stores the following in e():

  - 8 means not estimable
- e(L) matrix that produces the margin differences from the model coefficients
- e(k_groups) number of significance groups for each term

Methods and formulas
Methods and formulas are presented under the following headings:

Notation
- Unadjusted comparisons
- Bonferroni’s method
- Šidák’s method
- Scheffé’s method
- Tukey’s method
- Student–Newman–Keuls’ method
- Duncan’s method
- Dunnett’s method

Notation

pwcompare performs comparisons of margins; see Methods and formulas in [R] contrast.

If there are \( k \) margins for a given factor term, then there are

\[
m = \binom{k}{2} = \frac{k(k - 1)}{2}
\]

unique pairwise comparisons. Let the \( i \)th pairwise comparison be denoted by

\[
\hat{\delta}_i = \mathbf{t}_i' \mathbf{b}
\]
where $b$ is a column vector of coefficients from the fitted model and $l_i$ is a column vector that forms the corresponding linear combination. If $\hat{V}$ denotes the estimated variance matrix for $b$, then the standard error for $\hat{\delta}_i$ is given by

$$
\hat{\text{se}}(\hat{\delta}_i) = \sqrt{l_i' \hat{V} l_i}
$$

The corresponding test statistic is then

$$
t_i = \frac{\hat{\delta}_i}{\hat{\text{se}}(\hat{\delta}_i)}
$$

and the limits for a $100(1 - \alpha)$% confidence interval for the expected value of $\hat{\delta}_i$ are

$$
\hat{\delta}_i \pm c_i(\alpha) \hat{\text{se}}(\hat{\delta}_i)
$$

where $c_i(\alpha)$ is the critical value corresponding to the chosen multiple-comparison method.

**Unadjusted comparisons**

`pwcompare` computes unadjusted $p$-values and confidence intervals by default. `pwcompare` uses the $t$ distribution with $\nu = e(df_r)$ degrees of freedom when $e(df_r)$ is posted by the estimation command. The unadjusted two-sided $p$-value is

$$
u p_i = 2 \Pr(t_\nu > |t_i|)
$$

and the unadjusted critical value $\nu c_i(\alpha)$ satisfies the following probability statement:

$$
\alpha = 2 \Pr\{t_\nu > \nu c_i(\alpha)\}
$$

`pwcompare` uses the standard normal distribution when $e(df_r)$ is not posted.

**Bonferroni’s method**

For `mcompare(bonferroni)`, the adjusted $p$-value is

$$
b p_i = \min(1, m u p_i)
$$

and the adjusted critical value is

$$
b c_i(\alpha) = \frac{u c_i(\alpha)}{m}
$$
Šidák’s method

For \texttt{mcompare(sidak)}, the adjusted \( p \)-value is

\[ si p_i = 1 - (1 - u p_i)^m \]

and the adjusted critical value is

\[ si c_i(\alpha) = u c_i \left\{ 1 - (1 - \alpha)^{1/m} \right\} \]

Scheffé’s method

For \texttt{mcompare(scheffe)}, the adjusted \( p \)-value is

\[ sc p_i = \Pr \left( F_{d,\nu} > t_i^2 / d \right) \]

where \( F_{d,\nu} \) is distributed as an \( F \) with \( d \) numerator and \( \nu \) denominator degrees of freedom and \( d \) is the rank of the VCE for the term. The adjusted critical value satisfies the following probability statement:

\[ \alpha = \Pr \left[ F_{d,\nu} > \left\{ sc c_i(\alpha) \right\}^2 / d \right] \]

\texttt{pwcompare} uses the \( \chi^2 \) distribution when \( \text{e(df}_r) \) is not posted.

Tukey’s method

For \texttt{mcompare(tukey)}, the adjusted \( p \)-value is

\[ t p_i = \Pr \left( q_{k,\nu} > |t_i| \sqrt{2} \right) \]

where \( q_{k,\nu} \) is distributed as the Studentized range statistic for \( k \) means and \( \nu \) residual degrees of freedom (Miller 1981). The adjusted critical value satisfies the following probability statement:

\[ \alpha = \Pr \left\{ q_{k,\nu} > t c_i(\alpha) \sqrt{2} \right\} \]

Student–Newman–Keuls’ method

For \texttt{mcompare(snk)}, suppose \( t_i \) is comparing two margins that have \( r \) other margins between them. Then the adjusted \( p \)-value is

\[ snk p_i = \Pr \left( q_{r+2,\nu} > |t_i| \sqrt{2} \right) \]

where \( r \) ranges from 0 to \( k - 2 \). The adjusted critical value \( snk c_i(\alpha) \) satisfies the following probability statement:

\[ \alpha = \Pr \left\{ q_{r+2,\nu} > snk c_i(\alpha) \sqrt{2} \right\} \]
Duncan’s method

For `mcompare(duncan)`, the adjusted $p$-value is

$$duncp_i = 1 - (1 - snkp_i)^{1/(r+1)}$$

and the adjusted critical value is

$$dunc_c_i(\alpha) = snkc_i \{1 - (1 - \alpha)^{r+1}\}$$

Dunnett’s method

For `mcompare(dunnett)`, the margins are compared with a reference category, resulting in only $k - 1$ pairwise comparisons. The adjusted $p$-value is

$$dunn_p_i = \Pr(d_{k-1,\nu} > |t_i|)$$

where $d_{k-1,\nu}$ is distributed as the many-one $t$ statistic (Miller 1981, 76). The adjusted critical value $dunn_c_i(\alpha)$ satisfies the following probability statement:

$$\alpha = \Pr\{d_{k-1,\nu} > dunn_c_i(\alpha)\}$$

The multiple-comparison methods for `mcompare(tukey)`, `mcompare(snk)`, `mcompare(duncan)`, and `mcompare(dunnett)` assume the normal distribution with equal variance; thus these methods are allowed only with results from `anova`, `regress`, `manova`, and `mvreg`. `mcompare(snk)`, `mcompare(duncan)`, and `mcompare(dunnett)` assume equal sample size for each marginal mean. These options will cause `pwcompare` to report a footnote if unbalanced factors are detected.

Title

pwcompare postestimation — Postestimation tools for pwcompare

Description

The following postestimation commands are available after `pwcompare, post`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>lincom</code></td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td><code>nlcom</code></td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

Remarks and examples

When we use the `post` option with `pwcompare`, the marginal linear predictions are posted as estimation results, and we can use postestimation commands to perform further analysis on them.

In *Pairwise comparisons of means* of [R] `pwcompare`, we fit a regression of wheat yield on types of fertilizers.

```
. use http://www.stata-press.com/data/r13/yield
(Artificial wheat yield dataset)
. regress yield i.fertilizer
(output omitted)
```

We also used `pwcompare` with the `cimargins` option to obtain the marginal mean yield for each fertilizer. We can add the `post` option to this command to post these marginal means and their VCEs as estimation results.
Pairwise comparisons of marginal linear predictions

<table>
<thead>
<tr>
<th></th>
<th>Margin</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>fertilizer</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>10-10-10</td>
<td>41.36243</td>
<td>1.124298</td>
<td>39.14509 43.57977</td>
</tr>
<tr>

<td>1.124298</td>
<td>44.06789 48.50258</td>
</tr>
<tr>
<td>29-03-04</td>
<td>40.1241</td>
<td>1.124298</td>
<td>37.90676 42.34145</td>
</tr>
</tbody>
</table>

Now we can use `nlcom` to compute a percentage improvement in the mean yield for fertilizer 2 when compared with fertilizer 1.

```
. nlcom (pct_chg: 100*(_b[2.fertilizer] - _b[1.fertilizer])/_b[1.fertilizer])
    pct_chg: 100*(_b[2.fertilizer] - _b[1.fertilizer])/_b[1.fertilizer]
```

|       | Coef.   | Std. Err. | z     | P>|z|   | [95% Conf. Interval] |
|-------|---------|-----------|-------|-------|----------------------|
| pct_chg | 8.758479 | 4.015932  | 2.18  | 0.029 | .8873982 16.62956 |

The mean yield for fertilizer 2 is about 9% higher than that of fertilizer 1, with a standard error of 4%.

Syntax

    pwmean varname, over(varlist)  [options]

options          Description

Main

*over(varlist)    compare means across each combination of the levels in varlist

mcompare(method)  adjust for multiple comparisons; default is mcompare(noadjust)

Reporting

level(#)          confidence level; default is level(95)

cieffects        display a table of mean differences and confidence intervals; the default

pveffects        display a table of mean differences and p-values

peffects         display a table of mean differences with p-values and confidence

                 intervals

ceffects         display a table of means and confidence intervals

groups           display a table of means with codes that group them with other means
                 that are not significantly different

sort             sort results tables by displayed mean or difference

display_options  control column formats, line width, and factor-variable labeling

*over(varlist) is required.

method           Description

noadjust         do not adjust for multiple comparisons; the default

bonferroni       Bonferroni’s method

sidak            Šidák’s method

scheffe          Scheffé’s method

tukey            Tukey’s method

snk              Student–Newman–Keuls’ method

duncan           Duncan’s method

dunnett          Dunnett’s method

Menu

Statistics  >  Summaries, tables, and tests  >  Summary and descriptive statistics  >  Pairwise comparisons of means
Description

\texttt{pwmean} performs pairwise comparisons of means. It computes all pairwise differences of the means of \texttt{varname} over the combination of the levels of the variables in \texttt{varlist}. The tests and confidence intervals for the pairwise comparisons assume equal variances across groups. \texttt{pwmean} also allows for adjusting the confidence intervals and \textit{p}-values to account for multiple comparisons using Bonferroni’s method, Scheffé’s method, Tukey’s method, Dunnett’s method, and others.

See [\texttt{R}] \texttt{pwcompare} for performing pairwise comparisons of means, estimated marginal means, and other types of marginal linear predictions after \texttt{anova}, \texttt{regress}, and most other estimation commands.

See [\texttt{R}] \texttt{margins}, \texttt{pwcompare} for performing pairwise comparisons of marginal probabilities and other linear and nonlinear predictions after estimation commands.

Options

\texttt{over(varlist)} is required and specifies that means are computed for each combination of the levels of the variables in \texttt{varlist}.

\texttt{mcompare(method)} specifies the method for computing \textit{p}-values and confidence intervals that account for multiple comparisons.

Most methods adjust the comparisonwise error rate, $\alpha_c$, to achieve a prespecified experimentwise error rate, $\alpha_e$.

\texttt{mcompare(noadjust)} is the default; it specifies no adjustment.

\hspace{1cm} $\alpha_c = \alpha_e$

\texttt{mcompare(bonferroni)} adjusts the comparisonwise error rate based on the upper limit of the Bonferroni inequality:

\hspace{1cm} $\alpha_e \leq m\alpha_c$

where \textit{m} is the number of comparisons within the term.

The adjusted comparisonwise error rate is

\hspace{1cm} $\alpha_c = \alpha_e / m$

\texttt{mcompare(sidak)} adjusts the comparisonwise error rate based on the upper limit of the probability inequality

\hspace{1cm} $\alpha_c \leq 1 - (1 - \alpha_e)^m$

where \textit{m} is the number of comparisons within the term.

The adjusted comparisonwise error rate is

\hspace{1cm} $\alpha_c = 1 - (1 - \alpha_e)^{1/m}$

This adjustment is exact when the \textit{m} comparisons are independent.

\texttt{mcompare(scheffe)} controls the experimentwise error rate using the $F$ (or $\chi^2$) distribution with degrees of freedom equal to $k - 1$ where \textit{k} is the number of means being compared.

\texttt{mcompare(tukey)} uses what is commonly referred to as Tukey’s honestly significant difference. This method uses the Studentized range distribution instead of the \textit{t} distribution.
mcompare(snk) is a variation on mcompare(tukey) that counts only the number of means participating in the range for a given comparison instead of the full number of means.

mcompare(duncan) is a variation on mcompare(snk) with additional adjustment to the significance probabilities.

mcompare(dunnett) uses Dunnett’s method for making comparisons with a reference category.

Reporting

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals. The significance level used by the groups option is 100 – #, expressed as a percentage.

cieffects specifies that a table of the pairwise comparisons of means with their standard errors and confidence intervals be reported. This is the default.

pveffects specifies that a table of the pairwise comparisons of means with their standard errors, test statistics, and p-values be reported.

effects specifies that a table of the pairwise comparisons of means with their standard errors, test statistics, p-values, and confidence intervals be reported.

cimeans specifies that a table of the means with their standard errors and confidence intervals be reported.

groups specifies that a table of the means with their standard errors and group codes be reported. Means with the same letter in the group code are not significantly different at the specified significance level.

sort specifies that the reported tables be sorted by the mean or difference that is displayed in the table.

display_options: nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch.

nofvlabel displays factor-variable level values rather than attached value labels. This option overrides the fvlabel setting; see [R] set showbaselevels.

fvwrap(#) specifies how many lines to allow when long value labels must be wrapped. Labels requiring more than # lines are truncated. This option overrides the fvwrap setting; see [R] set showbaselevels.

fvwrapon(style) specifies whether value labels that wrap will break at word boundaries or break based on available space.

fvwrapon(word), the default, specifies that value labels break at word boundaries.

fvwrapon(width) specifies that value labels break based on available space.

This option overrides the fvwrapon setting; see [R] set showbaselevels.

cformat(%fmt) specifies how to format means, standard errors, and confidence limits in the table of pairwise comparison of means.

pformat(%fmt) specifies how to format p-values in the table of pairwise comparison of means.

sformat(%fmt) specifies how to format test statistics in the table of pairwise comparison of means.

nolstretch specifies that the width of the table of pairwise comparisons not be automatically widened to accommodate longer variable names. The default, lstretch, is to automatically
widen the table of pairwise comparisons up to the width of the Results window. To change the default, use `set lstretch off`. `nolstretch` is not shown in the dialog box.

**Remarks and examples**

`pwmean` performs pairwise comparisons (differences) of means, assuming a common variance among groups. It can easily adjust the $p$-values and confidence intervals for the differences to account for the elevated type I error rate due to multiple comparisons. Adjustments for multiple comparisons can be made using Bonferroni’s method, Scheffé’s method, Tukey’s method, Dunnett’s method, and others.

Remarks are presented under the following headings:

- Group means
- Pairwise differences of means
- Group output
- Adjusting for multiple comparisons
  - Tukey’s method
  - Dunnett’s method
- Multiple over() variables
- Equal variance assumption

**Group means**

Suppose we have data on the wheat yield of fields that were each randomly assigned an application of one of five types of fertilizers. Let’s first look at the mean yield for each type of fertilizer.

```
. use http://www.stata-press.com/data/r13/yield
(Artificial wheat yield dataset)
. pwmean yield, over(fertilizer) cimeans
```

<table>

| 10-08-22 vs 29-03-04 | -6.161132| 1.589997  | -3.87 | 0.000 | -9.29693 -3.025333 |

The contrast in the row labeled (10-08-22 vs 10-10-10) is the difference in the mean wheat yield for fertilizer 10-08-22 and fertilizer 10-10-10. At a 5% significance level, we conclude that there is a difference in the means for these two fertilizers. Likewise, the rows labeled (18-24-06 vs 10-10-10), (29-03-04 vs 10-08-22), (18-24-06 vs 16-04-08) and (29-03-04 vs 18-24-06) show differences in these pairs of means. In all, we find that 5 of the 10 mean differences are significantly different from zero at a 5% significance level.
We can specify the `sort` option to order the differences from smallest to largest in the table.

```
pwmean yield, over(fertilizer) effects sort
```

Pairwise comparisons of means with equal variances over : fertilizer

| fertilizer | Contrast | Std. Err. | t | P>|t| | [95% Conf. Interval] |
|------------|----------|-----------|---|-------|---------------------|
| 29-03-04   | -6.161132| 1.589997  | -3.87 | 0.000 | -9.29693 -3.025333 |
| 18-24-06   | -4.861048| 1.589997  | -3.06 | 0.003 | -7.996847 -1.725249 |
| 10-08-22   | -3.13209 | 1.589997  | -1.97 | 0.050 | -6.267889 0.0037086 |
| 16-04-08   | -1.728958| 1.589997  | -1.09 | 0.278 | -4.864757 1.406841 |
| 10-10-10   | -1.238328| 1.589997  | -0.78 | 0.437 | -2.645169 3.626428 |
| 18-24-06   | .4906299 | 1.589997  | 0.31  | 0.758 | -2.645169 3.626428 |
| 10-08-22   | 1.300083 | 1.589997  | 0.82  | 0.415 | -1.835715 4.435882 |
| 10-10-10   | 3.62272  | 1.589997  | 2.28  | 0.024 | .4869212 6.758518  |
| 16-04-08   | 4.432173 | 1.589997  | 2.79  | 0.006 | 1.296375 7.567972  |
| 10-10-10   | 4.922803 | 1.589997  | 3.10  | 0.002 | 1.787005 8.058602  |

Ordering the pairwise differences is particularly convenient when we are comparing means for a large number of groups.

**Group output**

We can use the `group` option to see the mean of each group and a visual representation of the tests for differences.
. pwmean yield, over(fertilizer) group sort
Pairwise comparisons of means with equal variances
over : fertilizer

<table>
<thead>
<tr>
<th>fertilizer</th>
<th>Mean</th>
<th>Std. Err.</th>

</tr>
</tbody>
</table>

Note: Means sharing a letter in the group label are not significantly different at the 5% level.

Fertilizers 29-03-04, 10-10-10, and 16-04-08 are all in group A. This means that at our 5% level of significance, we have insufficient information to distinguish their means. Likewise, fertilizers 16-04-08 and 10-08-22 are in group B and cannot be distinguished at the 5% level. The same is true for fertilizers 10-08-22 and 18-24-06 in group C.

Fertilizer 29-03-04 and fertilizer 10-08-22 have no letters in common, indicating that the mean yields of these two groups are significantly different at the 5% level. We can conclude that any other fertilizers without a letter in common have significantly different means as well.

**Adjusting for multiple comparisons**

The statistics in the examples above take no account that we are performing 10 comparisons. With our 5% significance level and assuming the comparisons are independent, we expect 1 in 20 tests of comparisons to be significant, even if all the population means are truly the same. If we are performing many comparisons, then we should account for the fact that some tests will be found significant by chance alone. More formally, the test for each pairwise comparison is made without adjusting for the elevated type I experimentwise error rate that is introduced when performing multiple tests. We can use the `mcompare()` option to adjust the confidence intervals and `p`-values for multiple comparisons.

**Tukey’s method**

Of the available adjustments for multiple comparisons, Tukey’s honestly significant difference, Student–Newman–Keuls’ method, and Duncan’s method are most often used when performing all pairwise comparisons of means. Of these, Tukey’s method is the most conservative and Duncan’s method is the least conservative. For further discussion of each of the multiple-comparison adjustments, see [R] `pwcompare`.

Here we use Tukey’s adjustment to compute `p`-values and confidence intervals for the pairwise differences.

When using a 5% significance level, Tukey’s adjustment indicates that four pairs of means are different. With the adjustment, we no longer conclude that the difference in the mean yields for fertilizers 10-08-22 and 10-10-10 is significantly different from zero.
Dunnett’s method

Now let’s suppose that fertilizer 10-10-10 actually represents fields on which no fertilizer was applied. In this case, we can use Dunnett’s method for comparing each of the fertilizers to the control.

```
pwmean yield, over(fertilizer) effects mcompare(dunnett)
```

Pairwise comparisons of means with equal variances

```
over : fertilizer
```

<table>
<thead>
<tr>
<th>fertilizer</th>
<th>Number of Comparisons</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>4</td>
</tr>
</tbody>
</table>

| yield   | Contrast | Std. Err. | t   | P>|t| | [95% Conf. Interval] |

Using Dunnett’s adjustment, we conclude that only fertilizer 4 (18-24-06) produces a mean yield that is significantly different from the mean yield of the field with no fertilizer applied.

By default, `pwmean` treats the lowest level of the group variable as the control. If, for instance, fertilizer 3 (16-04-08) was our control group, we could type

```
pwmean yield, over(b3.fertilizer) effects mcompare(dunnett)
```

using the `b3.` factor-variable operator to specify this level as the reference level.
Multiple over() variables

When we specify more than one variable in the over() option, pairwise comparisons are performed for the means defined by each combination of levels of these variables.

```
. pwmean yield, over(fertilizer irrigation) group
```

Pairwise comparisons of means with equal variances

```
over : fertilizer irrigation
```

<table>
<thead>
<tr>

<td>1.116571</td>
<td>B D</td>
</tr>
</tbody>
</table>

Note: Means sharing a letter in the group label are not significantly different at the 5% level.

Here the row labeled 10-10-10#0 is the mean for the fields treated with fertilizer 10-10-10 and without irrigation. This mean is significantly different from the mean of all fertilizer/irrigation pairings that do not have an A in the “Unadjusted Groups” column. These include all pairings where the fields were irrigated as well as the fields treated with fertilizer 18-24-06 but without irrigation.

Equal variance assumption

`pwmean` performs multiple comparisons assuming that there is a common variance for all groups. In the case of two groups, this is equivalent to performing the familiar two-sample t test when equal variances are assumed.
. ttest yield, by(irrigation)

The signs for the difference, the test statistic, and the confidence intervals are reversed because the difference is taken in the opposite direction. The \( p \)-value from \texttt{pwmean} is equivalent to the one for the two-sided test in the \texttt{ttest} output.

\texttt{pwmean} extends the capabilities of \texttt{ttest} to allow for simultaneously comparing all pairs of means and to allow for using one common variance estimate for all the tests instead of computing a separate pooled variance for each pair of means when using multiple \texttt{ttest} commands. In addition, \texttt{pwmean} allows adjustments for multiple comparisons, many of which rely on an assumption of equal variances among groups.
Stored results

`pwmean` stores the following in `e()`:

Scalars
- `e(df_r)`: variance degrees of freedom
- `e(balanced)`: 1 if fully balanced data; 0 otherwise

Macros
- `e(cmd)`: `pwmean`
- `e(cmdline)`: command as typed
- `e(title)`: title in output
- `e(depvar)`: name of variable from which the means are computed
- `e(over)`: `varlist` from `over()`
- `e(properties)`: `b V`

Matrices
- `e(b)`: mean estimates
- `e(V)`: variance–covariance matrix of the mean estimates
- `e(error)`: mean estimability codes;
  - 0 means estimable,
  - 8 means not estimable
- `e(b_vs)`: mean difference estimates
- `e(V_vs)`: variance–covariance matrix of the mean difference estimates
- `e(error_vs)`: mean difference estimability codes;
  - 0 means estimable,
  - 8 means not estimable
- `e(k_groups)`: number of significance groups for each term

Methods and formulas

`pwmean` is a convenience command that uses `pwcompare` after fitting a fully factorial linear model. See Methods and formulas described in [R] `pwcompare`.

<td>-6.161132</td>
<td>1.589997</td>
</tr>
</tbody>
</table>

After `pwmean`, we can use `testnl` to test whether the improvement in mean wheat yield when using fertilizer 18-24-06 instead of fertilizer 29-03-04 is significantly different from 10%.
. testnl (_b[4.fertilizer] - _b[5.fertilizer])/_b[5.fertilizer] = 0.1
(1) (_b[4.fertilizer] - _b[5.fertilizer])/_b[5.fertilizer] = 0.1

    chi2(1) = 1.57
    Prob > chi2 = 0.2106

The improvement is not significantly different from 10%.

**Menu**

**cchart**
Statistics > Other > Quality control > C chart

**pchart**
Statistics > Other > Quality control > P chart

**rchart**
Statistics > Other > Quality control > R chart
**xchart**
Statistics > Other > Quality control > X-bar chart

**shewhart**
Statistics > Other > Quality control > Vertically aligned X-bar and R chart

**Description**

These commands provide standard quality-control charts. **cchart** draws a c chart; **pchart**, a p (fraction-defective) chart; **rchart**, an R (range or dispersion) chart; **xchart**, an $\overline{X}$ (control line) chart; and **shewhart**, vertically aligned $\overline{X}$ and R charts.

**Options**

- **Main**
  - **stabilized** stabilizes the p chart when sample sizes are unequal.
  - **std(#)** specifies the standard deviation of the process. The R chart is calculated (based on the range) if this option is not specified.
  - **mean(#)** specifies the grand mean, which is calculated if not specified.
  - **lower(#)** and **upper(#)** must be specified together or not at all. They specify the lower and upper limits of the $\overline{X}$ chart. Calculations based on the mean and standard deviation (whether specified by option or calculated) are used otherwise.
  - **nograph** suppresses the graph.
  - **generate(newvar\_f newvar\_lcl newvar\_ucl)** stores the plotted values in the p chart. **newvar\_f** will contain the fractions of defective elements; **newvar\_lcl** and **newvar\_ucl** will contain the lower and upper control limits, respectively.

- **Plot**
  - **connect_options** affect whether lines connect the plotted points and the rendition of those lines; see [G-3] connect_options.
  - **marker_options** affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.
  - **marker\_label\_options** specify if and how the markers are to be labeled; see [G-3] marker\_label\_options.
  - **clopts(cline\_options)** affects the rendition of the control limits; see [G-3] cline_options.

- **Add plots**
  - **addplot(plot)** provides a way to add other plots to the generated graph. See [G-3] addplot_option.

- **Y axis, X axis, Titles, Legend, Overall**
  - **twoway\_options** are any of the options documented in [G-3] twoway\_options, excluding by(). These include options for titling the graph (see [G-3] title\_options) and for saving the graph to disk (see [G-3] saving\_option).
combine_options (shewhart only) are any of the options documented in [G-2] graph combine. These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples

Control charts may be used to define the goal of a repetitive process, to control that process, and to determine if the goal has been achieved. Walter A. Shewhart of Bell Telephone Laboratories devised the first control chart in 1924. In 1931, Shewhart published *Economic Control of Quality of Manufactured Product*. According to Burr, “Few fields of knowledge have ever been so completely explored and charted in the first exposition” (1976, 29). Shewhart states that “a phenomenon will be said to be controlled when, through the use of past experience, we can predict, at least within limits, how the phenomenon may be expected to vary in the future. Here it is understood that prediction within limits means that we can state, at least approximately, the probability that the observed phenomenon will fall within given limits” (1931, 6).

For more information on quality-control charts, see Burr (1976), Duncan (1986), Harris (1999), or Ryan (2000).

Example 1: cchart

`cchart` graphs a c chart showing the number of nonconformities in a unit, where `defect_var` records the number of defects in each inspection unit and `unit_var` records the unit number. The unit numbers need not be in order. For instance, consider the following example dataset from Ryan (2000, 156):

```
. use http://www.stata-press.com/data/r13/ncu
. describe
Contains data from http://www.stata-press.com/data/r13/ncu.dta
obs: 30
vars: 2 31 Mar 2013 03:56
size: 240

storage  display value
variable name  type  format  label variable label

day float %9.0g Days in April
defects float %9.0g Numbers of Nonconforming Units
```

Sorted by:
```
. list in 1/5

<table>
<thead>
<tr>
<th>day</th>
<th>defects</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>7</td>
</tr>
<tr>
<td>2</td>
<td>5</td>
</tr>
<tr>
<td>3</td>
<td>11</td>
</tr>
<tr>
<td>4</td>
<td>13</td>
</tr>
<tr>
<td>5</td>
<td>9</td>
</tr>
</tbody>
</table>
```
The expected number of defects is 10.6, with lower and upper control limits of 0.8327 and 20.37, respectively. No units are out of control.

Example 2: pchart

pchart graphs a p chart, which shows the fraction of nonconforming items in a subgroup, where `reject_var` records the number rejected in each inspection unit, `unit_var` records the inspection unit number, and `ssize_var` records the number inspected in each unit.

Consider the example dataset from Ryan (2000, 156) of the number of nonconforming transistors out of 1,000 inspected each day during the month of April:

```
. use http://www.stata-press.com/data/r13/ncu2
. describe
Contains data from http://www.stata-press.com/data/r13/ncu2.dta
    obs: 30                               31 Mar 2013 14:13
    vars: 3
    size: 360

storage  display value
variable name  type    format  label               variable label
day          float    %9.0g          Days in April
rejects      float    %9.0g          Numbers of Nonconforming Units
ssize        float    %9.0g          Sample size
```

Sorted by:
All the points are within the control limits, which are 0.0009 for the lower limit and 0.0203 for the upper limit.

Here the sample sizes are fixed at 1,000, so the `ssize` variable contains 1,000 for each observation. Sample sizes need not be fixed, however. Say that our data were slightly different:

```stata
. use http://www.stata-press.com/data/r13/ncu3
. list in 1/5
```

<table>
<thead>
<tr>
<th>day</th>
<th>rejects</th>
<th>ssize</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>1</td>
<td>920</td>

<td>3</td>
<td>920</td>
</tr>
<tr>
<td>4.</td>
<td>4</td>
<td>950</td>
</tr>
<tr>
<td>5.</td>
<td>5</td>
<td>950</td>
</tr>
</tbody>
</table>

0 units are out of control
Here the control limits are, like the sample size, no longer constant. The `stabilize` option will stabilize the control chart:

```
pchart rejects day ssize, stabilize
```

![Stabilized p Chart, average number of defects = 0.0119](image)
Example 3: rchart

rchart displays an R chart showing the range for repeated measurements at various times. Variables within observations record measurements. Observations represent different samples.

For instance, say that we take five samples of 5 observations each. In our first sample, our measurements are 10, 11, 10, 11, and 12. The data are

```
. list

<table>
<thead>
<tr>
<th>m1</th>
<th>m2</th>
<th>m3</th>
<th>m4</th>
<th>m5</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>10</td>
<td>11</td>
<td>10</td>
<td>11</td>
</tr>
<tr>
<td>2</td>
<td>12</td>
<td>10</td>
<td>9</td>
<td>10</td>
</tr>
<tr>
<td>3</td>
<td>10</td>
<td>11</td>
<td>10</td>
<td>12</td>
</tr>
<tr>
<td>4</td>
<td>9</td>
<td>9</td>
<td>9</td>
<td>10</td>
</tr>
<tr>
<td>5</td>
<td>12</td>
<td>12</td>
<td>12</td>
<td>12</td>
</tr>
</tbody>
</table>
```

```
. rchart m1-m5, connect(l)
```

The expected range in each sample is 2 with lower and upper control limits of 0 and 4.23, respectively. If we know that the process standard deviation is 0.3, we could specify
Example 4: xchart

xchart graphs an $\bar{X}$ chart for repeated measurements at various times. Variables within observations record measurements, and observations represent different samples. Using the same data as in the previous example, we type

```
. xchart m1-m5, connect(l)
```

The average measurement in the sample is 10.64, and the lower and upper control limits are 9.486 and 11.794, respectively. Suppose that we knew from prior information that the mean of the process is 11. Then we would type
. xchart m1-m5, connect(l) mean(11)

2 units are out of control

If we also know that the standard deviation of the process is 0.3, we could type

. xchart m1-m5, connect(l) mean(11) std(.3)

3 units are out of control

Finally, xchart allows us to specify our own control limits:
Walter Andrew Shewhart (1891–1967) was born in Illinois and educated as a physicist, with degrees from the Universities of Illinois and California. After a brief period teaching physics, he worked for the Western Electric Company and (from 1925) the Bell Telephone Laboratories. His name is most associated with control charts used in quality controls, but his many other interests ranged generally from quality assurance to the philosophy of science.

Example 5: shewhart

shewhart displays a vertically aligned $\bar{X}$ and R chart in the same image. To produce the best-looking combined image possible, you will want to use the xchart and rchart commands separately and then combine the graphs. shewhart, however, is more convenient.

Using the same data as previously, but realizing that the standard deviation should have been 0.4, we type
Stored results

ccchart stores the following in r():

Scalars
- r(cbar) expected number of nonconformities
- r(lcl_c) lower control limit
- r(ucl_c) upper control limit
- r(N) number of observations
- r(out_c) number of units out of control
- r(below_c) number of units below the lower limit
- r(above_c) number of units above the upper limit

pchart stores the following in r():

Scalars
- r(pbar) average fraction of nonconformities
- r(lcl_p) lower control limit
- r(ucl_p) upper control limit
- r(N) number of observations
- r(out_p) number of units out of control
- r(below_p) number of units below the lower limit
- r(above_p) number of units above the upper limit

rchart stores the following in r():

Scalars
- r(central_line) ordinate of the central line
- r(lcl_r) lower control limit
- r(ucl_r) upper control limit
- r(N) number of observations
- r(out_r) number of units out of control
- r(below_r) number of units below the lower limit
- r(above_r) number of units above the upper limit
\texttt{xchart} stores the following in \( r() \):

Scalars
- \( r(\text{xbar}) \) grand mean
- \( r(\text{lcl}_x) \) lower control limit
- \( r(\text{ucl}_x) \) upper control limit
- \( r(N) \) number of observations
- \( r(\text{out}_x) \) number of units out of control
- \( r(\text{below}_x) \) number of units below the lower limit
- \( r(\text{above}_x) \) number of units above the upper limit

\texttt{shewhart} stores in \( r() \) the combination of stored results from \texttt{xchart} and \texttt{rchart}.

### Methods and Formulas

For the \( c \) chart, the number of defects per unit, \( C \), is taken to be a value of a random variable having a Poisson distribution. If \( k \) is the number of units available for estimating \( \lambda \), the parameter of the Poisson distribution, and if \( C_i \) is the number of defects in the \( i \)th unit, then \( \lambda \) is estimated by \( \overline{C} = \frac{\sum_i C_i}{k} \). Then

\[
\begin{align*}
\text{central line} & = \overline{C} \\
\text{UCL} & = \overline{C} + 3\sqrt{\overline{C}} \\
\text{LCL} & = \overline{C} - 3\sqrt{\overline{C}}
\end{align*}
\]

Control limits for the \( p \) chart are based on the sampling theory for proportions, using the normal approximation to the binomial. If \( k \) samples are taken, the estimator of \( p \) is given by \( \overline{p} = \frac{\sum_i \hat{p}_i}{k} \), where \( \hat{p}_i = \frac{x_i}{n_i} \), and \( x_i \) is the number of defects in the \( i \)th sample of size \( n_i \). The central line and the control limits are given by

\[
\begin{align*}
\text{central line} & = \overline{p} \\
\text{UCL} & = \overline{p} + 3\sqrt{\frac{\overline{p}(1-\overline{p})}{n_i}} \\
\text{LCL} & = \overline{p} - 3\sqrt{\frac{\overline{p}(1-\overline{p})}{n_i}}
\end{align*}
\]

Control limits for the \( R \) chart are based on the distribution of the range of samples of size \( n \) from a normal population. If the standard deviation of the process, \( \sigma \), is known,

\[
\begin{align*}
\text{central line} & = d_2 \sigma \\
\text{UCL} & = D_2 \sigma \\
\text{LCL} & = D_1 \sigma
\end{align*}
\]

where \( d_2, D_1, \) and \( D_2 \) are functions of the number of observations in the sample and are obtained from the table published in \textit{Beyer} (1976).

When \( \sigma \) is unknown,

\[
\begin{align*}
\text{central line} & = \overline{R} \\
\text{UCL} & = (D_2/d_2)\overline{R} \\
\text{LCL} & = (D_1/d_2)\overline{R}
\end{align*}
\]

where \( \overline{R} = \frac{\sum_i R_i}{k} \) is the range of the \( k \) sample ranges \( R_i \).
Control limits for the $\bar{X}$ chart are given by
\[
\text{central line} = \bar{x} \\
\text{UCL} = \bar{x} + \left(\frac{3}{\sqrt{n}}\right)\sigma \\
\text{LCL} = \bar{x} - \left(\frac{3}{\sqrt{n}}\right)\sigma
\]
if $\sigma$ is known. If $\sigma$ is unknown,
\[
\text{central line} = \bar{x} \\
\text{UCL} = \bar{x} + A_2 \bar{R} \\
\text{LCL} = \bar{x} - A_2 \bar{R}
\]
where $\bar{R}$ is the average range as defined above and $A_2$ is a function (op. cit.) of the number of observations in the sample.

Control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

indepvars may contain factor variables; see [U] 11.4.3 Factor variables.

by, mi estimate, rolling, and statsby, are allowed by qreg, iqreg, sqreg, and bsqreg; mfp, nestreg, and stepwise are allowed only with qreg; see [U] 11.1.10 Prefix commands.

qreg allows fweights, iweights, and pweights; see [U] 11.1.6 weight.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
iqreg estimates interquantile range regressions, regressions of the difference in quantiles. The estimated variance–covariance matrix of the estimators (VCE) is obtained via bootstrapping.

sqreg estimates simultaneous-quantile regression. It produces the same coefficients as qreg for each quantile. Reported standard errors will be similar, but sqreg obtains an estimate of the VCE via bootstrapping, and the VCE includes between-quantile blocks. Thus you can test and construct confidence intervals comparing coefficients describing different quantiles.

bsqreg is equivalent to sqreg with one quantile.

Options for qreg

- **Model**
  - `quantile(#)`: specifies the quantile to be estimated and should be a number between 0 and 1, exclusive. Numbers larger than 1 are interpreted as percentages. The default value of 0.5 corresponds to the median.

- **SE/Robust**
  - `vce([vcetype], [vceopts])`: specifies the type of VCE to compute and the density estimation method to use in computing the VCE.
    - `vcetype`: specifies the type of VCE to compute. Available types are `iid` and `robust`.
      - `vce(iid)`, the default, computes the VCE under the assumption that the residuals are independent and identically distributed (i.i.d.).
      - `vce(robust)`: computes the robust VCE under the assumption that the residual density is continuous and bounded away from 0 and infinity at the specified `quantile()`; see Koenker (2005, sec. 4.2).
    - `vceopts`: consists of available `denmethod` and `bwidth` options.
      - `denmethod`: specifies the method to use for the nonparametric density estimator. Available methods are `fitted`, `residual`, or `kernel[ (kernel) ]`, where the optional `kernel` must be one of the kernel choices listed below.
        - `fitted` and `residual` specify that the nonparametric density estimator use some of the structure imposed by quantile regression. The default `fitted` uses a function of the fitted values and `residual` uses a function of the residuals. `vce(robust, residual)` is not allowed.
        - `kernel()` specifies that the nonparametric density estimator use a kernel method. The available kernel functions are `epanechnikov`, `epan2`, `biweight`, `cosine`, `gaussian`, `parzen`, `rectangle`, and `triangle`. The default is `epanechnikov`. See \[R\] `kdensity` for the kernel function forms.
      - `bwidth`: specifies the bandwidth method to use by the nonparametric density estimator. Available methods are `hsheather` for the Hall–Sheather bandwidth, `bofinger` for the Bofinger bandwidth, and `chamberlain` for the Chamberlain bandwidth.

See Koenker (2005, sec. 3.4 and 4.10) for a description of the sparsity estimation techniques and the Hall–Sheather and Bofinger bandwidth formulas. See Chamberlain (1994, eq. 2.2) for the Chamberlain bandwidth.

- **Reporting**
  - `level(#)`: see \[R\] estimation options.
display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see [R] estimation options.

Optimization

optimization_options: iterate(#), [no] log, trace. iterate() specifies the maximum number of iterations; log/nolog specifies whether to show the iteration log; and trace specifies that the iteration log should include the current parameter vector. These options are seldom used.

wlsiter(#) specifies the number of weighted least-squares iterations that will be attempted before the linear programming iterations are started. The default value is 1. If there are convergence problems, increasing this number should help.

Options for iqreg

Model

quantiles(# #) specifies the quantiles to be compared. The first number must be less than the second, and both should be between 0 and 1, exclusive. Numbers larger than 1 are interpreted as percentages. Not specifying this option is equivalent to specifying quantiles(.25 .75), meaning the interquantile range.

reps(#) specifies the number of bootstrap replications to be used to obtain an estimate of the variance–covariance matrix of the estimators (standard errors). reps(20) is the default and is arguably too small. reps(100) would perform 100 bootstrap replications. reps(1000) would perform 1,000 replications.

Reporting

level(#); see [R] estimation options.

nodots suppresses display of the replication dots.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see [R] estimation options.

Options for sqreg

Model

quantiles(# [ # [ # ... ]]) specifies the quantiles to be estimated and should contain numbers between 0 and 1, exclusive. Numbers larger than 1 are interpreted as percentages. The default value of 0.5 corresponds to the median.

reps(#) specifies the number of bootstrap replications to be used to obtain an estimate of the variance–covariance matrix of the estimators (standard errors). reps(20) is the default and is arguably too small. reps(100) would perform 100 bootstrap replications. reps(1000) would perform 1,000 replications.

Reporting

level(#); see [R] estimation options.

nodots suppresses display of the replication dots.
display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

Options for bsqreg

Model

quantile(#) specifies the quantile to be estimated and should be a number between 0 and 1, exclusive. Numbers larger than 1 are interpreted as percentages. The default value of 0.5 corresponds to the median.

reps(#) specifies the number of bootstrap replications to be used to obtain an estimate of the variance–covariance matrix of the estimators (standard errors). reps(20) is the default and is arguably too small. reps(100) would perform 100 bootstrap replications. reps(1000) would perform 1,000 replications.

Reporting

level(#); see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

Remarks and examples

Remarks are presented under the following headings:

Median regression
Quantile regression
Estimated standard errors
Interquantile and simultaneous-quantile regression
What are the parameters?

Median regression

qreg fits quantile regression models. The default form is median regression, where the objective is to estimate the median of the dependent variable, conditional on the values of the independent variables. This method is similar to ordinary regression, where the objective is to estimate the conditional mean of the dependent variable. Simply put, median regression finds a line through the data that minimizes the sum of the absolute residuals rather than the sum of the squares of the residuals, as in ordinary regression. Equivalently, median regression expresses the median of the conditional distribution of the dependent variable as a linear function of the conditioning (independent) variables. Cameron and Trivedi (2010, chap. 7) provide a nice introduction to quantile regression using Stata.
Example 1: Estimating the conditional median

Consider a two-group experimental design with 5 observations per group:

```
use http://www.stata-press.com/data/r13/twogrp
list
```

```
qreg y x
```

Iteration 1: WLS sum of weighted deviations = 60.941342
Iteration 1: sum of abs. weighted deviations = 55.5
Iteration 2: sum of abs. weighted deviations = 55

Median regression

| y  | Coef. | Std. Err. | t    | P>|t|  | [95% Conf. Interval] |
|----|-------|-----------|------|------|----------------------|
| x  | 17    | 18.23213  | 0.93 | 0.378 | -25.04338, 59.04338  |
| _cons | 3    | 12.89207  | 0.23 | 0.822 | -26.72916, 32.72916  |

We have estimated the equation

\[ \hat{y}_{\text{median}} = 3 + 17x \]

We look back at our data. \( x \) takes on the values 0 and 1, so the median for the \( x = 0 \) group is 3, whereas for \( x = 1 \) it is \( 3 + 17 = 20 \). The output reports that the raw sum of absolute deviations about 14 is 78.5; that is, the sum of \(|y - 14|\) is 78.5. Fourteen is the unconditional median of \( y \), although in these data, any value between 14 and 19 could also be considered an unconditional median (we have an even number of observations, so the median is bracketed by those two values). In any case, the raw sum of deviations of \( y \) about the median would be the same no matter what number we choose between 14 and 19. (With a “median” of 14, the raw sum of deviations is 78.5. Now think of choosing a slightly larger number for the median and recalculating the sum. Half the observations will have larger negative residuals, but the other half will have smaller positive residuals, resulting in no net change.)

We turn now to the actual estimated equation. The sum of the absolute deviations about the solution \( \hat{y}_{\text{median}} = 3 + 17x \) is 55. The pseudo-\( R^2 \) is calculated as \( 1 - 55/78.5 \approx 0.2994 \). This result is based on the idea that the median regression is the maximum likelihood estimate for the double-exponential distribution.
Technical note

qreg is an alternative to regular regression or robust regression—see \[R\] `regress` and \[R\] `rreg`. Let’s compare the results:

```
. regress y x

Source | SS       | df | MS
------|----------|----|----
Model  | 2.5      | 1  | 2.5
Residual | 6978.4   | 8  | 872.3
Total | 6980.9   | 9  | 775.655556

Number of obs = 10
F(1, 8) = 0.00
Prob > F = 0.9586
R-squared = 0.0004
Adj R-squared = -0.1246
Root MSE = 29.535

y Coef. Std. Err. t P>|t| [95% Conf. Interval]
x -1     18.6794 -0.05 0.959 -44.07477 42.07477
_cons 20.6     13.20833 1.56 0.157 -9.858465 51.05847
```

Unlike \[R\] `regress`, \[R\] `qreg` fits ordinary linear regression and is concerned with predicting the mean rather than the median, so both results are, in a technical sense, correct. Putting aside those technicalities, however, we tend to use either regression to describe the central tendency of the data, of which the mean is one measure and the median another. Thus we can ask, “which method better describes the central tendency of these data?”

Means—and therefore ordinary linear regression—are sensitive to outliers, and our data were purposely designed to contain two such outliers: 95 for \(x = 0\) and 14 for \(x = 1\). These two outliers dominated the ordinary regression and produced results that do not reflect the central tendency well—you are invited to enter the data and graph \(y\) against \(x\).

Robust regression attempts to correct the outlier-sensitivity deficiency in ordinary regression:

```
. rreg y x, genwt(wt)

Huber iteration 1: maximum difference in weights = .7311828

```

Here \[R\] `rreg` discarded the first outlier completely. (We know this because we included the \texttt{genwt()} option on \[R\] `rreg` and, after fitting the robust regression, examined the weights.) For the other “outlier”, \[R\] `rreg` produced a weight of 0.47.

In any case, the answers produced by \[R\] `qreg` and \[R\] `rreg` to describe the central tendency are similar, but the standard errors are different. In general, robust regression will have smaller standard errors because it is not as sensitive to the exact placement of observations near the median. You are welcome to try removing the first outlier in the \[R\] `qreg` estimation to observe an improvement in the standard errors by typing...
. qreg y x if _n!=5

Also, some authors (Rousseeuw and Leroy 1987, 11) have noted that quantile regression, unlike the unconditional median, may be sensitive to even one outlier if its leverage is high enough. Rousseeuw and Leroy (1987) discuss estimators that are more robust to perturbations to the data than either mean regression or quantile regression.

In the end, quantile regression may be more useful for the interpretation of the parameters that it estimates than for its robustness to perturbations to the data.

Example 2: Median regression

Let’s now consider a less artificial example using the automobile data described in Example datasets. Using median regression, we will regress each car’s price on its weight and length and whether it is of foreign manufacture:

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. qreg price weight length foreign
Iteration 1:  WLS sum of weighted deviations =  56397.829
Iteration 1:  sum of abs. weighted deviations =  55950.5
Iteration 2:  sum of abs. weighted deviations =  55264.718
Iteration 3:  sum of abs. weighted deviations =  54762.283
Iteration 4:  sum of abs. weighted deviations =  54734.152
Iteration 5:  sum of abs. weighted deviations =  54552.638
note: alternate solutions exist
Iteration 6:  sum of abs. weighted deviations =  54465.511
Iteration 7:  sum of abs. weighted deviations =  54443.699
Iteration 8:  sum of abs. weighted deviations =  54411.294
Median regression Number of obs =  74
Raw sum of deviations  71102.5 (about 4934)
Min sum of deviations 54411.29 Pseudo R2 =  0.2347

 price Coef. Std. Err.  t  P>|t|  [95% Conf. Interval]
weight  3.933588  1.328718  2.96  0.004  1.283543  6.583632
length -41.25191  45.46469 -0.91  0.367 -131.9284  49.42456
foreign  3377.771  885.4198  3.81  0.000  1611.857  5143.685
_cons  344.6489  5182.394  0.07  0.947 -9991.31 10680.61
```

The estimated equation is

\[
\text{price}_{\text{median}} = 3.93 \text{weight} - 41.25 \text{length} + 3377.8 \text{foreign} + 344.65
\]

The output may be interpreted in the same way as linear regression output; see [R] regress. The variables weight and foreign are significant, but length is not significant. The median price of the cars in these data is $4,934. This value is a median (one of the two center observations), not the median, which would typically be defined as the midpoint of the two center observations.
Quantile regression

Quantile regression is similar to median regression in that it estimates an equation expressing a quantile of the conditional distribution, albeit one that generally differs from the 0.5 quantile that is the median. For example, specifying `quantile(.25)` estimates the parameters that describe the 25th percentile (first quartile) of the conditional distribution.

Quantile regression allows for effects of the independent variables to differ over the quantiles. For example, Chamberlain (1994) finds that union membership has a larger effect on the lower quantiles than on the higher quantiles of the conditional distribution of U.S. wages. That the effects of the independent variables may vary over quantiles of the conditional distribution is an important advantage of quantile regression over mean regression.

Example 3: Estimating quantiles other than the median

Returning to real data, the equation for the 25th percentile of `price` conditional on `weight`, `length`, and `foreign` in our automobile data is

```
use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
.qreg price weight length foreign, quantile(.25)
```

```
Iteration 1: WLS sum of weighted deviations = 49469.235
Iteration 1: sum of abs. weighted deviations = 49728.883
Iteration 2: sum of abs. weighted deviations = 45669.89
Iteration 3: sum of abs. weighted deviations = 43416.646
Iteration 4: sum of abs. weighted deviations = 41947.221
Iteration 5: sum of abs. weighted deviations = 41947.221
Iteration 6: sum of abs. weighted deviations = 41093.025
Iteration 7: sum of abs. weighted deviations = 37623.424
Iteration 8: sum of abs. weighted deviations = 35721.453
Iteration 9: sum of abs. weighted deviations = 34823.319
Iteration 10: sum of abs. weighted deviations = 34801.777
```

```
.25 Quantile regression
Number of obs = 74
Raw sum of deviations 41912.75 (about 4187)
Min sum of deviations 34801.78
Pseudo R2 = 0.1697
```

|       | Coef.  | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|-------|--------|-----------|-------|------|---------------------|
| price |        |           |       |      |                     |
| weight| 1.83179| .6328903  | 2.89  | 0.005| .5695289 3.094049   |
| length| 2.84556| 21.65558  | 0.13  | 0.896| -40.34514 46.03626  |
| foreign| 2209.925| 421.7401  | 5.24  | 0.000| 1368.791 3051.059  |
| _cons | -1879.775| 2468.46  | -0.76 | 0.449| -6802.963 3043.413  |

Compared with our previous median regression, the coefficient on `length` now has a positive sign, and the coefficients on `foreign` and `weight` are reduced. The actual lower quantile is $4,187, substantially less than the median $4,934.
We can also estimate the upper quartile as a function of the same three variables:

\[ \text{qreg price weight length foreign, quantile(.75)} \]

Iteration 1: WLS sum of weighted deviations = 55465.741
Iteration 1: sum of abs. weighted deviations = 55652.957
Iteration 2: sum of abs. weighted deviations = 52994.785
Iteration 3: sum of abs. weighted deviations = 50189.446
Iteration 4: sum of abs. weighted deviations = 49898.245
Iteration 5: sum of abs. weighted deviations = 49398.106
Iteration 6: sum of abs. weighted deviations = 49241.835
Iteration 7: sum of abs. weighted deviations = 49197.967

.75 Quantile regression

\begin{align*}
\text{Number of obs} & = 74 \\
\text{Raw sum of deviations} & = 79860.75 \text{ (about 6342)} \\
\text{Min sum of deviations} & = 49197.97 \\
\text{Pseudo R2} & = 0.3840
\end{align*}

| price | Coef. | Std. Err. | t | P>|t| | [95% Conf. Interval] |
|-------|-------|-----------|---|-----|---------------------|
| weight | 9.22291 | 1.785767 | 5.16 | 0.000 | 5.66131 - 12.78451 |
| length | -220.7833 | 61.10352 | -3.61 | 0.001 | -342.6504 - -98.91616 |
| foreign | 3595.133 | 1189.984 | 3.02 | 0.004 | 1221.785 - 5968.482 |
| _cons | 20242.9 | 6965.02 | 2.91 | 0.005 | 6351.61 - 34134.2 |

This result tells a different story: weight is much more important, and length is now significant—with a negative coefficient! The prices of high-priced cars seem to be determined by factors different from those affecting the prices of low-priced cars.

Technical note

One explanation for having substantially different regression functions for different quantiles is that the data are heteroskedastic, as we will demonstrate below. The following statements create a sharply heteroskedastic set of data:

\begin{verbatim}
. drop _all
. set obs 10000
obs was 0, now 10000
. set seed 50550
. gen x = .1 + .9 * runiform()
. gen y = x * runiform()^2
\end{verbatim}
Let’s now fit the regressions for the 5th and 95th quantiles:

```
. qreg y x, quantile(.05)
Iteration 1: WLS sum of weighted deviations = 540.36365
Iteration 1: sum of abs. weighted deviations = 539.15959
Iteration 2: sum of abs. weighted deviations = 141.36772
Iteration 3: sum of abs. weighted deviations = 91.23460
Iteration 4: sum of abs. weighted deviations = 91.127281
Iteration 5: sum of abs. weighted deviations = 91.126351
Iteration 6: sum of abs. weighted deviations = 91.126229
Iteration 7: sum of abs. weighted deviations = 91.126224
Iteration 8: sum of abs. weighted deviations = 91.126221
Iteration 9: sum of abs. weighted deviations = 91.126221
.05 Quantile regression
Number of obs = 10000
Raw sum of deviations 91.17849 (about .0009234)
Min sum of deviations 91.12622 Pseudo R2 = 0.0006

 y | Coef. Std. Err. t P>|t| [95% Conf. Interval]
---|-------------------+-------------------+-------------------+-------------------
x | 0.002601 .0004576 5.68 0.000 .001704 .003498
_cons | -.0001393 .0002782 -0.50 0.617 -.0006846 .000406
```

```
. qreg y x, quantile(.95)

x | .8898259 .0090984 97.80 0.000 .8719912 .9076605
_cons | .0021514 .0055307 0.39 0.697 -.00869 .0129927
```

The coefficient on \( x \), in particular, differs markedly between the two estimates. For the mathematically inclined, it is not too difficult to show that the theoretical lines are \( y = 0.0025 x \) for the 5th percentile and \( y = 0.9025 x \) for the 95th, numbers in close agreement with our numerical results.

The estimator for the standard errors computed by \texttt{qreg} assumes that the sample is independent and identically distributed (i.i.d.); see \textit{Estimated standard errors} and \textit{Methods and formulas} for details. Because the data are conditionally heteroskedastic, we should have used \texttt{bsqreg} to consistently estimate the standard errors using a bootstrap method.

---

**Estimated standard errors**

The variance–covariance matrix of the estimator (VCE) depends on the reciprocal of the density of the dependent variable evaluated at the quantile of interest. This function, known as the “sparsity function”, is hard to estimate.
The default method, which uses the fitted values for the predicted quantiles, generally performs well, but other methods may be preferred in larger samples. The vce() suboptions denmethod and bwidth provide other estimators of the sparsity function, the details of which are described in Methods and formulas.

Example 4: Obtaining robust standard errors

Example 2 of qreg on real data above was a median regression of price on weight, length, and foreign using auto.dta. Suppose, after investigation, we are convinced that car price observations are not independent. We decide that standard errors robust to non-i.i.d. errors would be appropriate and use the option vce(robust).

```
. use http://www.stata-press.com/data/r13/auto, clear
    (1978 Automobile Data)
. qreg price weight length foreign, vce(robust)
Iteration 1: WLS sum of weighted deviations = 56397.829
Iteration 1: sum of abs. weighted deviations = 55950.5
Iteration 2: sum of abs. weighted deviations = 55264.718
Iteration 3: sum of abs. weighted deviations = 54762.283
Iteration 4: sum of abs. weighted deviations = 54734.152
Iteration 5: sum of abs. weighted deviations = 54552.638
    note: alternate solutions exist
Iteration 6: sum of abs. weighted deviations = 54465.511
Iteration 7: sum of abs. weighted deviations = 54443.699
Iteration 8: sum of abs. weighted deviations = 54411.294
Median regression Number of obs = 74
Raw sum of deviations 71102.5 (about 4934)
Min sum of deviations 54411.29 Pseudo R2 = 0.2347

|        | Coef. | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|--------|-------|-----------|-------|------|---------------------|
| price  |       |           |       |      |                     |
| weight | 3.933  | 1.694     | 2.32  | 0.023| .55406              |
| length | -41.25 | 51.735    | -0.80 | 0.428| -144.4355           |
| foreign| 3377.7 | 728.51    | 4.64  | 0.000| 1924.801            |
| _cons  | 344.68 | 5096.528  | 0.07  | 0.946| -9820.055           |
```

We see that the robust standard error for weight increases making it less significant in modifying the median automobile price. The standard error for length also increases, but the standard error for the foreign indicator decreases.
For comparison, we repeat the estimation using bootstrap standard errors:

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. set seed 1001
. bsqreg price weight length foreign
    (fitting base model)
```

\[
\begin{array}{c}
\text{Bootstrap replications (20)} \\
\hline
1 & 2 & 3 & 4 & 5 \\
\hline
\end{array}
\]

```
Median regression, bootstrap(20) SEs
 Number of obs = 74
Raw sum of deviations 71102.5 (about 4934)
Min sum of deviations 54411.29 Pseudo R2 = 0.2347
```

| price   | Coef.       | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|---------|-------------|-----------|-------|-----|----------------------|
| weight  | 3.933588    | 3.12446   | 1.26  | 0.212 | -2.297951 -10.16513  |
| length  | -41.25191   | 83.71267  | -0.49 | 0.624 | -208.2116 125.7077   |
| foreign | 3377.771    | 1057.281  | 3.19  | 0.002 | 1269.09 5486.452    |
| _cons   | 344.6489    | 7053.301  | 0.05  | 0.961 | -13722.72 14412.01  |

The coefficient estimates are the same—indeed, they are obtained using the same technique. Only the standard errors differ. Therefore, the \( t \) statistics, significance levels, and confidence intervals also differ.

Because `bsqreg` (as well as `sqreg` and `iqreg`) obtains standard errors by randomly resampling the data, the standard errors it produces will not be the same from run to run unless we first set the random-number seed to the same number; see [R] `set seed`. 
By default, bsqreg, sqreg, and iqreg use 20 replications. We can control the number of replications by specifying the reps() option:

```
. bsqreg price weight length i.foreign, reps(1000)
(fitting base model)
```

Bootstrap replications (1000)

```

The results shown above are typical for models with heteroskedastic errors. (Our dependent variable is price; if our model had been in terms of ln(price), the standard errors estimated by qreg and bsqreg would have been nearly identical.) Also, even for heteroskedastic errors, 20 replications is generally sufficient for hypothesis tests against 0.
Interquantile and simultaneous-quantile regression

Consider a quantile regression model where the $q$th quantile is given by

$$Q_q(y) = a_q + b_{q,1}x_1 + b_{q,2}x_2$$

For instance, the 75th and 25th quantiles are given by

$$Q_{0.75}(y) = a_{0.75} + b_{0.75,1}x_1 + b_{0.75,2}x_2$$
$$Q_{0.25}(y) = a_{0.25} + b_{0.25,1}x_1 + b_{0.25,2}x_2$$

The difference in the quantiles is then

$$Q_{0.75}(y) - Q_{0.25}(y) = (a_{0.75} - a_{0.25}) + (b_{0.75,1} - b_{0.25,1})x_1 + (b_{0.75,2} - b_{0.25,2})x_2$$

qreg fits models such as $Q_{0.75}(y)$ and $Q_{0.25}(y)$. iqreg fits interquantile models, such as $Q_{0.75}(y) - Q_{0.25}(y)$. The relationships of the coefficients estimated by qreg and iqreg are exactly as shown: iqreg reports coefficients that are the difference in coefficients of two qreg models, and, of course, iqreg reports the appropriate standard errors, which it obtains by bootstrapping.

sqreg is like qreg in that it estimates the equations for the quantiles

$$Q_{0.75}(y) = a_{0.75} + b_{0.75,1}x_1 + b_{0.75,2}x_2$$
$$Q_{0.25}(y) = a_{0.25} + b_{0.25,1}x_1 + b_{0.25,2}x_2$$

The coefficients it obtains are the same that would be obtained by estimating each equation separately using qreg. sqreg differs from qreg in that it estimates the equations simultaneously and obtains an estimate of the entire variance–covariance matrix of the estimators by bootstrapping. Thus you can perform hypothesis tests concerning coefficients both within and across equations.

For example, to fit the above model, you could type

```
  . qreg y x1 x2, quantile(.25)
  . qreg y x1 x2, quantile(.75)
```

By doing this, you would obtain estimates of the parameters, but you could not test whether $b_{0.25,1} = b_{0.75,1}$ or, equivalently, $b_{0.75,1} - b_{0.25,1} = 0$. If your interest really is in the difference of coefficients, you could type

```
  . iqreg y x1 x2, quantiles(.25 .75)
```

The “coefficients” reported would be the difference in quantile coefficients. You could also estimate both quantiles simultaneously and then test the equality of the coefficients:

```
  . sqreg y x1 x2, quantiles(.25 .75)
  . test [q25]x1 = [q75]x1
```

Whether you use iqreg or sqreg makes no difference for this test. sqreg, however, because it estimates the quantiles simultaneously, allows you to test other hypotheses. iqreg, by focusing on quantile differences, presents results in a way that is easier to read.

Finally, sqreg can estimate quantiles singly,

```
  . sqreg y x1 x2, quantiles(.5)
```

and can thereby be used as a substitute for the slower bsqreg. (Gould [1997b] presents timings demonstrating that sqreg is faster than bsqreg.) sqreg can also estimate more than two quantiles simultaneously:

```
  . sqreg y x1 x2, quantiles(.25 .5 .75)
```
Example 5: Simultaneous quantile estimation

In demonstrating `qreg`, we performed quantile regressions using `auto.dta`. We discovered that the regression of `price` on `weight`, `length`, and `foreign` produced vastly different coefficients for the 0.25, 0.5, and 0.75 quantile regressions. Here are the coefficients that we obtained:

<table>
<thead>
<tr>
<th>Variable</th>
<th>25th percentile</th>
<th>50th percentile</th>
<th>75th percentile</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>1.83</td>
<td>3.93</td>
<td>9.22</td>
</tr>
<tr>
<td>length</td>
<td>2.85</td>
<td>-41.25</td>
<td>-220.8</td>
</tr>
<tr>
<td>foreign</td>
<td>2209.9</td>
<td>3377.8</td>
<td>3595.1</td>
</tr>
<tr>
<td>_cons</td>
<td>-1879.8</td>
<td>344.6</td>
<td>20242.9</td>
</tr>
</tbody>
</table>

All we can say, having estimated these equations separately, is that `price` seems to depend differently on the `weight`, `length`, and `foreign` variables depending on the portion of the `price` distribution we examine. We cannot be more precise because the estimates have been made separately. With `sqreg`, however, we can estimate all the effects simultaneously:

```
. use http://www.stata-press.com/data/r13/auto, clear
  (1978 Automobile Data)
. set seed 1001
. sqreg price weight length foreign, q(.25 .5 .75) reps(100)
  (fitting base model)
Simultaneous quantile regression
  Number of obs = 74
  bootstrap(100) SEs
    .25 Pseudo R2 = 0.1697
    .50 Pseudo R2 = 0.2347
    .75 Pseudo R2 = 0.3840
```

```
| Bootstrap | Coef. | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|-----------|-------|-----------|-------|------|---------------------|
| q25       |       |           |       |      |                     |
| weight    | 1.83  | 1.57      | 1.16  | 0.249| -1.309005 to 4.972583|
| length    | 2.8456| 38.6352   | 0.07  | 0.941| -74.20998 to 79.9011 |
| foreign   | 2209.9| 1008.52   | 2.19  | 0.032| 198.494 to 4221.357 |
| _cons     | -1879.8| 3665.184 | -0.51 | 0.610| -9189.753 to 5430.204|
| q50       |       |           |       |      |                     |
| weight    | 3.933588| 2.529541| 1.56  | 0.124| -1.11423 to 8.978599 |
| length    | -41.25191| 68.62258| -0.60 | 0.550| -178.1153 to 95.61151 |
| foreign   | 3377.771| 1025.882| 3.29  | 0.002| 1331.715 to 5423.827 |
| _cons     | 344.6489| 6199.257| 0.06  | 0.956| -12019.38 to 12708.68 |
| q75       |       |           |       |      |                     |
| weight    | 9.22291| 2.483676 | 3.71  | 0.000| 4.269374 to 14.17645 |
| length    | -220.7833| 86.17422| -2.56 | 0.013| -392.6524 to -48.91421 |
| foreign   | 3595.133| 1145.124| 3.14  | 0.002| 1311.255 to 5879.011 |
| _cons     | 20242.9| 9414.242| 2.15  | 0.035| 1466.79 to 39019.02 |
```

The coefficient estimates above are the same as those previously estimated, although the standard error estimates are a little different. `sqreg` obtains estimates of variance by bootstrapping. The important thing here, however, is that the full covariance matrix of the estimators has been estimated and stored, and thus it is now possible to perform hypothesis tests. Are the effects of `weight` the same at the 25th and 75th percentiles?
. test [q25]weight = [q75]weight  
( 1)  [q25]weight - [q75]weight = 0  
F( 1, 70) = 8.97  
Prob > F = 0.0038  

It appears that they are not. We can obtain a confidence interval for the difference by using lincom:

. lincom [q75]weight-[q25]weight  
( 1)  -[q25]weight + [q75]weight = 0

| price          | Coef.  | Std. Err. | t    | P>|t| | [95% Conf. Interval] |
|---------------|--------|-----------|-----|-----|---------------------|
| (1)           | 7.391 | 2.467548  | 3.00| 0.004| 2.469752 -12.31249  |

Indeed, we could test whether the weight and length sets of coefficients are equal at the three quantiles estimated:

. quietly test [q25]weight = [q50]weight  
. quietly test [q25]weight = [q75]weight, accumulate  
. quietly test [q25]length = [q50]length, accumulate  
. test [q25]length = [q75]length, accumulate  
( 1)  [q25]weight - [q50]weight = 0  
( 2)  [q25]weight - [q75]weight = 0  
( 3)  [q25]length - [q50]length = 0  
( 4)  [q25]length - [q75]length = 0  
F( 4, 70) = 2.43  
Prob > F = 0.0553  

*iqreg* focuses on one quantile comparison but presents results that are more easily interpreted:

. set seed 1001  
. iqreg price weight length foreign, q(.25 .75) reps(100) nolog  
  .75-.25 Interquartile regression  
  Number of obs = 74  
  bootstrap(100) SEs  
  .75 Pseudo R2 = 0.3840  
  .25 Pseudo R2 = 0.1697

| price          | Coef.  | Std. Err. | t    | P>|t| | [95% Conf. Interval] |
|---------------|--------|-----------|-----|-----|---------------------|
| weight        | 7.391 | 2.467548  | 3.00| 0.004| 2.469752 -12.31249  |
| length        | -223.6| 83.09868  | -2.69| 0.009| -389.3639 -57.89376 |
| foreign       | 1385.2| 1191.018  | 1.16| 0.249| -990.2036 3760.619  |
| _cons         | 22122.6| 9009.159 | 2.46| 0.017| 4154.478 40090.88   |

Looking only at the 0.25 and 0.75 quantiles (the interquartile range), the *iqreg* command output is easily interpreted. Increases in *weight* correspond significantly to increases in *price* dispersion. Increases in *length* correspond to decreases in *price* dispersion. The *foreign* variable does not significantly change *price* dispersion.

Do not make too much of these results; the purpose of this example is simply to illustrate the *sqreg* and *iqreg* commands and to do so in a context that suggests why analyzing dispersion might be of interest.
lincom after sqreg produced the same $t$ statistic for the interquartile range of weight, as did the iqreg command above. In general, they will not agree exactly because of the randomness of bootstrapping, unless the random-number seed is set to the same value before estimation (as was done here).

Gould (1997a) presents simulation results showing that the coverage—the actual percentage of confidence intervals containing the true value—for iqreg is appropriate.

**What are the parameters?**

In this section, we use a specific data-generating process (DGP) to illustrate the interpretation of the parameters estimated by qreg. If simulation experiments are not intuitive to you, skip this section.

In general, quantile regression parameterizes the quantiles of the distribution of $y$ conditional on the independent variables $x$ as $x\beta$, where $\beta$ is a vector of estimated parameters. In our example, we include a constant term and a single independent variable, and we express quantiles of the distribution of $y$ conditional on $x$ as $\beta_0 + \beta_1 x$.

We use simulated data to illustrate what we mean by a conditional distribution and how to interpret the parameters $\beta$ estimated by qreg. We also note how we could change our example to illustrate a DGP for which the estimator in qreg would be misspecified.

We suppose that the distribution of $y$ conditional on $x$ has a Weibull form. If $y$ has a Weibull distribution, the distribution function is $F(y) = 1 - \exp\{-y/(\lambda^k)\}$, where the scale parameter $\lambda > 0$ and the shape parameter $k > 0$. We can make $y$ have a Weibull distribution function conditional on $x$ by making the scale parameter or the shape parameter functions of $x$. In our example, we specify a particular DGP by supposing that $\lambda = (1 + \alpha x)$, $\alpha = 1.5$, $x = 1 + \sqrt{\nu}$, and that $\nu$ has a $\chi^2(1)$ distribution. For the moment, we leave the parameter $k$ as is so that we can discuss how this decision relates to model specification.

Plugging in for $\lambda$ yields the functional form for the distribution of $y$ conditional on $x$, which is known as the conditional distribution function and is denoted $F(y|x)$. $F(y|x)$ is the distribution for $y$ for each given value of $x$.

Some algebra yields that $F(y|x) = 1 - \exp[-\{y/(1 + \alpha x)\}^k]$. Letting $\tau = F(y|x)$ implies that $0 \leq \tau \leq 1$, because probabilities must be between 0 and 1.

To obtain the $\tau$ quantile of the distribution of $y$ conditional on $x$, we solve

$$\tau = 1 - \exp[-\{y/(1 + \alpha x)\}^k]$$

for $y$ as a function of $\tau$, $x$, $\alpha$, and $k$. The solution is

$$y = (1 + \alpha x)\{-\ln(1 - \tau)\}^{(1/k)}$$

(1)

For any value of $\tau \in (0, 1)$, expression (1) gives the $\tau$ quantile of the distribution of $y$ conditional on $x$. To use qreg, we must rewrite (1) as a function of $x$, $\beta_0$, and $\beta_1$. Some algebra yields that (1) can be rewritten as

$$y = \beta_0 + \beta_1 * x$$

where $\beta_0 = \{-\ln(1 - \tau)\}^{(1/k)}$ and $\beta_1 = \alpha\{-\ln(1 - \tau)\}^{(1/k)}$. We can express the conditional quantiles as linear combinations of $x$, which is a property of the estimator implemented in qreg.
If we parameterize \( k \) as a nontrivial function of \( x \), the conditional quantiles will not be linear in \( x \). If the conditional quantiles cannot be represented as linear functions of \( x \), we cannot estimate the true parameters of the DGP. This restriction illustrates the limits of the estimator implemented in \texttt{qreg}.

We set \( k = 2 \) for our example.

Conditional quantile regression allows the coefficients to change with the specified quantile. For our DGP, the coefficients \( \beta_0 \) and \( \beta_1 \) increase as \( \tau \) gets larger. Substituting in for \( \alpha \) and \( k \) yields that \( \beta_0 = \sqrt{-\ln(1-\tau)} \) and \( \beta_1 = 1.5 \sqrt{-\ln(1-\tau)} \). Table 1 presents the true values for \( \beta_0 \) and \( \beta_1 \) implied by our DGP when \( \tau \in \{0.25, 0.5, 0.8\} \).

<table>
<thead>
<tr>
<th>( \tau )</th>
<th>( \beta_0 )</th>
<th>( \beta_1 )</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.25</td>
<td>0.53636</td>
<td>0.80454</td>
</tr>
<tr>
<td>0.5</td>
<td>0.8325546</td>
<td>1.248832</td>
</tr>
<tr>
<td>0.8</td>
<td>1.268636</td>
<td>1.902954</td>
</tr>
</tbody>
</table>

We can also use (1) to generate data from the specified distribution of \( y \) conditional on \( x \) by plugging in random uniform numbers for \( \tau \). Each random uniform number substituted in for \( \tau \) in (1) yields a draw from the conditional distribution of \( y \) given \( x \).

### Example 6

In this example, we generate 100,000 observations from our specified DGP by substituting random uniform numbers for \( \tau \) in (1), with \( \alpha = 1.5 \), \( k = 2 \), \( x = 1 + \sqrt{\nu} \), and \( \nu \) coming from a \( \chi^2(1) \) distribution.

We begin by executing the code that implements this method; below we discuss each line of the output produced.

```plaintext
. clear // drop existing variables
. set seed 1234571 // set random-number seed
. set obs 100000 // set number of observations
obs was 0, now 100000
. generate double tau = runiform() // generate uniform variate
. generate double x = 1 + sqrt(rchi2(1)) // generate values for x
. generate double lambda = 1 + 1.5*x // lambda is 1 + alpha*x
. generate double k = 2 // fix value of k
. generate double y = lambda*((-ln(1-tau))^(1/k)) // generate random values for y given x
```

Although the comments at the end of each line briefly describe what each line is doing, we provide a more careful description. The first line drops any variables in memory. The second sets the seed of the random-number generator so that we will always get the same sequence of random uniform numbers. The third line sets the sample size to 100,000 observations, and the fourth line reports the change in sample size.

The fifth line substitutes random uniform numbers for \( \tau \). This line is the key to the algorithm. This standard method, known as inverse-probability transforms, for computing random numbers is discussed by Cameron and Trivedi (2010, 126–127), among others.
Lines 6–8 generate $x$, $\lambda$, and $k$ per our specified DGP. Lines 9–11 implement (1) using the previously generated $\lambda$, $x$, and $k$.

At the end, we have 100,000 observations on $y$ and $x$, with $y$ coming from the conditional distribution that we specified above.

Example 7

In the example below, we use `qreg` to estimate $\beta_1$ and $\beta_0$, the parameters from the conditional quantile function, for the 0.5 quantile from our simulated data.

```
. qreg y x, quantile(.5)
Iteration 1: WLS sum of weighted deviations = 68975.517
Iteration 1: sum of abs. weighted deviations = 68975.325
Iteration 2: sum of abs. weighted deviations = 68843.958
Iteration 3: sum of abs. weighted deviations = 68629.64
Iteration 4: sum of abs. weighted deviations = 68626.382
Iteration 5: sum of abs. weighted deviations = 68625.659
Iteration 6: sum of abs. weighted deviations = 68625.657
Iteration 7: sum of abs. weighted deviations = 68625.657
Median regression Number of obs = 100000
Raw sum of deviations 73840.51 (about 2.944248)
Min sum of deviations 68625.66 Pseudo R2 = 0.0706

|       | Coef.  | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|-------|--------|-----------|-------|-------|----------------------|
|       |        |           |       |       |                      |
| $x$   | 1.228536 | .0118791 | 103.42| 0.000 | 1.205253             | 1.251819 |
| _cons | .8693355 | .0225288 | 38.59 | 0.000 | .8251793             | .9134917 |
```

In the `qreg` output, the results for $x$ correspond to the estimate of $\beta_1$, and the results for `_cons` correspond to the estimate of $\beta_0$. The reported estimates are close to their true values of 1.248832 and 0.8325546, which are given in table 1.

The intuition in this example comes from the ability of `qreg` to recover the true parameters of our specified DGP. As we increase the number of observations in our sample size, the `qreg` estimates will get closer to the true values.
Example 8

In the example below, we estimate the parameters of the conditional quantile function for the 0.25 quantile and compare them with the true values.

```
. qreg y x, quantile(.25)
Iteration 1: WLS sum of weighted deviations = 65497.284
Iteration 1: sum of abs. weighted deviations = 65492.359
Iteration 2: sum of abs. weighted deviations = 60139.477
Iteration 3: sum of abs. weighted deviations = 49999.793
Iteration 4: sum of abs. weighted deviations = 49999.479
Iteration 5: sum of abs. weighted deviations = 49999.465
Iteration 6: sum of abs. weighted deviations = 49999.465
```

.25 Quantile regression
Number of obs = 100000
Raw sum of deviations 52014.79 (about 1.857329)
Min sum of deviations 49999.47 Pseudo R2 = 0.0387

|    | Coef.  | Std. Err. | t     | P>|t|  | 95% Conf. Interval |
|----|--------|-----------|-------|------|-------------------|
| x  | .7844305 | .0107092 | 73.25 | 0.000 | .7634405 - .8054204 |
| _cons | .5633285 | .0203102 | 27.74 | 0.000 | .5235209 - .6031362 |

As above, qreg reports the estimates of $\beta_1$ and $\beta_0$ in the output table for x and _cons, respectively. The reported estimates are close to their true values of 0.80454 and 0.53636, which are given in table 1. As expected, the estimates are close to their true values. Also as expected, the estimates for the 0.25 quantile are smaller than the estimates for the 0.5 quantile.
Example 9

We finish this section by estimating the parameters of the conditional quantile function for the 0.8 quantile and comparing them with the true values.

```
. qreg y x, quantile(.8)
Iteration 1: WLS sum of weighted deviations = 66332.299
Iteration 1: sum of abs. weighted deviations = 66332.194
Iteration 2: sum of abs. weighted deviations = 60076.645
Iteration 3: sum of abs. weighted deviations = 52589.193
Iteration 4: sum of abs. weighted deviations = 52340.961
Iteration 5: sum of abs. weighted deviations = 52262.505
Iteration 6: sum of abs. weighted deviations = 52249.305
Iteration 7: sum of abs. weighted deviations = 52245.124
Iteration 8: sum of abs. weighted deviations = 52245.103
Iteration 9: sum of abs. weighted deviations = 52245.081
Iteration 10: sum of abs. weighted deviations = 52245.075
Iteration 11: sum of abs. weighted deviations = 52245.074
Iteration 12: sum of abs. weighted deviations = 52245.073
Iteration 13: sum of abs. weighted deviations = 52245.073
Iteration 14: sum of abs. weighted deviations = 52245.073
Iteration 15: sum of abs. weighted deviations = 52245.073
```

```
.8 Quantile regression                                   Number of obs = 100000
Raw sum of deviations 60093.34 (about 4.7121822)        Pseudo R2 = 0.1306
Min sum of deviations 52245.07
```

```
         y |      Coef.     Std. Err.     t    P>|t|     [95% Conf. Interval]  
----------+--------------------------------- 
         x |  1.889702    .0146895   128.64    0.000     1.860911    1.918493  
     _cons |  1.293773    .0278587    46.44    0.000     1.23917     1.348375  
```

As above, `qreg` reports the estimates of $\beta_1$ and $\beta_0$ in the output table for `x` and `_cons`, respectively. The reported estimates are close to their true values of 1.902954 and 1.268636, which are given in Table 1. As expected, the estimates are close to their true values. Also as expected, the estimates for the 0.8 quantile are larger than the estimates for the 0.5 quantile.
Stored results

Scalars
- e(N): number of observations
- e(df_r): residual degrees of freedom
- e(q): quantile requested
- e(q_v): value of the quantile
- e(reps): number of replications
- e(sum_aedev): sum of absolute deviations
- e(sum_rdev): sum of raw deviations
- e(rank): rank of e(V)
- e(convcode): 0 if converged; otherwise, return code for why nonconvergence

Macros
- e(cmd): bsqreg
- e(cmdline): command as typed
- e(depvar): name of dependent variable
- e(properties): b V
- e(predict): program used to implement predict
- e(marginsnotok): predictions disallowed by margins

Matrices
- e(b): coefficient vector
- e(V): variance–covariance matrix of the estimators

Functions
- e(sample): marks estimation sample

Methods and formulas

Methods and formulas are presented under the following headings:

Introduction

Linear programming formulation of quantile regression

Standard errors when residuals are i.i.d.

Pseudo-$R^2$

Introduction

According to Stuart and Ord (1991, 1084), the method of minimum absolute deviations was first proposed by Boscovich in 1757 and was later developed by Laplace; Stigler (1986, 39–55) and Hald (1998, 97–103, 112–116) provide historical details. According to Bloomfield and Steiger (1980), Harris (1950) later observed that the problem of minimum absolute deviations could be turned into the linear programming problem that was first implemented by Wagner (1959). Interest has grown in this method because robust methods and extreme value modeling have become more popular. Statistical and computational properties of minimum absolute deviation estimators are surveyed by Narula and Wellington (1982). Cameron and Trivedi (2005), Hao and Naiman (2007), and Wooldridge (2010) provide excellent introductions to quantile regression methods, while Koenker (2005) gives an in-depth review of the topic.

Linear programming formulation of quantile regression

Define $\tau$ as the quantile to be estimated; the median is $\tau = 0.5$. For each observation $i$, let $\varepsilon_i$ be the residual

$$\varepsilon_i = y_i - x_i^T \hat{\beta}_\tau$$
The objective function to be minimized is
\[
c_\tau(\varepsilon_i) = (\tau 1 \{\varepsilon_i \geq 0\} + (1 - \tau)1 \{\varepsilon_i < 0\}) |\varepsilon_i|
\]
\[
= (\tau 1 \{\varepsilon_i \geq 0\} - (1 - \tau)1 \{\varepsilon_i < 0\}) \varepsilon_i
\]
\[
= (\tau - 1 \{\varepsilon_i < 0\}) \varepsilon_i
\]
where \(1\{\cdot\}\) is the indicator function. This function is sometimes referred to as the check function because it resembles a check mark (Wooldridge 2010, 450); the slope of \(c_\tau(\varepsilon_i)\) is \(\tau\) when \(\varepsilon_i > 0\) and is \(\tau - 1\) when \(\varepsilon_i < 0\), but is undefined for \(\varepsilon_i = 0\). Choosing the \(\hat{\beta}_\tau\) that minimize \(c_\tau(\varepsilon_i)\) is equivalent to finding the \(\hat{\beta}_\tau\) that make \(x_i \hat{\beta}_\tau\) best fit the quantiles of the distribution of \(y\) conditional on \(x\).

This minimization problem is set up as a linear programming problem and is solved with linear programming techniques, as suggested by Armstrong, Frome, and Kung (1979) and described in detail by Koenker (2005). Here \(2n\) slack variables, \(u_{n \times 1}\) and \(v_{n \times 1}\), are introduced, where \(u_i \geq 0, v_i \geq 0,\) and \(u_i \times v_i = 0\), reformulating the problem as
\[
\min_{\beta_\tau, u, v} \{\tau 1_n u + (1 - \tau)1_n v \mid y - X \beta_\tau = u - v\}
\]
where \(1_n\) is a vector of 1s. This is a linear objective function on a polyhedral constraint set with \(\binom{n}{k}\) vertices, and our goal is to find the vertex that minimizes (2). Each step in the search is described by a set of \(k\) observations through which the regression plane passes, called the basis. A step is taken by replacing a point in the basis if the linear objective function can be improved. If this occurs, a line is printed in the iteration log. The definition of convergence is exact in the sense that no amount of added iterations could improve the objective function.

A series of weighted least-squares (WLS) regressions is used to identify a set of observations as a starting basis. The WLS algorithm for \(\tau = 0.5\) is taken from Schlossmacher (1973) with a generalization for \(0 < \tau < 1\) implied from Hunter and Lange (2000).

**Standard errors when residuals are i.i.d.**

The estimator for the VCE implemented in `qreg` assumes that the errors of the model are independent and identically distributed (i.i.d.). When the errors are i.i.d., the large-sample VCE is
\[
cov(\beta_\tau) = \frac{\tau(1 - \tau)}{f_Y'(\xi_\tau)} \{E(x_i x_i')\}^{-1}
\]
where \(\xi_\tau = F_Y^{-1}(\tau)\) and \(F_Y(y)\) is the distribution function of \(Y\) with density \(f_Y(y)\). See Koenker (2005, 73) for this result. From (3), we see that the regression precision depends on the inverse of the density function, termed the sparsity function, \(s_\tau = 1/f_Y(\xi_\tau)\).

While \(1/n \sum_{i=1}^n x_i x_i'\) estimates \(E(x_i x_i')\), estimating the sparsity function is more difficult. `qreg` provides several methods to estimate the sparsity function. The different estimators are specified through the suboptions of `vce(iid, denmethod bwidth)`. The suboption `denmethod` specifies the functional form for the sparsity estimator. The default is `fitted`.

Here we outline the logic underlying the fitted estimator. Because \(F_Y(y)\) is the distribution function for \(Y\), we have \(f_Y(y) = \{dF_Y(y)\}/dy, \tau = F_Y(\xi_\tau),\) and \(\xi_\tau = F_Y^{-1}(\tau)\). When differentiating the identity \(F_Y\{F_Y^{-1}(\tau)\} = \tau\), the sparsity function can be written as \(s_\tau = \{F_Y^{-1}(\tau)\}/dt\). Numerically, we can approximate the derivative using the centered difference,
\[
\frac{F_Y^{-1}(\tau)}{dt} \approx \frac{F_Y^{-1}(\tau + h) - F_Y^{-1}(\tau - h)}{2h} = \frac{\xi_{\tau+h} - \xi_{\tau-h}}{2h} = \hat{s}_\tau \tag{4}
\]

where \( h \) is the bandwidth.

The empirical quantile function is computed by first estimating \( \beta_{\tau+h} \) and \( \beta_{\tau-h} \), and then computing
\[
\hat{F}_Y^{-1}(\tau + h) = \hat{x}' \beta_{\tau+h} \quad \text{and} \quad \hat{F}_Y^{-1}(\tau - h) = \hat{x}' \beta_{\tau-h},
\]
where \( \hat{x} \) is the sample mean of the independent variables \( x \). These quantities are then substituted into (4).

Alternatively, as the option suggests, \textit{vce(iid, residual)} specifies that \texttt{qreg} use the empirical quantile function of the residuals to estimate the sparsity. Here we substitute \( F_e \), the distribution of the residuals, for \( F_Y \), which only differ by their first moments.

The \( k \) residuals associated with the linear programming basis will be zero, where \( k \) is the number of regression coefficients. These zero residuals are removed before computing the \( \tau + h \) and \( \tau - h \) quantiles, \( \varepsilon_{\tau+h} = \hat{F}_e^{-1}(\tau + h) \) and \( \varepsilon_{\tau-h} = \hat{F}_e^{-1}(\tau - h) \). The \( \hat{F}_e^{-1} \) estimates are then substituted for \( F_Y^{-1} \) in (4).

Each of the estimators for the sparsity function depends on a bandwidth. The \texttt{vce()} suboption \textit{bwidth} specifies the bandwidth method to use. The three bandwidth options and their citations are \texttt{hsheather} (Hall and Sheather 1988), \texttt{bofinger} (Bofinger 1975), and \texttt{chamberlain} (Chamberlain 1994).

Their formulas are
\[
\begin{align*}
\hat{h}_s &= n^{-1/3} \Phi^{-1} \left( 1 - \frac{\alpha}{2} \right)^{2/3} \left[ \frac{3}{2} + \frac{\phi \{ \Phi^{-1}(\tau) \}^4}{2 \Phi^{-1}(\tau)^2 + 1} \right]^{1/3} \\
\hat{h}_b &= n^{-1/5} \left[ \frac{9}{2} \frac{\phi \{ 2 \Phi^{-1}(\tau) \}^4}{(2 \Phi^{-1}(\tau)^2 + 1)^2} \right]^{1/5} \\
\hat{h}_c &= \Phi^{-1} \left( 1 - \frac{\alpha}{2} \right) \sqrt{\frac{\tau (1 - \tau)}{n}}
\end{align*}
\]

where \( \hat{h}_s \) is the Hall–Sheather bandwidth, \( \hat{h}_b \) is the Bofinger bandwidth, \( \hat{h}_c \) is the Chamberlain bandwidth, \( \Phi() \) and \( \phi() \) are the standard normal distribution and density functions, \( n \) is the sample size, and\( 100 (1 - \alpha) \) is the confidence level set by the \texttt{level()} option. Koenker (2005) discusses the derivation of the Hall–Sheather and the Bofinger bandwidth formulas. You should avoid modifying the confidence level when replaying estimates that use the Hall–Sheather or Chamberlain bandwidths because these methods use the confidence level to estimate the coefficient standard errors.

Finally, the \texttt{vce()} suboption \texttt{kernel(kernel)} specifies that \texttt{qreg} use one of several kernel-density estimators to estimate the sparsity function. \texttt{kernel} allows you to choose which kernel function to use, where the default is the Epanechnikov kernel. See \cite{kdensity} for the functional form of the eight kernels.

The kernel bandwidth is computed using an adaptive estimate of scale
\[
\hat{h}_k = \min \left( \hat{\sigma}, \frac{r_q}{1.34} \right) \times \left\{ \Phi^{-1}(\tau + h) - \Phi^{-1}(\tau - h) \right\}
\]

where \( h \) is one of \( \hat{h}_s, \hat{h}_b, \) or \( \hat{h}_c; \) \( r_q \) is the interquartile range; and \( \hat{\sigma} \) is the standard deviation of \( y \); see Silverman (1992, 47) and Koenker (2005, 81) for discussions. Let \( \hat{f}_e(\varepsilon_i) \) be the kernel density estimate for the \( i \)th residual, and then the kernel estimator for the sparsity function is
\[
\hat{s}_\tau = \frac{nh_k}{\sum_{i=1}^{n} \hat{f}_e(\varepsilon_i)}
\]
Finally, substituting your choice of sparsity estimate into (3) results in the i.i.d. variance–covariance matrix

\[ V_n = \hat{s}_\tau^2 \tau (1 - \tau) \left( \sum_{i=1}^{n} x_i x_i' \right)^{-1} \]

**Pseudo-\( R^2 \)**

The pseudo-\( R^2 \) is calculated as

\[
1 - \frac{\text{sum of weighted deviations about estimated quantile}}{\text{sum of weighted deviations about raw quantile}}
\]

This is based on the likelihood for a double-exponential distribution \( e^{v_i |\varepsilon_i|} \), where \( v_i \) are multipliers

\[
v_i = \begin{cases} 
2\tau & \text{if } \varepsilon_i > 0 \\
2(1 - \tau) & \text{otherwise}
\end{cases}
\]

Minimizing the objective function (2) with respect to \( \beta_\tau \) also minimizes \( \sum_i |\varepsilon_i| v_i \), the sum of weighted least absolute deviations. For example, for the 50th percentile \( v_i = 1 \), for all \( i \), and we have median regression. If we want to estimate the 75th percentile, we weight the negative residuals by 0.50 and the positive residuals by 1.50. It can be shown that the criterion is minimized when 75% of the residuals are negative.

qreg postestimation — Postestimation tools for qreg, iqreg, sqreg, and bsqreg

Description

The following postestimation commands are available after qreg, iqreg, bsqreg, and sqreg:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>estat summarize</td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td>estat vce</td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td>estimates</td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td>forecast¹</td>
<td>dynamic forecasts and simulations</td>
</tr>
<tr>
<td>lincom</td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td>linktest</td>
<td>link test for model specification</td>
</tr>
<tr>
<td>margins</td>
<td>marginal means, predictive margins, marginal effects, and average marginal effects</td>
</tr>
<tr>
<td>marginsplot</td>
<td>graph the results from margins (profile plots, interaction plots, etc.)</td>
</tr>
<tr>
<td>nlcem</td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td>predict</td>
<td>predictions, residuals, influence statistics, and other diagnostic measures</td>
</tr>
<tr>
<td>predictnl</td>
<td>point estimates, standard errors, testing, and inference for generalized predictions</td>
</tr>
<tr>
<td>test</td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td>testnl</td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

¹ forecast is not appropriate with mi estimation results.
Syntax for predict

For qreg, iqreg, and bsqreg

```
predict [type] newvar [if] [in] [, xb|stdp|residuals]
```

For sqreg

```
predict [type] newvar [if] [in] [, equation(eqno[,eqno]) statistic]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td>stddp</td>
<td>standard error of the difference in linear predictions</td>
</tr>
<tr>
<td>residuals</td>
<td>residuals</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

```
Main
xb, the default, calculates the linear prediction.
stdp calculates the standard error of the linear prediction.
stddp is allowed only after you have fit a model using sqreg. The standard error of the difference in linear predictions \( (x_{1j}b - x_{2j}b) \) between equations 1 and 2 is calculated.
residuals calculates the residuals, that is, \( y_j - x_jb \).
equation(eqno[,eqno]) specifies the equation to which you are making the calculation.
```

If you do not specify equation(), results are the same as if you had specified equation(#1).

To use stddp, you must specify two equations. You might specify equation(#1, #2) or equation(q80, q20) to indicate the 80th and 20th quantiles.
Remarks and examples

Example 1

In example 4 of [R] qreg, we fit regressions for the lower and the upper quartile of the price variable. The predict command can be used to obtain the linear prediction after each regression.

```stata
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. qreg price weight length foreign, quantile(.25)
(output omitted)
. predict q25
(option xb assumed; fitted values)
. qreg price weight length foreign, quantile(.75)
(output omitted)
. predict q75
(option xb assumed; fitted values)
```

We can use the variables generated by predict to compute the predicted interquartile range, that is,

```stata
. generate iqr1 = q75 - q25
```

If we directly perform the interquartile range regression with the iqreg command, we can predict the interquartile range and also the standard error for the prediction.

```stata
. iqreg price weight length foreign, quantile(.25 .75)
(output omitted)
. predict iqr2
(option xb assumed; fitted values)
. predict stdp, stdp
```

We now plot the predicted interquartile range versus variable length:

```stata
. scatter iqr2 length
```

As stated in example 5 of [R] qreg, the negative coefficient for the length variable means that increases in length imply decreases in the interquartile range and therefore in price dispersion. Consequently, we could have expected a downward trend in the plot, but there is not. This is because
the regression output indicates that when we hold the rest of the variables constant, an increase in `length` leads to a decrease in `iqr2`. However, there is a high correlation between `weight` and `length`, which could be masking the effect of `length` on `iqr2`. We can achieve a better visualization by using a contour plot.

```
. twoway contour iqr2 weight length, level(10)
```

![Contour plot](image)

We can see the effect by setting a fixed value of `length` on the vertical axis, say, 3,000 lbs. When we move from left to right on the horizontal axis, we see that for small values of `length`, `iqr2` values are shown in red, meaning high values, and when we move toward the right, the graph indicates transition into increasingly smaller values.

Title

query — Display system parameters

Syntax

query [ memory | output | interface | graphics | efficiency | network | update | trace | mata | other ]

Description

query displays the settings of various Stata parameters.

Remarks and examples

query provides more system information than you will ever want to know. You do not need to understand every line of output that query produces if all you need is one piece of information. Here is what happens when you type query:

```
. query
```

The output is broken into several divisions: memory, output, interface, graphics, efficiency, network, update, trace, mata, and other settings. We will discuss each one in turn.

We generated the output above using Stata/MP for Windows. Here is what happens when we type `query` and we are running Stata/SE for Mac:

```
. query
```

### Memory settings
- `set maxvar 5000` (2048-32767; max. vars allowed)
- `set matsize 400` (10-11000; max. # vars in models)
- `set niceness 5` (0-10)
- `set min_memory 0` (0-1600g)
- `set max_memory .` (32m-1600g or .)
- `set segmentsize 32m` (1m-32g)

### Output settings
- `set more off`
- `set rmsg off`
- `set dp period` (may be period or comma)
- `set linesize 80` (characters)
- `set pagesize 23` (lines)
- `set level 95` (percent confidence intervals)
- `set showbaselevels` (may be empty, off, on, or all)
- `set showemptycells` (may be empty, off, or on)
- `set showomitted` (may be empty, off, or on)
- `set fvlabel on`
- `set fvwrap 1`
- `set fvwrapon word` (may be word or width)
- `set lstretch` (may be empty, off, or on)
- `set cformat` (may be empty or a numerical format)
- `set pformat` (may be empty or a numerical format)
- `set sformat` (may be empty or a numerical format)
- `set coeftabresults on`
- `set logtype smcl` (may be smcl or text)

Memory settings

Memory settings indicate how memory is allocated, the maximum number of variables, and the maximum size of a matrix.

For more information, see

- `maxvar` [D] memory
- `matsize` [R] matsize
- `niceness` [D] memory
- `min_memory` [D] memory
- `max_memory` [D] memory
- `segmentsize` [D] memory

Output settings

Output settings show how Stata displays output on the screen and in log files.

For more information, see

- `more` [R] more
- `rmsg` [P] rmsg
- `dp` [D] format
- `linesize` [R] log
- `pagesize` [R] more
- `level` [R] level
- `showbaselevels` [R] set showbaselevels
- `showemptycells` [R] set showbaselevels
- `showomitted` [R] set showbaselevels
- `fylabel` [R] set showbaselevels
- `fwwrap` [R] set showbaselevels
- `fwrapon` [R] set showbaselevels
- `cformat` [R] set cformat
- `pformat` [R] set cformat
- `sformat` [R] set cformat
coeftabresults [R] set
lstretch [R] set
logtype [R] log
charset [R] set
eolchar [R] set
notifyuser [R] set
playsnd [R] set
include_bitmap [R] set

Interface settings

Interface settings control how Stata’s interface works.

For more information, see

dockable [R] set
dockingguides [R] set
floatwindows [R] set
locksplitters [R] set
pinnable [R] set
doublebuffer [R] set
revelwidth [R] set
varkeyboard [R] set
smoothfonts [R] set
linelabel [R] set
scrollbufsize [R] set
fastscroll [R] set
reventries [R] set
maxdb [R] db

Graphics settings

Graphics settings indicate how Stata’s graphics are displayed.

For more information, see

graphics [G-2] set graphics
autotabgraphs [R] set
scheme [G-2] set scheme
printcolor [G-2] set printcolor
copycolor [G-2] set printcolor

Efficiency settings

The efficiency settings set the maximum amount of memory allocated to automatically loaded do-files, the maximum number of remembered-contents dialog boxes, and the use of virtual memory.

For more information, see

adosize [P] sysdir
Network settings

Network settings determine how Stata interacts with the Internet.
For more information, see [R] netio.

Update settings

Update settings determine how Stata performs updates.
For more information, see [R] update.

Trace settings

Trace settings adjust Stata’s behavior and are particularly useful in debugging code.
For more information, see [P] trace.

Mata settings

Mata settings affect Mata’s system parameters.
For more information, see [M-3] mata set.

Other settings

The other settings are a miscellaneous collection.
For more information, see

```
    type [D] generate
    maxiter [R] maximize
    searchdefault [R] search
    seed [R] set seed
    varabbrev [R] set
    emptycells [R] set
    processors [R] set
    odbcmgr [D] odbc
    haverdir [D] import haver
```

In general, the parameters displayed by query can be changed by set; see [R] set.

Statistics > Nonparametric analysis > Tests of hypotheses > Wilcoxon rank-sum test

**median**

Statistics > Nonparametric analysis > Tests of hypotheses > K-sample equality-of-medians test
Description

`ranksum` tests the hypothesis that two independent samples (that is, *unmatched* data) are from populations with the same distribution by using the Wilcoxon rank-sum test, which is also known as the Mann–Whitney two-sample statistic (Wilcoxon 1945; Mann and Whitney 1947).

`median` performs a nonparametric *k*-sample test on the equality of medians. It tests the null hypothesis that the *k* samples were drawn from populations with the same median. For two samples, the chi-squared test statistic is computed both with and without a continuity correction.

`ranksum` and `median` are for use with *unmatched* data. For equality tests on matched data, see [R] `signrank`.

Options for `ranksum`

- `by(groupvar)` is required. It specifies the name of the grouping variable.
- `porder` displays an estimate of the probability that a random draw from the first population is larger than a random draw from the second population.

Options for `median`

- `by(groupvar)` is required. It specifies the name of the grouping variable.
- `exact` displays the significance calculated by Fisher’s exact test. For two samples, both one- and two-sided probabilities are displayed.
- `medianties(below | above | drop | split)` specifies how values equal to the overall median are to be handled. The median test computes the median for `varname` by using all observations and then divides the observations into those falling above the median and those falling below the median. When values for an observation are equal to the sample median, they can be dropped from the analysis by specifying `medianties(drop)`, added to the group above or below the median by specifying `medianties(above)` or `medianties(below)`, respectively; or if there is more than 1 observation with values equal to the median, they can be equally divided into the two groups by specifying `medianties(split)`. If this option is not specified, `medianties(below)` is assumed.

Remarks and examples

Example 1

We are testing the effectiveness of a new fuel additive. We run an experiment with 24 cars: 12 cars with the fuel treatment and 12 cars without. We input these data by creating a dataset with 24 observations. `mpg` records the mileage rating, and `treat` records 0 if the mileage corresponds to untreated fuel and 1 if it corresponds to treated fuel.
. use http://www.stata-press.com/data/r13/fuel2
. ranksum mpg, by(treat)

Two-sample Wilcoxon rank-sum (Mann-Whitney) test

<table>
<thead>
<tr>
<th>treat</th>
<th>obs</th>
<th>rank sum</th>
<th>expected</th>
</tr>
</thead>
<tbody>
<tr>
<td>untreated</td>
<td>12</td>
<td>128</td>
<td>150</td>
</tr>
<tr>
<td>treated</td>
<td>12</td>
<td>172</td>
<td>150</td>
</tr>
<tr>
<td>combined</td>
<td>24</td>
<td>300</td>
<td>300</td>
</tr>
</tbody>
</table>

unadjusted variance 300.00
adjustment for ties -4.04
adjusted variance 295.96

Ho: mpg(treat==untreated) = mpg(treat==treated)
    z = -1.279
    Prob > |z| = 0.2010

These results indicate that the medians are not statistically different at any level smaller than 20.1%. Similarly, the median test,

. median mpg, by(treat) exact

Median test

<table>
<thead>
<tr>
<th>Greater than the median</th>
<th>whether car received fuel additive</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>untreated</td>
<td>fuel additive</td>
<td></td>
</tr>
<tr>
<td>yes</td>
<td>5</td>
<td>7</td>
</tr>
<tr>
<td>no</td>
<td>7</td>
<td>5</td>
</tr>
<tr>
<td>Total</td>
<td>12</td>
<td>12</td>
</tr>
</tbody>
</table>

Pearson chi2(1) = 0.6667    Pr = 0.414
Fisher's exact = 0.684
1-sided Fisher's exact = 0.342
Continuity corrected:
    Pearson chi2(1) = 0.1667    Pr = 0.683

fails to reject the null hypothesis that there is no difference between the fuel with the additive and the fuel without the additive.

Compare these results from these two tests with those obtained from the signrank and signtest where we found significant differences; see [R] signrank. An experiment run on 24 different cars is not as powerful as a before-and-after comparison using the same 12 cars.

Stored results

ranksum stores the following in r():

Scalars

r(N_1)    sample size $n_1$
r(N_2)    sample size $n_2$
r(z)      z statistic
r(Var_a)  adjusted variance
r(group1) value of variable for first group
r(sum_obs) actual sum of ranks for first group
r(sum_exp) expected sum of ranks for first group
r(porder) probability that draw from first population is larger than draw from second population
\textbf{median} stores the following in \texttt{r()}: \\
\begin{itemize}
  \item \texttt{r(N)} \quad \text{sample size}
  \item \texttt{r(chi2)} \quad \text{Pearson’s } \chi^2
  \item \texttt{r(p)} \quad \text{significance of Pearson’s } \chi^2
  \item \texttt{r(p_exact)} \quad \text{Fisher’s exact } p
  \item \texttt{r(groups)} \quad \text{number of groups compared}
  \item \texttt{r(chi2_cc)} \quad \text{continuity-corrected Pearson’s } \chi^2
  \item \texttt{r(p_cc)} \quad \text{continuity-corrected significance}
  \item \texttt{r(p1_exact)} \quad \text{one-sided Fisher’s exact } p
\end{itemize}

\section*{Methods and formulas}

For a practical introduction to these techniques with an emphasis on examples rather than theory, see Acock (2014), Bland (2000), or Sprent and Smeeton (2007). For a summary of these tests, see Snedecor and Cochran (1989).

Methods and formulas are presented under the following headings:

\begin{itemize}
  \item \textit{ranksum}
  \item \textit{median}
\end{itemize}

\subsection*{ranksum}

For the Wilcoxon rank-sum test, there are two independent random variables, \(X_1\) and \(X_2\), and we test the null hypothesis that \(X_1 \sim X_2\). We have a sample of size \(n_1\) from \(X_1\) and another of size \(n_2\) from \(X_2\).

The data are then ranked without regard to the sample to which they belong. If the data are tied, averaged ranks are used. Wilcoxon’s test statistic (1945) is the sum of the ranks for the observations in the first sample:

\[ T = \sum_{i=1}^{n_1} R_{1i} \]

Mann and Whitney’s \(U\) statistic (1947) is the number of pairs \((X_{1i}, X_{2j})\) such that \(X_{1i} > X_{2j}\). These statistics differ only by a constant:

\[ U = T - \frac{n_1(n_1 + 1)}{2} \]

Again Fisher’s principle of randomization provides a method for calculating the distribution of the test statistic, ties or not. The randomization distribution consists of the \(\binom{n}{n_1}\) ways to choose \(n_1\) ranks from the set of all \(n = n_1 + n_2\) ranks and assign them to the first sample.

It is a straightforward exercise to verify that

\[ E(T) = \frac{n_1(n + 1)}{2} \quad \text{and} \quad \text{Var}(T) = \frac{n_1n_2s^2}{n} \]

where \(s\) is the standard deviation of the combined ranks, \(r_i\), for both groups:

\[ s^2 = \frac{1}{n - 1} \sum_{i=1}^{n}(r_i - \bar{r})^2 \]
This formula for the variance is exact and holds both when there are no ties and when there are ties and we use averaged ranks. (Indeed, the variance formula holds for the randomization distribution of choosing $n_1$ numbers from any set of $n$ numbers.)

Using a normal approximation, we calculate

$$z = \frac{T - E(T)}{\sqrt{\text{Var}(T)}}$$

When the `porder` option is specified, the probability

$$p = \frac{U}{n_1n_2}$$

is computed.

**Technical note**

We follow the great majority of the literature in naming these tests for Wilcoxon, Mann, and Whitney. However, they were independently developed by several other researchers in the late 1940s and early 1950s. In addition to Wilcoxon, Mann, and Whitney, credit is due to Festinger (1946), Whitfield (1947), Haldane and Smith (1947), and Van der Reyden (1952). Leon Festinger (1919–1989), John Burdon Sanderson Haldane (1892–1964), and Cedric Austen Bardell Smith (1917–2002) are well known for other work, but little seems to be known about Whitfield or van der Reyden. For a detailed study, including information on these researchers, see Berry, Mielke, and Johnston (2012).

**median**

The median test examines whether it is likely that two or more samples came from populations with the same median. The null hypothesis is that the samples were drawn from populations with the same median. The alternative hypothesis is that at least one sample was drawn from a population with a different median. The test should be used only with ordinal or interval data.

Assume that there are score values for $k$ independent samples to be compared. The median test is performed by first computing the median score for all observations combined, regardless of the sample group. Each score is compared with this computed grand median and is classified as being above the grand median, below the grand median, or equal to the grand median. Observations with scores equal to the grand median can be dropped, added to the “above” group, added to the “below” group, or split between the two groups.

Once all observations are classified, the data are cast into a $2 \times k$ contingency table, and a Pearson’s chi-squared test or Fisher’s exact test is performed.
Henry Berthold Mann (1905–2000) was born in Vienna, Austria, where he completed a doctorate in algebraic number theory. He moved to the United States in 1938 and for several years made his livelihood by tutoring in New York. During this time, he proved a celebrated conjecture in number theory and studied statistics at Columbia with Abraham Wald, with whom he wrote three papers. After the war, he taught at Ohio State and the Universities of Wisconsin and Arizona. In addition to his work in number theory and statistics, he made major contributions to algebra and combinatorics.

Donald Ransom Whitney (1915–2007) studied at Oberlin, Princeton, and Ohio State Universities and worked at the latter throughout his career. His PhD thesis under Henry Mann was on nonparametric statistics. It was this work that produced the test that bears their names.

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Ratios

Description

ratio produces estimates of ratios, along with standard errors.

Options

Model

stdize(varname) specifies that the point estimates be adjusted by direct standardization across the strata identified by varname. This option requires the stdweight() option.

stdweight(varname) specifies the weight variable associated with the standard strata identified in the stdize() option. The standardization weights must be constant within the standard strata.

nostdrescale prevents the standardization weights from being rescaled within the over() groups. This option requires stdize() but is ignored if the over() option is not specified.

over(varlist [, nolabel]) specifies that estimates be computed for multiple subpopulations, which are identified by the different values of the variables in varlist.

When this option is supplied with one variable name, such as over(varname), the value labels of varname are used to identify the subpopulations. If varname does not have labeled values (or there are unlabeled values), the values themselves are used, provided that they are nonnegative integers. Noninteger values, negative values, and labels that are not valid Stata names are substituted with a default identifier.

When over() is supplied with multiple variable names, each subpopulation is assigned a unique default identifier.

nolabel requests that value labels attached to the variables identifying the subpopulations be ignored.

SE/Cluster

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (linearized), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

vce(linearized), the default, uses the linearized or sandwich estimator of variance.

Reporting

level(#) ; see [R] estimation options.

noheader prevents the table header from being displayed. This option implies nolegend.

nolegend prevents the table legend identifying the subpopulations from being displayed.

display_options: cformat(%fmt) and nolstretch; see [R] estimation options.

The following option is available with ratio but is not shown in the dialog box:

coefflegend; see [R] estimation options.
Remarks and examples

Example 1

Using the fuel data from example 3 of [R] ttest, we estimate the ratio of mileage for the cars without the fuel treatment (mpg1) to those with the fuel treatment (mpg2).

```
. use http://www.stata-press.com/data/r13/fuel
. ratio myratio: mpg1/mpg2
```

<table>
<thead>
<tr>
<th></th>
<th>Linearized</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Ratio</td>
<td>Std. Err.</td>
<td>[95% Conf. Interval]</td>
</tr>
<tr>
<td>myratio</td>
<td>.9230769</td>
<td>.032493</td>
<td>.8515603 .9945936</td>
</tr>
</tbody>
</table>

Using these results, we can test to see if this ratio is significantly different from one.

```
. test _b[myratio] = 1
   ( 1) myratio = 1
    F( 1, 11) = 5.60
    Prob > F = 0.0373
```

We find that the ratio is different from one at the 5% significance level but not at the 1% significance level.

Example 2

Using state-level census data, we want to test whether the marriage rate is equal to the death rate.

```
. use http://www.stata-press.com/data/r13/census2
   (1980 Census data by state)
. ratio (deathrate: death/pop) (marrate: marriage/pop)
```

<table>
<thead>
<tr>
<th></th>
<th>Linearized</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Ratio</td>
<td>Std. Err.</td>
<td>[95% Conf. Interval]</td>
</tr>
<tr>
<td>deathrate</td>
<td>.0087368</td>
<td>.0002052</td>
<td>.0083244 .0091492</td>
</tr>
<tr>
<td>marrate</td>
<td>.0105577</td>
<td>.0006184</td>
<td>.009315 .0118005</td>
</tr>
</tbody>
</table>

```
. test _b[deathrate] = _b[marrate]
   ( 1) deathrate - marrate = 0
    F( 1, 49) = 6.93
    Prob > F = 0.0113
```
Stored results

`ratio` stores the following in `e()`:

**Scalars**
- `e(N)` number of observations
- `e(N_over)` number of subpopulations
- `e(N_stdize)` number of standard strata
- `e(N_clust)` number of clusters
- `e(k_eq)` number of equations in `e(b)`
- `e(df_r)` sample degrees of freedom
- `e(rank)` rank of `e(V)`

**Macros**
- `e(cmd)` `ratio`
- `e(cmdline)` command as typed
- `e(varlist)` `varlist`
- `e(stdize)` `varname` from `stdize()`
- `e(stdweight)` `varname` from `stdweight()`
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(cluster)` name of cluster variable
- `e(over)` `varlist` from `over()`
- `e(over_labels)` labels from `over()` variables
- `e(over_namelist)` names from `e(over_labels)`
- `e(namelist)` ratio identifiers
- `e(vce)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(properties)` `b V`
- `e(estat_cmd)` program used to implement `estat`
- `e(marginsnotok)` predictions disallowed by `margins`

**Matrices**
- `e(b)` vector of ratio estimates
- `e(V)` (co)variance estimates
- `e(N)` vector of numbers of nonmissing observations
- `e(N_stdsum)` number of nonmissing observations within the standard strata
- `e(p_stdize)` standardizing proportions
- `e(error)` error code corresponding to `e(b)`

**Functions**
- `e(sample)` marks estimation sample

### Methods and formulas

Methods and formulas are presented under the following headings:

- The ratio estimator
- Survey data
- The survey ratio estimator
- The standardized ratio estimator
- The poststratified ratio estimator
- The standardized poststratified ratio estimator
- Subpopulation estimation
The ratio estimator

Let \( R = Y/X \) be the ratio to be estimated, where \( Y \) and \( X \) are totals; see \([R] total\). The estimate for \( R \) is \( \hat{R} = \hat{Y}/\hat{X} \) (the ratio of the sample totals). From the delta method (that is, a first-order Taylor expansion), the approximate variance of the sampling distribution of the linearized \( \hat{R} \) is

\[
V(\hat{R}) \approx \frac{1}{\hat{X}^2} \left\{ V(\hat{Y}) - 2R \text{Cov}(\hat{Y}, \hat{X}) + R^2 V(\hat{X}) \right\}
\]

Direct substitution of \( \hat{X}, \hat{R}, \) and the estimated variances and covariance of \( \hat{X} \) and \( \hat{Y} \) leads to the following variance estimator:

\[
\hat{V}(\hat{R}) = \frac{1}{\hat{X}^2} \left\{ \hat{V}(\hat{Y}) - 2\hat{R} \text{Cov}(\hat{Y}, \hat{X}) + \hat{R}^2 \hat{V}(\hat{X}) \right\}
\] (1)

Survey data

See [SVY] variance estimation, [SVY] direct standardization, and [SVY] poststratification for discussions that provide background information for the following formulas.

The survey ratio estimator

Let \( Y_j \) and \( X_j \) be survey items for the \( j \)th individual in the population, where \( j = 1, \ldots, M \) and \( M \) is the size of the population. The associated population ratio for the items of interest is \( R = Y/X \) where

\[
Y = \sum_{j=1}^{M} Y_j \quad \text{and} \quad X = \sum_{j=1}^{M} X_j
\]

Let \( y_j \) and \( x_j \) be the corresponding survey items for the \( j \)th sampled individual from the population, where \( j = 1, \ldots, m \) and \( m \) is the number of observations in the sample.

The estimator \( \hat{R} \) for the population ratio \( R \) is \( \hat{R} = \hat{Y}/\hat{X} \), where

\[
\hat{Y} = \sum_{j=1}^{m} w_j y_j \quad \text{and} \quad \hat{X} = \sum_{j=1}^{m} w_j x_j
\]

and \( w_j \) is a sampling weight. The score variable for the ratio estimator is

\[
z_j(\hat{R}) = \frac{y_j - \hat{R} x_j}{\hat{X}} = \frac{\hat{X} y_j - \hat{Y} x_j}{\hat{X}^2}
\]
The standardized ratio estimator

Let $D_g$ denote the set of sampled observations that belong to the $g$th standard stratum and define $I_{D_g}(j)$ to indicate if the $j$th observation is a member of the $g$th standard stratum; where $g = 1, \ldots, L_D$ and $L_D$ is the number of standard strata. Also, let $\pi_g$ denote the fraction of the population that belongs to the $g$th standard stratum, thus $\pi_1 + \cdots + \pi_{L_D} = 1$. Note that $\pi_g$ is derived from the stdweight() option.

The estimator for the standardized ratio is

\[ \hat{R}^D = \sum_{g=1}^{L_D} \pi_g \frac{\hat{Y}_g}{\hat{X}_g} \]

where

\[ \hat{Y}_g = \sum_{j=1}^{m} I_{D_g}(j) w_j y_j \]

and $\hat{X}_g$ is similarly defined. The score variable for the standardized ratio is

\[ z_j(\hat{R}^D) = \sum_{g=1}^{L_D} \pi_g I_{D_g}(j) \frac{\hat{X}_g y_j - \hat{Y}_g x_j}{\hat{X}_g^2} \]

The poststratified ratio estimator

Let $P_k$ denote the set of sampled observations that belong to poststratum $k$, and define $I_{P_k}(j)$ to indicate if the $j$th observation is a member of poststratum $k$, where $k = 1, \ldots, L_P$ and $L_P$ is the number of poststrata. Also, let $M_k$ denote the population size for poststratum $k$. $P_k$ and $M_k$ are identified by specifying the poststrata() and postweight() options on svyset; see [SVY] svyset.

The estimator for the poststratified ratio is

\[ \hat{R}^P = \frac{\hat{Y}^P}{\hat{X}^P} \]

where

\[ \hat{Y}^P = \sum_{k=1}^{L_P} \frac{M_k}{M^*} \hat{Y}_k = \sum_{k=1}^{L_P} \frac{M_k}{M^*} \sum_{j=1}^{m} I_{P_k}(j) w_j y_j \]

and $\hat{X}^P$ is similarly defined. The score variable for the poststratified ratio is

\[ z_j(\hat{R}^P) = \frac{z_j(\hat{Y}^P) - \hat{R}^P z_j(\hat{X}^P)}{\hat{X}^P} = \frac{\hat{X}^P z_j(\hat{Y}^P) - \hat{Y}^P z_j(\hat{X}^P)}{(\hat{X}^P)^2} \]

where

\[ z_j(\hat{Y}^P) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{M^*} \left( y_j - \frac{\hat{Y}_k}{M_k} \right) \]

and $z_j(\hat{X}^P)$ is similarly defined.
The standardized poststratified ratio estimator

The estimator for the standardized poststratified ratio is

\[ \hat{R}^{DP} = \sum_{g=1}^{L_D} \pi_g \frac{\hat{Y}_g^P}{\hat{X}_g^P} \]

where

\[ \hat{Y}_g^P = \sum_{k=1}^{L_p} \frac{M_k}{M_k} \hat{Y}_{g,k} = \sum_{k=1}^{L_p} \frac{M_k}{M_k} \sum_{j=1}^{m} I_{D_g}(j) I_{P_k}(j) w_j y_j \]

and \( \hat{X}_g^P \) is similarly defined. The score variable for the standardized poststratified ratio is

\[ z_j(\hat{R}^{DP}) = \sum_{g=1}^{L_D} \pi_g \frac{\hat{X}_g^P z_j(\hat{Y}_g^P) - \hat{Y}_g^P z_j(\hat{X}_g^P)}{(\hat{X}_g^P)^2} \]

where

\[ z_j(\hat{Y}_g^P) = \sum_{k=1}^{L_p} I_{P_k}(j) \frac{M_k}{M_k} \left\{ I_{D_g}(j) y_j - \frac{\hat{Y}_{g,k}}{M_k} \right\} \]

and \( z_j(\hat{X}_g^P) \) is similarly defined.

Subpopulation estimation

Let \( S \) denote the set of sampled observations that belong to the subpopulation of interest, and define \( I_S(j) \) to indicate if the \( j \)th observation falls within the subpopulation.

The estimator for the subpopulation ratio is \( \hat{R}^S = \hat{Y}^S / \hat{X}^S \), where

\[ \hat{Y}^S = \sum_{j=1}^{m} I_S(j) w_j y_j \quad \text{and} \quad \hat{X}^S = \sum_{j=1}^{m} I_S(j) w_j x_j \]

Its score variable is

\[ z_j(\hat{R}^S) = I_S(j) \frac{y_j - \hat{X}^S x_j}{\hat{X}^S} = I_S(j) \frac{\hat{X}^S y_j - \hat{Y}^S x_j}{(\hat{X}^S)^2} \]

The estimator for the standardized subpopulation ratio is

\[ \hat{R}^{DS} = \sum_{g=1}^{L_D} \pi_g \frac{\hat{Y}_g^S}{\hat{X}_g^S} \]

where

\[ \hat{Y}_g^S = \sum_{j=1}^{m} I_{D_g}(j) I_S(j) w_j y_j \]

and \( \hat{X}_g^S \) is similarly defined. Its score variable is

\[ z_j(\hat{R}^{DS}) = \sum_{g=1}^{L_D} \pi_g I_{D_g}(j) I_S(j) \frac{\hat{X}_g^S y_j - \hat{Y}_g^S x_j}{(\hat{X}_g^S)^2} \]
The estimator for the poststratified subpopulation ratio is

\[ \hat{R}_{PS} = \frac{\hat{Y}_{PS}}{\hat{X}_{PS}} \]

where

\[ \hat{Y}_{PS} = \sum_{k=1}^{L_P} \frac{M_k}{M} \hat{Y}_k = \sum_{k=1}^{L_P} \frac{M_k}{M} \sum_{j=1}^{m} I_{P_k}(j) I_S(j) w_j y_j \]

and \( \hat{X}_{PS} \) is similarly defined. Its score variable is

\[ z_j(\hat{R}_{PS}) = \frac{\hat{X}_{PS} z_j(\hat{Y}_{PS}) - \hat{Y}_{PS} z_j(\hat{X}_{PS})}{(\hat{X}_{PS})^2} \]

where

\[ z_j(\hat{Y}_{PS}) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{M} \left\{ I_S(j) y_j - \frac{\hat{Y}_k}{M_k} \right\} \]

and \( z_j(\hat{X}_{PS}) \) is similarly defined.

The estimator for the standardized poststratified subpopulation ratio is

\[ \hat{R}^{DPS} = \sum_{g=1}^{L_D} \pi_g \frac{\hat{Y}_{PS}}{\hat{X}_{PS}} \]

where

\[ \hat{Y}_{PS} = \sum_{k=1}^{L_P} \frac{M_k}{M} \hat{Y}_{g,k} = \sum_{k=1}^{L_P} \frac{M_k}{M} \sum_{j=1}^{m} I_{D_g}(j) I_{P_k}(j) I_S(j) w_j y_j \]

and \( \hat{X}_{g} = \) is similarly defined. Its score variable is

\[ z_j(\hat{R}^{DPS}) = \sum_{g=1}^{L_D} \pi_g \frac{\hat{X}_{PS} z_j(\hat{Y}_{PS}) - \hat{Y}_{PS} z_j(\hat{X}_{PS})}{(\hat{X}_{PS})^2} \]

where

\[ z_j(\hat{Y}_{PS}) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{M} \left\{ I_{D_g}(j) I_S(j) y_j - \frac{\hat{Y}_{g,k}}{M_k} \right\} \]

and \( z_j(\hat{X}_{PS}) \) is similarly defined.

Syntax

Basic syntax

```
reg3 (depvar\_1 varlist\_1) (depvar\_2 varlist\_2) ... (depvar\_N varlist\_N) [if] [in] [weight]
```

Full syntax

```
reg3 ([eqname\_1:] depvar\_1a [ depvar\_1b ... = ] varlist\_1 [, noconstant])
([eqname\_2:] depvar\_2a [ depvar\_2b ... = ] varlist\_2 [, noconstant])
...
([eqname\_N:] depvar\_Na [ depvar\_Nb ... = ] varlist\_N [, noconstant])
[if] [in] [weight] [ , options]
```

options Description

Model

- `ireg3` iterate until estimates converge
- `constraints(constraints)` apply specified linear constraints

Model 2

- `exog(varlist)`, exogenous variables not specified in system equations
- `endog(varlist)`, additional right-hand-side endogenous variables
- `inst(varlist)`, full list of exogenous variables
- `allxog`, all right-hand-side variables are exogenous
- `noconstant`, suppress constant from instrument list

Est. method

- `3sls`, three-stage least squares; the default
- `2sls`, two-stage least squares
- `ols`, ordinary least squares (OLS)
- `sure`, seemingly unrelated regression estimation (SURE)
- `mvreg`, sure with OLS degrees-of-freedom adjustment
- `corr(correlation)`, unstructured or independent correlation structure; default is unstructured

df adj.

- `small`, report small-sample statistics
- `dfk`, use small-sample adjustment
- `dfk2`, use alternate adjustment
reg3 estimates a system of structural equations, where some equations contain endogenous variables among the explanatory variables. Estimation is via three-stage least squares (3SLS); see Zellner and Theil (1962). Typically, the endogenous explanatory variables are dependent variables from other equations in the system. reg3 supports iterated GLS estimation and linear constraints.

reg3 can also estimate systems of equations by seemingly unrelated regression estimation (SURE), multivariate regression (MVREG), and equation-by-equation ordinary least squares (OLS) or two-stage least squares (2SLS).

Nomenclature

Under 3SLS or 2SLS estimation, a *structural equation* is defined as one of the equations specified in the system. A *dependent variable* will have its usual interpretation as the left-hand-side variable in an equation with an associated disturbance term. All dependent variables are explicitly taken to be *endogenous* to the system and are treated as correlated with the disturbances in the system’s equations. Unless specified in an `endog()` option, all other variables in the system are treated as *exogenous* to the system and uncorrelated with the disturbances. The exogenous variables are taken to be *instruments* for the endogenous variables.
Options

ireg3 causes reg3 to iterate over the estimated disturbance covariance matrix and parameter estimates until the parameter estimates converge. Although the iteration is usually successful, there is no guarantee that it will converge to a stable point. Under SURE, this iteration converges to the maximum likelihood estimates.

canstraints(constraints); see [R] estimation options.

exog(varlist) specifies additional exogenous variables that are included in none of the system equations. This can occur when the system contains identities that are not estimated. If implicitly exogenous variables from the equations are listed here, reg3 will just ignore the additional information. Specified variables will be added to the exogenous variables in the system and used in the first stage as instruments for the endogenous variables. By specifying dependent variables from the structural equations, you can use exog() to override their endogeneity.

endog(varlist) identifies variables in the system that are not dependent variables but are endogenous to the system. These variables must appear in the variable list of at least one equation in the system. Again the need for this identification often occurs when the system contains identities. For example, a variable that is the sum of an exogenous variable and a dependent variable may appear as an explanatory variable in some equations.

inst(varlist) specifies a full list of all exogenous variables and may not be used with the endog() or exog() options. It must contain a full list of variables to be used as instruments for the endogenous regressors. Like exog(), the list may contain variables not specified in the system of equations. This option can be used to achieve the same results as the endog() and exog() options, and the choice is a matter of convenience. Any variable not specified in the varlist of the inst() option is assumed to be endogenous to the system. As with exog(), including the dependent variables from the structural equations will override their endogeneity.

allexog indicates that all right-hand-side variables are to be treated as exogenous—even if they appear as the dependent variable of another equation in the system. This option can be used to enforce a SURE or MVREG estimation even when some dependent variables appear as regressors.

noconstant; see [R] estimation options.

3sls specifies the full 3SLS estimation of the system and is the default for reg3.

2sls causes reg3 to perform equation-by-equation 2SLS on the full system of equations. This option implies dfk, small, and corr(independent).

Cross-equation testing should not be performed after estimation with this option. With 2sls, no covariance is estimated between the parameters of the equations. For cross-equation testing, use 3sls.

ols causes reg3 to perform equation-by-equation OLS on the system—even if dependent variables appear as regressors or the regressors differ for each equation; see [MV] mvreg. ols implies allexog, dfk, small, and corr(independent); nodfk and nosmall may be specified to override dfk and small.

The covariance of the coefficients between equations is not estimated under this option, and cross-equation tests should not be performed after estimation with ols. For cross-equation testing, use sure or 3sls (the default).
sure causes \texttt{reg3} to perform a SURE of the system—even if dependent variables from some equations appear as regressors in other equations; see \texttt{[R] sureg}. sure is a synonym for \texttt{allexog}.

\texttt{mvreg} is identical to \texttt{sure}, except that the disturbance covariance matrix is estimated with an OLS degrees-of-freedom adjustment—the \texttt{dfk} option. If the regressors are identical for all equations, the parameter point estimates will be the standard MVREG results. If any of the regressors differ, the point estimates are those for SURE with an OLS degrees-of-freedom adjustment in computing the covariance matrix. \texttt{nodf} and \texttt{nosmall} may be specified to override \texttt{dfk} and \texttt{small}.

\texttt{corr(correlation)} specifies the assumed form of the correlation structure of the equation disturbances and is rarely requested explicitly. For the family of models fit by \texttt{reg3}, the only two allowable correlation structures are \texttt{unstructured} and \texttt{independent}. The default is \texttt{unstructured}.

This option is used almost exclusively to estimate a system of equations by 2SLS or to perform OLS regression with \texttt{reg3} on multiple equations. In these cases, the correlation is set to \texttt{independent}, forcing \texttt{reg3} to treat the covariance matrix of equation disturbances as diagonal in estimating model parameters. Thus a set of two-stage coefficient estimates can be obtained if the system contains endogenous right-hand-side variables, or OLS regression can be imposed, even if the regressors differ across equations. Without imposing independent disturbances, \texttt{reg3} would estimate the former by 3SLS and the latter by SURE.

Any tests performed after estimation with the \texttt{independent} option will treat coefficients in different equations as having no covariance; cross-equation tests should not be used after specifying \texttt{corr(independent)}.

\texttt{small} specifies that small-sample statistics be computed. It shifts the test statistics from $\chi^2$ and $z$ statistics to $F$ statistics and $t$ statistics. This option is intended primarily to support MVREG. Although the standard errors from each equation are computed using the degrees of freedom for the equation, the degrees of freedom for the $t$ statistics are all taken to be those for the first equation. This approach poses no problem under MVREG because the regressors are the same across equations.

\texttt{dfk} specifies the use of an alternative divisor in computing the covariance matrix for the equation residuals. As an asymptotically justified estimator, \texttt{reg3} by default uses the number of sample observations $n$ as a divisor. When the \texttt{dfk} option is set, a small-sample adjustment is made, and the divisor is taken to be $\sqrt{(n-k_i)(n-k_j)}$, where $k_i$ and $k_j$ are the numbers of parameters in equations $i$ and $j$, respectively.

\texttt{dfk2} specifies the use of an alternative divisor in computing the covariance matrix for the equation errors. When the \texttt{dfk2} option is set, the divisor is taken to be the mean of the residual degrees of freedom from the individual equations.

\texttt{level(#)}; see \texttt{[R] estimation options}.

\texttt{first} requests that the first-stage regression results be displayed during estimation.

\texttt{nocnsreport}; see \texttt{[R] estimation options}.

\texttt{display_options}: \texttt{nomitted}, \texttt{vsquish}, \texttt{noemptycells}, \texttt{baselevels}, \texttt{allbaselevels}, \texttt{nofvlabel}, \texttt{fwrap(#)}, \texttt{fwrapon(style)}, \texttt{cformat(\%fmt)}, \texttt{pformat(\%fmt)}, \texttt{sformat(\%fmt)}, and \texttt{nolstretch}; see \texttt{[R] estimation options}. 
reg3 — Three-stage estimation for systems of simultaneous equations

Optimization

optimization_options control the iterative process that minimizes the sum of squared errors when reg3 is specified. These options are seldom used.

iterate(#) specifies the maximum number of iterations. When the number of iterations equals #, the optimizer stops and presents the current results, even if the convergence tolerance has not been reached. The default value of iterate() is the current value of set maxiter (see [R] maximize), which is iterate(16000) if maxiter has not been changed.

trace adds to the iteration log a display of the current parameter vector.

nolog suppresses the display of the iteration log.

tolerance(#) specifies the tolerance for the coefficient vector. When the relative change in the coefficient vector from one iteration to the next is less than or equal to #, the optimization process is stopped. tolerance(1e-6) is the default.

The following options are available with reg3 but are not shown in the dialog box:

noheader suppresses display of the header reporting the estimation method and the table of equation summary statistics.

notable suppresses display of the coefficient table.

nofooter suppresses display of the footer reporting the list of endogenous and exogenous variables in the model.

toll; see [R] estimation options.

Remarks and examples

reg3 estimates systems of structural equations where some equations contain endogenous variables among the explanatory variables. Generally, these endogenous variables are the dependent variables of other equations in the system, though not always. The disturbance is correlated with the endogenous variables—violating the assumptions of OLS. Further, because some of the explanatory variables are the dependent variables of other equations in the system, the error terms among the equations are expected to be correlated. reg3 uses an instrumental-variables approach to produce consistent estimates and generalized least squares (GLS) to account for the correlation structure in the disturbances across the equations. Good general references on three-stage estimation include Davidson and MacKinnon (1993, 651–661) and Greene (2012, 331–334).

Three-stage least squares can be thought of as producing estimates from a three-step process.

Step 1. Develop instrumented values for all endogenous variables. These instrumented values can simply be considered as the predicted values resulting from a regression of each endogenous variable on all exogenous variables in the system. This stage is identical to the first step in 2SLS and is critical for the consistency of the parameter estimates.

Step 2. Obtain a consistent estimate for the covariance matrix of the equation disturbances. These estimates are based on the residuals from a 2SLS estimation of each structural equation.

Step 3. Perform a GLS-type estimation using the covariance matrix estimated in the second stage and with the instrumented values in place of the right-hand-side endogenous variables.
Technical note

The estimation and use of the covariance matrix of disturbances in three-stage estimation is almost identical to the SURE method—sureg. As with SURE, using this covariance matrix improves the efficiency of the three-stage estimator. Even without the covariance matrix, the estimates would be consistent. (They would be 2SLS estimates.) This improvement in efficiency comes with a caveat. All the parameter estimates now depend on the consistency of the covariance matrix estimates. If one equation in the system is misspecified, the disturbance covariance estimates will be inconsistent, and the resulting coefficients will be biased and inconsistent. Alternatively, if each equation is estimated separately by 2SLS ([R] regress), only the coefficients in the misspecified equation are affected.

Technical note

If an equation is just identified, the 3SLS point estimates for that equation are identical to the 2SLS estimates. However, as with sureg, even if all equations are just identified, fitting the model via reg3 has at least one advantage over fitting each equation separately via ivregress; by using reg3, tests involving coefficients in different equations can be performed easily using test or testnl.

Example 1

A simple macroeconomic model relates consumption (consump) to private and government wages paid (wagepriv and wagegovt). Simultaneously, private wages depend on consumption, total government expenditures (govt), and the lagged stock of capital in the economy (capital1). Although this is not a plausible model, it does meet the criterion of being simple. This model could be written as

\[
\begin{align*}
\text{consump} &= \beta_0 + \beta_1 \text{wagepriv} + \beta_2 \text{wagegovt} + \epsilon_1 \\
\text{wagepriv} &= \beta_3 + \beta_4 \text{consump} + \beta_5 \text{govt} + \beta_6 \text{capital1} + \epsilon_2
\end{align*}
\]

If we assume that this is the full system, consump and wagepriv will be endogenous variables, with wagegovt, govt, and capital1 exogenous. Data for the U.S. economy on these variables are taken from Klein (1950). This model can be fit with reg3 by typing
Without showing the 2SLS results, we note that the consumption function in this system falls under the conditions noted earlier. That is, the 2SLS and 3SLS coefficients for the equation are identical.

---

### Example 2

Some of the most common simultaneous systems encountered are supply-and-demand models. A simple system could be specified as

\[
q_{\text{Demand}} = \beta_0 + \beta_1 price + \beta_2 p_{\text{compete}} + \beta_3 income + \epsilon_1
\]

\[
q_{\text{Supply}} = \beta_4 + \beta_5 price + \beta_6 raw + \epsilon_2
\]

Equilibrium condition: \( quantity = q_{\text{Demand}} = q_{\text{Supply}} \)

where

- **quantity** is the quantity of a product produced and sold,
- **price** is the price of the product,
- **p_{\text{compete}}** is the price of a competing product,
- **income** is the average income level of consumers, and
- **raw** is the price of raw materials used to produce the product.

In this system, price is assumed to be determined simultaneously with demand. The important statistical implications are that price is not a predetermined variable and that it is correlated with the disturbances of both equations. The system is somewhat unusual: quantity is associated with two disturbances. This fact really poses no problem because the disturbances are specified on the behavioral demand and supply equations—two separate entities. Often one of the two equations is rewritten to place price on the left-hand side, making this endogeneity explicit in the specification.
To provide a concrete illustration of the effects of simultaneous equations, we can simulate data for the above system by using known coefficients and disturbance properties. Specifically, we will simulate the data as

\[
q_{\text{Demand}} = 40 - 1.0 \text{ price} + 0.25 \text{ pcompete} + 0.5 \text{ income} + \epsilon_1 \\
q_{\text{Supply}} = 0.5 \text{ price} - 0.75 \text{ praw} + \epsilon_2
\]

where

\[
\epsilon_1 \sim N(0, 3.8) \\
\epsilon_2 \sim N(0, 2.4)
\]

For comparison, we can estimate the supply and demand equations separately by OLS. The estimates for the demand equation are

_cons    | -6.97 | 3.32  | -2.10 | 0.041 | -13.66 - 0.2839 |
```

Examining the coefficients from these regressions, we note that they are not close to the known parameters used to generate the simulated data. In particular, the positive coefficient on price in the demand equation stands out. We constructed our simulated data to be consistent with economic theory—people demand less of a product if its price rises and more if their personal income rises. Although the price coefficient is statistically insignificant, the positive value contrasts starkly with what is predicted from economic price theory and the $-1.0$ value that we used in the simulation. Likewise, we are disappointed with the insignificance and level of the coefficient on average income. The supply equation has correct signs on the two main parameters, but their levels are different from the known values. In fact, the coefficient on price (0.724675) is different from the simulated parameter (0.5) at the 5% level of significance.
All of these problems are to be expected. We explicitly constructed a simultaneous system of equations that violated one of the assumptions of least squares. Specifically, the disturbances were correlated with one of the regressors—price.

Two-stage least squares can be used to address the correlation between regressors and disturbances. Using instruments for the endogenous variable, price, 2SLS will produce consistent estimates of the parameters in the system. Let’s use ivregress (see [R] ivregress) to see how our simulated system behaves when fit using 2SLS.

```
. ivregress 2sls quantity (price = praw) pcompete income
Instrumental variables (2SLS) regression

|        | Coef.  | Std. Err. |    z  | P>|z| |  [95% Conf. Interval] |
|--------|--------|-----------|-------|------|----------------------|
| price  | -1.015817 | .374209  | -2.71 | 0.007 | -1.749253 to -.282381 |
| pcompete | .3319504  | .172912  | 1.92  | 0.055 | -.0069508 to .6708517 |
| income | .5090607  | .1919482 | 2.65  | 0.008 | .1328491 to .8852723  |
| _cons  | 39.89988  | 10.77738 | 3.70  | 0.000 | 18.78366 to 61.01611  |

Instrumented: price
Instruments: pcompete income praw
```

Finally, this system could be estimated using 3SLS. To demonstrate how large systems might be handled and to avoid multiline commands, we will use global macros (see [P] macro) to hold the specifications for our equations.

```
. ivregress 2sls quantity (price = pcompete income) praw
Instrumental variables (2SLS) regression

|        | Coef.  | Std. Err. |    z  | P>|z| |  [95% Conf. Interval] |
|--------|--------|-----------|-------|------|----------------------|
| price  | .5773133 | .1749974 | 3.30  | 0.001 | .2343247 to .9203019  |
| praw   | -.7835496 | .1312414| -5.97 | 0.000 | -1.040778 to -.5263213 |
| _cons  | -2.550694 | 5.273067 | -0.48 | 0.629 | -12.88571 to 7.784327 |

Instrumented: price
Instruments: praw pcompete income
```

We are now much happier with the estimation results. All the coefficients from both equations are close to the true parameter values for the system. In particular, the coefficients are all well within 95% confidence intervals for the parameters. The missing \( R^2 \)-squared in the demand equation seems unusual; we will discuss that more later.

Finally, this system could be estimated using 3SLS. To demonstrate how large systems might be handled and to avoid multiline commands, we will use global macros (see [P] macro) to hold the specifications for our equations.

```
. global demand "(qDemand: quantity price pcompete income)"
. global supply "(qSupply: quantity price praw)"
. reg3 $demand $supply, endog(price)
```

We must specify price as endogenous because it does not appear as a dependent variable in either equation. Without this option, reg3 would assume that there are no endogenous variables in the system and produce seemingly unrelated regression (sureg) estimates. The reg3 output from our series of commands is
Three-stage least-squares regression

The use of 3SLS over 2SLS is essentially an efficiency issue. The coefficients of the demand equation from 3SLS are close to the coefficients from two-stage least squares, and those of the supply equation are identical. The latter case was mentioned earlier for systems with some exactly identified equations. However, even for the demand equation, we do not expect the coefficients to change systematically. What we do expect from three-stage least squares are more precise estimates of the parameters given the validity of our specification and reg3’s use of the covariances among the disturbances.

Let’s summarize the results. With OLS, we got obviously biased estimates of the parameters. No amount of data would have improved the OLS estimates—they are inconsistent in the face of the violated OLS assumptions. With 2SLS, we obtained consistent estimates of the parameters, and these would have improved with more data. With 3SLS, we obtained consistent estimates of the parameters that are more efficient than those obtained by 2SLS.

Technical note

We noted earlier that the $R$-squared was missing from the two-stage estimates of the demand equation. Now we see that the $R$-squared is negative for the three-stage estimates of the same equation. How can we have a negative $R$-squared?

In most estimators, other than least squares, the $R$-squared is no more than a summary measure of the overall in-sample predictive power of the estimator. The computational formula for $R$-squared is $R$-squared = 1 − RSS/TSS, where RSS is the residual sum of squares (sum of squared residuals) and TSS is the total sum of squared deviations about the mean of the dependent variable. In a standard linear model with a constant, the model from which the TSS is computed is nested within the full model from which RSS is computed—they both have a constant term based on the same data. Thus it must be that TSS ≥ RSS and $R$-squared is constrained between 0 and 1.

For 2SLS and 3SLS, some of the regressors enter the model as instruments when the parameters are estimated. However, because our goal is to fit the structural model, the actual values, not the instruments for the endogenous right-hand-side variables, are used to determine $R$-squared. The model residuals are computed over a different set of regressors from those used to fit the model. The two-
or three-stage estimates are no longer nested within a constant-only model of the dependent variable, and the residual sum of squares is no longer constrained to be smaller than the total sum of squares.

A negative $R^2$-squared in 3SLS should be taken for exactly what it is—an indication that the structural model predicts the dependent variable worse than a constant-only model. Is this a problem? It depends on the application. Three-stage least squares applied to our contrived supply-and-demand example produced good estimates of the known true parameters. Still, the demand equation produced an $R^2$-squared of $-0.854$. How do we feel about our parameter estimates? This should be determined by the estimates themselves, their associated standard errors, and the overall model significance. On this basis, negative $R^2$-squared and all, we feel pretty good about all the parameter estimates for both the supply and demand equations. Would we want to make predictions about equilibrium quantity by using the demand equation alone? Probably not. Would we want to make these quantity predictions by using the supply equation? Possibly, because based on in-sample predictions, they seem better than those from the demand equations. However, both the supply and demand estimates are based on limited information. If we are interested in predicting quantity, a reduced-form equation containing all our independent variables would usually be preferred.

**Technical note**

As a matter of syntax, we could have specified the supply-and-demand model on one line without using global macros.

`. reg3 (quantity price pcompete income) (quantity price praw), endog(price)

Endogenous variables: quantity price
Exogenous variables: pcompete income praw

However, here reg3 has been forced to create a unique equation name for the supply equation—2quantity. Both the supply and demand equations could not be designated as quantity, so a number was prefixed to the name for the supply equation.
We could have specified

```
. reg3 (qDemand: quantity price pcompete income) (qSupply: quantity price praw),
   > endog(price)
```

and obtained the same results and equation labeling as when we used global macros to hold the equation specifications.

Without explicit equation names, `reg3` always assumes that the dependent variable should be used to name equations. When each equation has a different dependent variable, this rule causes no problems and produces easily interpreted result tables. If the same dependent variable appears in more than one equation, however, `reg3` will create a unique equation name based on the dependent variable name. Because equation names must be used for cross-equation tests, you have more control in this situation if explicit names are placed on the equations.

Example 3: Using the full syntax of `reg3`

Klein's (1950) model of the U.S. economy is often used to demonstrate system estimators. It contains several common features that will serve to demonstrate the full syntax of `reg3`. The Klein model is defined by the following seven relationships:

\[
\begin{align*}
    c &= \beta_0 + \beta_1 p + \beta_2 L.p + \beta_3 w + \epsilon_1 \\
    i &= \beta_4 + \beta_5 p + \beta_6 L.p + \beta_7 L.k + \epsilon_2 \\
    wp &= \beta_8 + \beta_9 y + \beta_{10} L.y + \beta_{11} yr + \epsilon_3 \\
    y &= c + i + g \\
    p &= y - t - wp \\
    k &= L.k + i \\
    w &= wg + wp
\end{align*}
\]

Here we have used Stata’s lag operator $L.$ to represent variables that appear with a one-period lag in our model; see [U] 13.9 Time-series operators.

The variables in the model are listed below. Two sets of variable names are shown. The concise first name uses traditional economics mnemonics, whereas the second name provides more guidance for everyone else. The concise names serve to keep the specification of the model small (and quite understandable to economists).

</table>
Equations (1)–(3) are behavioral and contain explicit disturbances \((\epsilon_1, \epsilon_2, \text{ and } \epsilon_3)\). The remaining equations are identities that specify additional variables in the system and their accounting relationships with the variables in the behavioral equations. Some variables are explicitly endogenous by appearing as dependent variables in (1)–(3). Others are implicitly endogenous as linear combinations that contain other endogenous variables (for example, \(w\) and \(p\)). Still other variables are implicitly exogenous by appearing in the identities but not in the behavioral equations (for example, \(wg\) and \(g\)).

Using the concise names, we can fit Klein’s model with the following command:

```stata
use http://www.stata-press.com/data/r13/klein2
reg3 (c p L.p w) (i p L.p L.k) (wp y L.y yr), endog(w p y) exog(t wg g)
```

Endogenous variables: c i wp w p y
Exogenous variables: L.p L.k L.y yr t wg g

We used the `exog()` option to identify \(t\), \(wg\), and \(g\) as exogenous variables in the system. These variables must be identified because they are part of the system but appear directly in none of the behavioral equations. Without this option, `reg3` would not know they were part of the system and could be used as instrumental variables. The `endog()` option specifying \(w\), \(p\), and \(y\) is also required. Without this information, `reg3` would be unaware that these variables are linear combinations that include endogenous variables. We did not include \(k\) in the `endog()` option because only its lagged value appears in the behavioral equations.
Rather than listing additional endogenous and exogenous variables, we could specify the full list of exogenous variables in an inst() option,

\[
\text{reg3 (c p L.p w) (i p L.p L.k) (w y L.y yr), inst(g t wg yr L.p L.k L.y)}
\]
or equivalently,

\[
\text{global conseqn "(c p L.p w)"}
\text{global inveqn "(i p L.p L.k)"}
\text{global wageqn "(w y L.y yr)"}
\text{global inlist "g t wg yr L.p L.k L.y"}
\text{reg3 $conseqn $inveqn $wageqn, inst($inlist)}
\]

Macros and explicit equations can also be mixed in the specification

\[
\text{reg3 $conseqn (i p L.p L.k) $wageqn, endog(w p y) exog(t wg g)}
\]
or

\[
\text{reg3 (c p L.p w) $inveqn (w y L.y yr), endog(w p y) exog(t wg g)}
\]

Placing the equation-binding parentheses in the global macros was also arbitrary. We could have used

\[
\text{global consump "c p L.p w"}
\text{global invest "i p L.p L.k"}
\text{global wagepriv "wp y L.y yr"}
\text{reg3 ($consump) ($invest) ($wagepriv), endog($enlist) exog($exlist)}
\]

reg3 is tolerant of all combinations, and these commands will produce identical output.

Switching to the full variable names, we can fit Klein’s model with the commands below. We will use global macros to store the lists of endogenous and exogenous variables. Again this is not necessary: these lists could have been typed directly on the command line. However, assigning the lists to local macros makes additional processing easier if alternative models are to be fit. We will also use the ireg3 option to produce the iterated estimates.

\[
\text{use http://www.stata-press.com/data/r13/kleinfull}
\text{global conseqn "(consump profits L.profits wagetot)"}
\text{global inveqn "(invest profits L.profits L.capital)"}
\text{global wageqn "(wagepriv totinc L.totinc year)"}
\text{global enlist "wagetot profits totinc"}
\text{global exlist "taxnetx wagegovt govt"}
\text{reg3 $conseqn $inveqn $wageqn, endog($enlist) exog($exlist) ireg3}
\]

### Example 4: Constraints with reg3

As a simple example of constraints, (1) above may be rewritten with both wages explicitly appearing (rather than as a variable containing the sum). Using the longer variable names, we have

\[
\text{consump} = \beta_0 + \beta_1 \text{profits} + \beta_2 \text{L.profits} + \beta_3 \text{wagepriv} + \beta_{12} \text{wagegovt} + \epsilon_1
\]

To retain the effect of the identity in (7), we need \( \beta_3 = \beta_{12} \) as a constraint on the system. We obtain this result by defining the constraint in the usual way and then specifying its use in `reg3`. Because `reg3` is a system estimator, we will need to use the full equation syntax of `constraint`. The assumption that the following commands are entered after the model above has been estimated. We are simply changing the definition of the consumption equation (`consump`) and adding a constraint on two of its parameters. The rest of the model definition is carried forward.

```stata
.global conseqn "(consump profits L.profits wagepriv wagegovt)"
.constraint define 1 [consump]wagepriv = [consump]wagegovt
.reg3 $conseqn $inveqn $wageqn, endog($enlist) exog($exlist) constr(1) ireg3
```

```
note: additional endogenous variables not in the system have no effect
and are ignored: wagetot
Iteration 1:  tolerance =  .3712547
Iteration 2:  tolerance =  .189471
Iteration 3:  tolerance =  .10764
(output omitted)
Iteration 24:  tolerance =  7.049e-07
```

Endogenous variables: consump invest wagepriv wagetot profits totinc
doctor

As expected, none of the parameter or standard error estimates has changed from the previous estimates (before the seventh significant digit). We have simply decomposed the total wage variable into its two parts and constrained the coefficients on these parts. The warning about additional endogenous variables was just reg3’s way of letting us know that we had specified some information that was irrelevant to the estimation of the system. We had left the wagetot variable in our endog macro. It does not mean anything to the system to specify wagetot as endogenous because it is no longer in the system. That’s fine with reg3 and fine for our current purposes.

We can also impose constraints across the equations. For example, the admittedly meaningless constraint of requiring profits to have the same effect in both the consumption and investment equations could be imposed. Retaining the constraint on the wage coefficients, we would estimate this constrained system.
constraint define 2 [consump]profits = [invest]profits
reg3 $conseqn $inveqn $wageqn, endog($enlist) exog($exlist) constr(1 2) ireg3
note: additional endogenous variables not in the system have no effect and are ignored: wagetot

Endogenous variables: consump invest wagepriv wagetot profits totinc
Exogenous variables: L.profits wagegovt L.capital L.totinc year taxnetx
Identification in a system of simultaneous equations involves the notion that there is enough information to estimate the parameters of the model given the specified functional form. Under-identification usually manifests itself as one matrix in the 3SLS computations. The most commonly violated order condition for 2SLS or 3SLS involves the number of endogenous and exogenous variables. There must be at least as many noncollinear exogenous variables in the remaining system as there are endogenous right-hand-side variables in an equation. This condition must hold for each structural equation in the system.

Put as a set of rules the following:

1. Count the number of right-hand-side endogenous variables in an equation and call this $m_i$.
2. Count the number of exogenous variables in the same equation and call this $k_i$.
3. Count the total number of exogenous variables in all the structural equations plus any additional variables specified in an `exog()` or `inst()` option and call this $K$.
4. If $m_i > (K - k_i)$ for any structural equation $(i)$, then the system is underidentified and cannot be estimated by 3SLS.

We are also possibly in trouble if any of the exogenous variables are linearly dependent. We must have $m_i$ linearly independent variables among the exogenous variables represented by $(K - k_i)$.

The complete conditions for identification involve rank-order conditions on several matrices. For a full treatment, see Theil (1971) or Greene (2012, 331–334).

---

Henri Theil (1924–2000) was born in Amsterdam and awarded a PhD in 1951 by the University of Amsterdam. He researched and taught econometric theory, statistics, microeconomics, macroeconomic modeling, and economic forecasting, and policy at (now) Erasmus University Rotterdam, the University of Chicago, and the University of Florida. Theil’s many specific contributions include work on 2SLS and 3SLS, inequality and concentration, and consumer demand.

---

 Stored results

`reg3` stores the following in `e()`:

Scalars

- $e(N)$: number of observations
- $e(k)$: number of parameters
- $e(k_{eq})$: number of equations in `e(b)`
- $e(mss_{#})$: model sum of squares for equation $#$
- $e(df_{m_{#}})$: model degrees of freedom for equation $#$
- $e(rss_{#})$: residual sum of squares for equation $#$
- $e(df_{r})$: residual degrees of freedom (small)
- $e(r^2_{#})$: $R^2$-squared for equation $#$
- $e(F_{#})$: $F$ statistic for equation $#$ (small)
- $e(rmse_{#})$: root mean squared error for equation $#$
- $e(dfk2_{adj})$: divisor used with VCE when dfk2 specified
- $e(ll)$: log likelihood
- $e(chi2_{#})$: $\chi^2$ for equation $#$
- $e(p_{#})$: significance for equation $#$
- $e(cons_{#})$: 1 when equation $#$ has a constant, 0 otherwise
- $e(rank)$: rank of $e(V)$
- $e(ic)$: number of iterations
Methods and formulas

The most concise way to represent a system of equations for 3SLS requires thinking of the individual equations and their associated data as being stacked. `reg3` does not expect the data in this format, but it is a convenient shorthand. The system could then be formulated as

\[
\begin{bmatrix}
y_1 \\
y_2 \\
\vdots \\
y_M
\end{bmatrix}
= 
\begin{bmatrix}
Z_1 & 0 & \ldots & 0 \\
0 & Z_2 & \ldots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \ldots & Z_M
\end{bmatrix}
\begin{bmatrix}
\beta_1 \\
\beta_2 \\
\vdots \\
\beta_M
\end{bmatrix}
+ 
\begin{bmatrix}
\epsilon_1 \\
\epsilon_2 \\
\vdots \\
\epsilon_M
\end{bmatrix}
\]

In full matrix notation, this is just

\[y = ZB + \epsilon\]

The \(Z\) elements in these matrices represent both the endogenous and the exogenous right-hand-side variables in the equations.

Also assume that there will be correlation between the disturbances of the equations so that

\[E(\epsilon \epsilon') = \Sigma\]

where the disturbances are further assumed to have an expected value of 0; \(E(\epsilon) = 0\).

The first stage of 3SLS regression requires developing instrumented values for the endogenous variables in the system. These values can be derived as the predictions from a linear regression of each endogenous regressor on all exogenous variables in the system or, more succinctly, as the projection of each regressor through the projection matrix of all exogenous variables onto the regressors. Designating the set of all exogenous variables as \(X\) results in
\[ \hat{z}_i = X(X'X)^{-1}X'z_i \] for each \( i \)

Taken collectively, these \( \hat{Z} \) contain the instrumented values for all the regressors. They take on the actual values for the exogenous variables and first-stage predictions for the endogenous variables. Given these instrumented variables, a generalized least squares (GLS) or Aitken (1935) estimator can be formed for the parameters of the system

\[ \hat{B} = \left( \hat{Z}'(\Sigma^{-1} \otimes I)\hat{Z} \right)^{-1} \hat{Z}'(\Sigma^{-1} \otimes I)y \]

All that remains is to obtain a consistent estimator for \( \Sigma \). This estimate can be formed from the residuals of 2SLS estimates of each equation in the system. Alternately, and identically, the residuals can be computed from the estimates formed by taking \( \Sigma \) to be an identity matrix. This maintains the full system of coefficients and allows constraints to be applied when the residuals are computed.

If we take \( E \) to be the matrix of residuals from these estimates, a consistent estimate of \( \Sigma \) is

\[ \hat{\Sigma} = \frac{E'E}{n} \]

where \( n \) is the number of observations in the sample. An alternative divisor for this estimate can be obtained with the \texttt{dfk} option as outlined under options.

With the estimate of \( \hat{\Sigma} \) placed into the GLS estimating equation,

\[ \hat{B} = \left( \hat{Z}'(\hat{\Sigma}^{-1} \otimes I)\hat{Z} \right)^{-1} \hat{Z}'(\hat{\Sigma}^{-1} \otimes I)y \]

is the 3SLS estimates of the system parameters.

The asymptotic variance–covariance matrix of the estimator is just the standard formulation for a GLS estimator

\[ V_{\hat{B}} = \left( \hat{Z}'(\hat{\Sigma}^{-1} \otimes I)\hat{Z} \right)^{-1} \]

Iterated 3SLS estimates can be obtained by computing the residuals from the three-stage parameter estimates, using these to formulate a new \( \hat{\Sigma} \), and recomputing the parameter estimates. This process is repeated until the estimates \( \hat{B} \) converge—if they converge. Convergence is not guaranteed. When estimating a system by SURE, these iterated estimates will be the maximum likelihood estimates for the system. The iterated solution can also be used to produce estimates that are invariant to choice of system and restriction parameterization for many linear systems under full 3SLS.

The exposition above follows the parallel developments in Greene (2012) and Davidson and MacKinnon (1993).

<td>residuals</td>
</tr>
<tr>
<td>difference</td>
<td>difference between the linear predictions of two equations</td>
</tr>
<tr>
<td>stddp</td>
<td>standard error of the difference in linear predictions</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ... if wanted only for the estimation sample.`
Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

equation(eqno[, eqno]) specifies to which equation you are referring.

equation() is filled in with one eqno for the xb, stdp, and residuals options. equation(#1) would mean the calculation is to be made for the first equation, equation(#2) would mean the second, and so on. You could also refer to the equations by their names. equation(income) would refer to the equation named income and equation(hours) to the equation named hours.

If you do not specify equation(), results are the same as if you specified equation(#1).

difference and stddp refer to between-equation concepts. To use these options, you must specify two equations, for example, equation(#1,#2) or equation(income,hours). When two equations must be specified, equation() is required.

xb, the default, calculates the linear prediction (fitted values)—the prediction of $x_jb$ for the specified equation.

stdp calculates the standard error of the prediction for the specified equation. It can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

residuals calculates the residuals.

difference calculates the difference between the linear predictions of two equations in the system. With equation(#1,#2), difference computes the prediction of equation(#1) minus the prediction of equation(#2).

stddp is allowed only after you have previously fit a multiple-equation model. The standard error of the difference in linear predictions ($x_{1j}b - x_{2j}b$) between equations 1 and 2 is calculated.

For more information on using predict after multiple-equation estimation commands, see [R] predict.

Remarks and examples

Example 1: Using predict

In example 2 of [R] reg3, we fit a simple supply-and-demand model. Here we obtain the fitted supply and demand curves assuming that the exogenous regressors equal their sample means. We first replace each of the three exogenous regressors with their sample means, then we call predict to obtain the predictions.

. use http://www.stata-press.com/data/r13/supDem
. global demand "(qDemand: quantity price pcompete income)"
. global supply "(qSupply: quantity price praw)"
. reg3 $demand $supply, endog(price)
(output omitted)
. summarize pcompete, meanonly
. replace pcompete = r(mean)
(49 real changes made)
As we would expect based on economic theory, the demand curve slopes downward while the supply curve slopes upward. With the exogenous variables at their mean levels, the equilibrium price and quantity are slightly less than 33 and 13, respectively.

Example 2: Obtaining forecasts

In example 3 of [R] reg3, we fit Klein’s (1950) model of the U.S. economy. That model includes three stochastic equations we fit using reg3 as well as four identities. Here we briefly illustrate how the forecast command can be used to obtain forecasts for all the endogenous variables in the model. For a more detailed discussion of how to forecast with this model, see [TS] forecast.

In Stata, we type

```
use http://www.stata-press.com/data/r13/klein2, clear
reg3 (c p L.p w) (i p L.p L.k) (wp y L.y yr), endog(w p y) exog(t wg g)
(output omitted)
estimates store kleineqs
forecast create kleinmodel
Forecast model kleinmodel started.
forecast estimates kleineqs
```

Added estimation results from reg3.
Forecast model kleinmodel now contains 3 endogenous variables.
. forecast identity \( y = c + i + g \)
  Forecast model kleinmodel now contains 4 endogenous variables.

. forecast identity \( p = y - t - wp \)
  Forecast model kleinmodel now contains 5 endogenous variables.

. forecast identity \( k = L.k + i \)
  Forecast model kleinmodel now contains 6 endogenous variables.

. forecast identity \( w = wg + wp \)
  Forecast model kleinmodel now contains 7 endogenous variables.

. forecast solve, begin(1937)
Computing dynamic forecasts for model kleinmodel.

Starting period: 1937
Ending period: 1941
Forecast prefix: f_

1937: ...........................................
1938: ...........................................
1939: ...........................................
1940: ...........................................
1941: ...........................................

Forecast 7 variables spanning 5 periods.

Here we have obtained dynamic forecasts for our 7 endogenous variables beginning in 1937. By default, the variables containing the forecasts begin with the prefix \( f_\). Next we plot the forecast and actual values of consumption:

. tsline c f_c

![Graph showing consumption and forecasted consumption](image)

For more information about producing forecasts, see [TS] forecast.

Methods and formulas

The computational formulas for the statistics produced by predict can be found in [R] predict and [R] regress postestimation.

_depname(varname)_       | substitute dependent variable name; programmer’s option
display_options          | control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

_noheader_               | suppress output header
_notable_                | suppress coefficient table
_plus_                   | make table extendable
_mse1_                   | force mean squared error to 1
_coeflegend_             | display legend instead of statistics
```

_indepvars_ may contain factor variables; see [U] 11.4.3 Factor variables.

_depvar_ and _indepvars_ may contain time-series operators; see [U] 11.4.4 Time-series varlists.

_bootstrap_, by, _fp_, _jackknife_, _mfp_, _mi estimate_, _nestreg_, _rolling_, _statsby_, _stepwise_, and _svy_ are allowed; see [U] 11.1.10 Prefix commands.

_vce(bootstrap)_ and _vce(jackknife)_ are not allowed with the _mi estimate_ prefix; see [MI] _mi estimate_.

Weights are not allowed with the _bootstrap_ prefix; see [R] _bootstrap_.

_aweights_ are not allowed with the _jackknife_ prefix; see [R] _jackknife_.

_hascons_, _tsscons_, _vce(),_ _beta_, _noheader_, _notable_, _plus_, _depname(),_ _mse1_, and weights are not allowed with the _svy_ prefix; see [SVY] _svy_.

_aweights_, _fweights_, _iweights_, and _pweights_ are allowed; see [U] 11.1.6 weight.

_noheader_, _notable_, _plus_, _mse1_, and _coeflegend_ do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
**regress** fits a model of *depvar* on *indepvars* using linear regression.

Here is a short list of other regression commands that may be of interest. See `help estimation commands` for a complete list.

Options

---

**Model**

- **noconstant**: see [R] estimation options.  
  
  *hascons* indicates that a user-defined constant or its equivalent is specified among the independent variables in *indepvars*. Some caution is recommended when specifying this option, as resulting estimates may not be as accurate as they otherwise would be. Use of this option requires “sweeping” the constant last, so the moment matrix must be accumulated in absolute rather than deviation form. This option may be safely specified when the means of the dependent and independent variables are all reasonable and there is not much collinearity between the independent variables. The best procedure is to view *hascons* as a reporting option—estimate with and without *hascons* and verify that the coefficients and standard errors of the variables not affected by the identity of the constant are unchanged.

- **tsscons**: forces the total sum of squares to be computed as though the model has a constant, that is, as deviations from the mean of the dependent variable. This is a rarely used option that has an effect only when specified with *noconstant*. It affects the total sum of squares and all results derived from the total sum of squares.

---

**SE/Robust**

-vce(*vcetype*) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (*ols*), that are robust to some kinds of misspecification (*robust*), that allow for intragroup correlation (*cluster clustvar*), and that use bootstrap or jackknife methods (*bootstrap*, *jackknife*); see [R] vce option.

- **vce(ols)**, the default, uses the standard variance estimator for ordinary least-squares regression. *regress* also allows the following:
  
  - **vce(hc2)** and **vce(hc3)** specify an alternative bias correction for the robust variance calculation. *vce(hc2)* and *vce(hc3)* may not be specified with *svy* prefix. In the unclustered case, *vce(robust)* uses \( \hat{\sigma}_j^2 = \{n/(n-k)\}u_j^2 \) as an estimate of the variance of the \( j \)th observation, where \( u_j \) is the calculated residual and \( n/(n-k) \) is included to improve the overall estimate’s small-sample properties.
  
  - *vce(hc2)* instead uses \( u_j^2/(1-h_{jj}) \) as the observation’s variance estimate, where \( h_{jj} \) is the diagonal element of the hat (projection) matrix. This estimate is unbiased if the model really is homoskedastic. *vce(hc2)* tends to produce slightly more conservative confidence intervals.
  
  - *vce(hc3)* uses \( u_j^2/(1-h_{jj})^2 \) as suggested by Davidson and MacKinnon (1993), who report that this method tends to produce better results when the model really is heteroskedastic. *vce(hc3)* produces confidence intervals that tend to be even more conservative.

  See Davidson and MacKinnon (1993, 554–556) and Angrist and Pischke (2009, 294–308) for more discussion on these two bias corrections.

---

**Reporting**

- **level(#)**: see [R] estimation options.

  *beta* asks that standardized beta coefficients be reported instead of confidence intervals. The beta coefficients are the regression coefficients obtained by first standardizing all variables to have a mean of 0 and a standard deviation of 1. *beta* may not be specified with *vce(cluster clustvar)* or the *svy* prefix.
eform() is used only in programs and ado-files that use regress to fit models other than linear regression. eform() specifies that the coefficient table be displayed in exponentiated form as defined in [R] maximize and that string be used to label the exponentiated coefficients in the table.

depname(varname) is used only in programs and ado-files that use regress to fit models other than linear regression. depname() may be specified only at estimation time. varname is recorded as the identity of the dependent variable, even though the estimates are calculated using depvar. This method affects the labeling of the output—not the results calculated—but could affect subsequent calculations made by predict, where the residual would be calculated as deviations from varname rather than depvar. depname() is most typically used when depvar is a temporary variable (see [P] macro) used as a proxy for varname.

depname() is not allowed with the svy prefix.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapping(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] estimation options.

The following options are available with regress but are not shown in the dialog box:

noheader suppresses the display of the ANOVA table and summary statistics at the top of the output; only the coefficient table is displayed. This option is often used in programs and ado-files.

notable suppresses display of the coefficient table.

plus specifies that the output table be made extendable. This option is often used in programs and ado-files.

mse1 is used only in programs and ado-files that use regress to fit models other than linear regression and is not allowed with the svy prefix. mse1 sets the mean squared error to 1, forcing the variance–covariance matrix of the estimators to be \( (X'DX)^{-1} \) (see Methods and formulas below) and affecting calculated standard errors. Degrees of freedom for \( t \) statistics is calculated as \( n \) rather than \( n - k \).

coefflegend; see [R] estimation options.

Remarks and examples

Remarks are presented under the following headings:

Ordinary least squares
Treatment of the constant
Robust standard errors
Weighted regression
Instrumental variables and two-stage least-squares regression
Video example

regress performs linear regression, including ordinary least squares and weighted least squares. For a general discussion of linear regression, see Draper and Smith (1998), Greene (2012), or Kmenta (1997).

See Wooldridge (2013) for an excellent treatment of estimation, inference, interpretation, and specification testing in linear regression models. This presentation stands out for its clarification of the statistical issues, as opposed to the algebraic issues. See Wooldridge (2010, chap. 4) for a more advanced discussion along the same lines.

Chatterjee and Hadi (2012) explain regression analysis by using examples containing typical problems that you might encounter when performing exploratory data analysis. We also recommend Weisberg (2005), who emphasizes the importance of the assumptions of linear regression and problems resulting from these assumptions. Becketti (2013) discusses regression analysis with an emphasis on time-series data. Angrist and Pischke (2009) approach regression as a tool for exploring relationships, estimating treatment effects, and providing answers to public policy questions. For a discussion of model-selection techniques and exploratory data analysis, see Mosteller and Tukey (1977). For a mathematically rigorous treatment, see Peracchi (2001, chap. 6). Finally, see Plackett (1972) if you are interested in the history of regression. Least squares, which dates back to the 1790s, was discovered independently by Legendre and Gauss.

**Ordinary least squares**

> **Example 1: Basic linear regression**

Suppose that we have data on the mileage rating and weight of 74 automobiles. The variables in our data are mpg, weight, and foreign. The last variable assumes the value 1 for foreign and 0 for domestic automobiles. We wish to fit the model

\[
mpg = \beta_0 + \beta_1 \text{weight} + \beta_2 \text{foreign} + \epsilon
\]

This model can be fit with `regress` by typing

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. regress mpg weight foreign
```

```
              Source |     SS      df    MS
-------------+-----------------------------
        Model | 1619.29 2  809.64
        Residual | 824.17 71  11.61
              Total | 2443.46 73  33.47
              Number of obs = 74
                        F( 2, 71) = 69.75
                        Prob > F = 0.0000
                        R-squared = 0.6627
                        Adj R-squared = 0.6532
                        Root MSE = 3.41

-------------+----------------------------------
            mpg |     Coef.   Std. Err.      t    P>|t|     [95% Conf. Interval]

-------------+----------------------------------
```

`regress` produces a variety of summary statistics along with the table of regression coefficients. At the upper left, `regress` reports an analysis-of-variance (ANOVA) table. The column headings SS, df, and MS stand for “sum of squares”, “degrees of freedom”, and “mean square”, respectively. In this example, the total sum of squares is 2,443.5: 1,619.3 accounted for by the model and 824.2 left unexplained. Because the regression included a constant, the total sum reflects the sum after removal of means, as does the sum of squares due to the model. The table also reveals that there are 73 total degrees of freedom (counted as 74 observations less 1 for the mean removal), of which 2 are consumed by the model, leaving 71 for the residual.
To the right of the ANOVA table are presented other summary statistics. The $F$ statistic associated with the ANOVA table is 69.75. The statistic has 2 numerator and 71 denominator degrees of freedom. The $F$ statistic tests the hypothesis that all coefficients excluding the constant are zero. The chance of observing an $F$ statistic that large or larger is reported as 0.0000, which is Stata’s way of indicating a number smaller than 0.00005. The $R$-squared ($R^2$) for the regression is 0.6627, and the $R$-squared adjusted for degrees of freedom ($R^2_a$) is 0.6532. The root mean squared error, labeled Root MSE, is 3.4071. It is the square root of the mean squared error reported for the residual in the ANOVA table.

Finally, Stata produces a table of the estimated coefficients. The first line of the table indicates that the left-hand-side variable is mpg. Thereafter follow the estimated coefficients. Our fitted model is

$$\text{mpg\_hat} = 41.68 - 0.0066 \text{weight} - 1.65 \text{foreign}$$

Reported to the right of the coefficients in the output are the standard errors. For instance, the standard error for the coefficient on weight is 0.0006371. The corresponding $t$ statistic is $-10.34$, which has a two-sided significance level of 0.000. This number indicates that the significance is less than 0.0005. The 95% confidence interval for the coefficient is $[-0.0079, -0.0053]$.

**Example 2: Transforming the dependent variable**

If we had a graph comparing mpg with weight, we would notice that the relationship is distinctly nonlinear. This is to be expected because energy usage per distance should increase linearly with weight, but mpg is measuring distance per energy used. We could obtain a better model by generating a new variable measuring the number of gallons used per 100 miles ($\text{gp100m}$) and then using this new variable in our model:

$$\text{gp100m} = \beta_0 + \beta_1 \text{weight} + \beta_2 \text{foreign} + \epsilon$$

We can now fit this model:

```
. generate gp100m = 100/mpg
. regress gp100m weight foreign
```

| foreign| .6220535 | .1997381 | 3.11 | 0.003 | .2237871 1.02032 |
| _cons  | -.0734839 | .4019932 | -0.18 | 0.855 | -.8750354 .7280677 |

Fitting the physically reasonable model increases our $R$-squared to 0.7625.
Example 3: Obtaining beta coefficients

`regress` shares the features of all estimation commands. Among other things, this means that after running a regression, we can use `test` to test hypotheses about the coefficients, `estat vce` to examine the covariance matrix of the estimators, and `predict` to obtain predicted values, residuals, and influence statistics. See [U] 20 Estimation and postestimation commands. Options that affect how estimates are displayed, such as `beta` or `level()`, can be used when replaying results.

Suppose that we meant to specify the `beta` option to obtain beta coefficients (regression coefficients normalized by the ratio of the standard deviation of the regressor to the standard deviation of the dependent variable). Even though we forgot, we can specify the option now:

```
. regress, beta
```

| _cons  | -.0734839 | .4019932  | -0.18| 0.855| .         |

Treatment of the constant

By default, `regress` includes an intercept (constant) term in the model. The `noconstant` option suppresses it, and the `hascons` option tells `regress` that the model already has one.

Example 4: Suppressing the constant term

We wish to fit a regression of the `weight` of an automobile against its `length`, and we wish to impose the constraint that the weight is zero when the length is zero.

If we simply type `regress weight length`, we are fitting the model

\[
\text{weight} = \beta_0 + \beta_1 \text{length} + \epsilon
\]

Here a `length` of zero corresponds to a `weight` of \(\beta_0\). We want to force \(\beta_0\) to be zero or, equivalently, estimate an equation that does not include an intercept:

\[
\text{weight} = \beta_1 \text{length} + \epsilon
\]
We do this by specifying the `noconstant` option:

```
. regress weight length, noconstant
```

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>703869302</td>
<td>1</td>
<td>703869302</td>
</tr>
<tr>
<td>Residual</td>
<td>14892897.8</td>
<td>73</td>
<td>204012.299</td>
</tr>
<tr>
<td>Total</td>
<td>718762200</td>
<td>74</td>
<td>9713002.7</td>
</tr>
</tbody>
</table>

Number of obs = 74

F( 1, 73) = 3450.13
Prob > F = 0.0000
R-squared = 0.9793
Adj R-squared = 0.9790
Root MSE = 451.68

| length | Coef. | Std. Err. | t    | P>|t| | [95% Conf. Interval] |
|--------|-------|-----------|------|-----|----------------------|
|        | 16.29829 | .2774752 | 58.74 | 0.000 | 15.74528 - 16.8513 |

In our data, `length` is measured in inches and `weight` in pounds. We discover that each inch of length adds 16 pounds to the weight.

Sometimes there is no need for Stata to include a constant term in the model. Most commonly, this occurs when the model contains a set of mutually exclusive indicator variables. `hascons` is a variation of the `noconstant` option—it tells Stata not to add a constant to the regression because the regression specification already has one, either directly or indirectly.

For instance, we now refit our model of `weight` as a function of `length` and include separate constants for foreign and domestic cars by specifying `bn.foreign`. `bn.foreign` is factor-variable notation for “no base for foreign” or “include all levels of variable foreign in the model”; see [U] 11.4.3 Factor variables.

```
. regress weight length bn.foreign, hascons
```

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>39647744.7</td>
<td>2</td>
<td>19823872.3</td>
</tr>
<tr>
<td>Residual</td>
<td>4446433.7</td>
<td>71</td>
<td>62625.8268</td>
</tr>
<tr>
<td>Total</td>
<td>44094178.4</td>
<td>73</td>
<td>604029.841</td>
</tr>
</tbody>
</table>

Number of obs = 74

F( 2, 71) = 316.54
Prob > F = 0.0000
R-squared = 0.8992
Adj R-squared = 0.8963
Root MSE = 250.25

| weight | Coef. | Std. Err. | t    | P>|t| | [95% Conf. Interval] |
|--------|-------|-----------|------|-----|----------------------|
| length | 31.44455 | 1.601234 | 19.64 | 0.000 | 28.25178 - 34.63732 |
| foreign | Domest | -2850.25 | 315.9691 | -9.02 | 0.000 | -3480.274 -2220.225 |
|        | Foreign | -2983.927 | 275.1041 | -10.85 | 0.000 | -3532.469 -2435.385 |
Technical note

There is a subtle distinction between the `hascons` and `noconstant` options. We can most easily reveal it by refitting the last regression, specifying `noconstant` rather than `hascons`:

```
. regress weight length bn.foreign, noconstant
```

```
Source | SS   | df  | MS
-------|------|-----|-----
Model  | 714315766 | 3 | 238105255
Residual | 4446433.7 | 71 | 62625.8268
Total   | 718762200 | 74 | 9713002.7
```

```
F(  3,  71) = 3802.03
Prob > F = 0.0000
R-squared = 0.9938
Adj R-squared = 0.9936
Root MSE = 250.25
```

```
weight | Coef. | Std. Err. | t     | P>|t|   | [95% Conf. Interval]
-------|------|-----------|-------|------|---------------------
length | 31.44455 | 1.601234 | 19.64 | 0.000 | 28.25178 - 34.63732
foreign | -2850.25 | 315.9691 | -9.02 | 0.000 | -3480.274 - -2220.225
Domestic | -2983.927 | 275.1041 | -10.85 | 0.000 | -3532.469 - -2435.385
```

Comparing this output with that produced by the previous `regress` command, we see that they are almost, but not quite, identical. The parameter estimates and their associated statistics—the second half of the output—are identical. The overall summary statistics and the ANOVA table—the first half of the output—are different, however.

In the first case, the $R^2$ is shown as 0.8992; here it is shown as 0.9938. In the first case, the $F$ statistic is 316.54; now it is 3,802.03. The numerator degrees of freedom is different as well. In the first case, the numerator degrees of freedom is 2; now the degrees of freedom is 3. Which is correct?

Both are. Specifying the `hascons` option causes `regress` to adjust the ANOVA table and its associated statistics for the explanatory power of the constant. The regression in effect has a constant; it is just written in such a way that a separate constant is unnecessary. No such adjustment is made with the `noconstant` option.

Technical note

When the `hascons` option is specified, `regress` checks to make sure that the model does in fact have a constant term. If `regress` cannot find a constant term, it automatically adds one. Fitting a model of `weight` on `length` and specifying the `hascons` option, we obtain

```
. regress weight length, hascons
(note: hascons false)
```

```
Source | SS   | df  | MS
-------|------|-----|-----
Model  | 39461306.8 | 1 | 39461306.8
Residual | 4632871.55 | 72 | 64345.4382
Total   | 44094178.4 | 73 | 604029.841
```

```
F(  1,  72) = 613.27
Prob > F = 0.0000
R-squared = 0.8949
Adj R-squared = 0.8935
Root MSE = 253.66
```

```
weight | Coef. | Std. Err. | t     | P>|t|   | [95% Conf. Interval]
-------|------|-----------|-------|------|---------------------
length | 33.01988 | 1.333364 | 24.76 | 0.000 | 30.36187 - 35.67789
_cons  | -3186.047 | 252.3113 | -12.63 | 0.000 | -3689.02 - -2683.073
```

```
Even though we specified hascons, *regress* included a constant, anyway. It also added a note to our output: “note: hascons false”.

### Technical note

Even if the model specification effectively includes a constant term, we need not specify the `hascons` option. *regress* is always on the lookout for collinear variables and omits them from the model. For instance,

```
. regress weight length bn.foreign
   note: 1.foreign omitted because of collinearity
```

### Robust standard errors

*regress* with the `vce(robust)` option substitutes a robust variance matrix calculation for the conventional calculation, or if `vce(cluster clustvar)` is specified, allows relaxing the assumption of independence within groups. How this method works is explained in [U] 20.21 Obtaining robust variance estimates. Below we show how well this approach works.

#### Example 5: Heteroskedasticity and robust standard errors

Specifying the `vce(robust)` option is equivalent to requesting White-corrected standard errors in the presence of heteroskedasticity. We use the automobile data and, in the process of looking at the energy efficiency of cars, analyze a variable with considerable heteroskedasticity.

We will examine the amount of energy—measured in gallons of gasoline—that the cars in the data need to move 1,000 pounds of their weight 100 miles. We are going to examine the relative efficiency of foreign and domestic cars.

```
. gen gpmw = ((1/mpg)/weight)*100*1000
. summarize gpmw

Variable | Obs | Mean    | Std. Dev. | Min | Max |
---------|-----|---------|-----------|-----|-----|
   gpmw   | 74  | 1.682184 |  .2426311 | 1.09553 | 2.30521 |
```

In these data, the engines consume between 1.10 and 2.31 gallons of gas to move 1,000 pounds of the car’s weight 100 miles. If we ran a regression with conventional standard errors of `gpmw` on `foreign`, we would obtain...
regress — Linear regression

```
. regress gpmw foreign

Source | SS      | df | MS
---|---------|----|---
Model  | .936705572 | 1  | .936705572
Residual | 3.36079459 | 72 | .046677703
Total   | 4.29750017 | 73 | .058869865

F( 1, 72) = 20.07
Prob > F = 0.0000
R-squared = 0.2180
Adj R-squared = 0.2071
Root MSE = .21605

foreign   | Coef.     | Std. Err. | t     | P>|t|    | [95% Conf. Interval]
---|-----------|------------|------|-------|-----------------------
   .2461526 | .0549487  | 4.48      |     | 0.000 | .1366143 , .3556909
_cons     | 1.609004  | .0299608  | 53.70| 0.000 | 1.549278 , 1.66873
```

regress with the `vce(robust)` option, on the other hand, reports

```
. regress gpmw foreign, vce(robust)

Number of obs = 74
F( 1, 72) = 13.13
Prob > F = 0.0005
R-squared = 0.2180
Root MSE = .21605

foreign   | Coef.     | Std. Err. | t     | P>|t|     | [95% Conf. Interval]
---|-----------|------------|------|--------|-----------------------
   .2461526 | .0679238  | 3.62      |     | 0.001  | .1107489 , .3815563
_cons     | 1.609004  | .0234535  | 68.60| 0.000  | 1.56225 , 1.655758
```

The point estimates are the same (foreign cars need one-quarter gallon more gas), but the standard errors differ by roughly 20%. Conventional regression reports the 95% confidence interval as [0.14, 0.36], whereas the robust standard errors make the interval [0.11, 0.38].

Which is right? Notice that gpmw is a variable with considerable heteroskedasticity:

```
. tabulate foreign, summarize(gpmw)

Summary of gpmw

<table>
<thead>
<tr>
<th>Car type</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Freq.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Domestic</td>
<td>1.6090039</td>
<td>.16845182</td>
<td>52</td>
</tr>
<tr>
<td>Foreign</td>
<td>1.8551565</td>
<td>.30186861</td>
<td>22</td>
</tr>
<tr>
<td>Total</td>
<td>1.6821844</td>
<td>.24263113</td>
<td>74</td>
</tr>
</tbody>
</table>
```

Thus here we favor the robust standard errors. In [U] 20.21 Obtaining robust variance estimates, we show another example using linear regression where it makes little difference whether we specify `vce(robust)`. The linear-regression assumptions were true, and we obtained nearly linear-regression results. The advantage of the robust estimate is that in neither case did we have to check assumptions.

Technical note

`regress` purposefully suppresses displaying the ANOVA table when `vce(robust)` is specified, as it is no longer appropriate in a statistical sense, even though, mechanically, the numbers would be unchanged. That is, sums of squares remain unchanged, but the meaning of those sums is no longer relevant. The $F$ statistic, for instance, is no longer based on sums of squares; it becomes a Wald test based on the robustly estimated variance matrix. Nevertheless, `regress` continues to report the $R^2$.
and the root MSE even though both numbers are based on sums of squares and are, strictly speaking, irrelevant. In this, the root MSE is more in violation of the spirit of the robust estimator than is $R^2$. As a goodness-of-fit statistic, $R^2$ is still fine; just do not use it in formulas to obtain $F$ statistics because those formulas no longer apply. The root MSE is valid in a literal sense—it is the square root of the mean squared error, but it is no longer an estimate of $\sigma$ because there is no single $\sigma$; the variance of the residual varies observation by observation.

Example 6: Alternative robust standard errors

The `vce(hc2)` and `vce(hc3)` options modify the robust variance calculation. In the context of linear regression without clustering, the idea behind the robust calculation is somehow to measure $\sigma_j^2$, the variance of the residual associated with the $j$th observation, and then to use that estimate to improve the estimated variance of $\hat{\beta}$. Because residuals have (theoretically and practically) mean 0, one estimate of $\sigma_j^2$ is the observation’s squared residual itself—$u_j^2$. A finite-sample correction could improve that by multiplying $u_j^2$ by $n/(n-k)$, and, as a matter of fact, `vce(robust)` uses \{\(n/(n-k)\)\}.$u_j^2$ as its estimate of the residual’s variance.

`vce(hc2)` and `vce(hc3)` use alternative estimators of the observation-specific variances. For instance, if the residuals are homoskedastic, we can show that the expected value of $u_j^2$ is $\sigma_j^2(1-h_{jj})$, where $h_{jj}$ is the $j$th diagonal element of the projection (hat) matrix. $h_{jj}$ has average value $k/n$, so $1-h_{jj}$ has average value $1-k/n = (n-k)/n$. Thus the default robust estimator $\hat{\sigma}_j = \{n/(n-k)\}u_j^2$ amounts to dividing $u_j^2$ by the average of the expectation.

`vce(hc2)` divides $u_j^2$ by $1-h_{jj}$ itself, so it should yield better estimates if the residuals really are homoskedastic. `vce(hc3)` divides $u_j^2$ by $(1-h_{jj})^2$ and has no such clean interpretation. Davidson and MacKinnon (1993) show that $u_j^2/(1-h_{jj})^2$ approximates a more complicated estimator that they obtain by jackknifing (MacKinnon and White 1985). Angrist and Pischke (2009) also illustrate the relative merits of these adjustments.

Here are the results of refitting our efficiency model using `vce(hc2)` and `vce(hc3)`: 

```
. regress gpmw foreign, vce(hc2)
Linear regression
Number of obs = 74

Example 7: Standard errors for clustered data

The `vce(cluster clustvar)` option relaxes the assumption of independence. Below we have 28,534 observations on 4,711 women aged 14–46 years. Data were collected on these women between 1968 and 1988. We are going to fit a classic earnings model, and we begin by ignoring that each woman appears an average of 6.057 times in the data.

. use http://www.stata-press.com/data/r13/regsmpl, clear
(NLS Women 14-26 in 1968)
. regress ln_wage age c.age#c.age tenure

| ln_wage | Coef. | Std. Err. | t    | P>|t|  | [95% Conf. Interval] |
|---------|-------|-----------|------|------|---------------------|
| age     | .0752172  | .0034736  | 21.65| 0.000 | .0684088 .0820257 |
| c.age#c.age | -.0010851 | .0000575  | -18.86| 0.000 | -.0011979 -.0009724 |
| tenure  | .0390877  | .0007743  | 50.48| 0.000 | .0375699 .0406054 |
| _cons  | .3339821  | .0504413  | 6.62 | 0.000 | .2351148 .4328495 |

The number of observations in our model is 28,101 because Stata drops observations that have a missing value for one or more of the variables in the model. We can be reasonably certain that the standard errors reported above are meaningless. Without a doubt, a woman with higher-than-average wages in one year typically has higher-than-average wages in other years, and so the residuals are not independent. One way to deal with this would be to fit a random-effects model—and we are going to do that—but first we fit the model using `regress` specifying `vce(cluster id)`, which treats only observations with different person ids as truly independent:
For comparison, we focus on the tenure coefficient, which in economics jargon can be interpreted as the rate of return for keeping your job. The 95% confidence interval we previously estimated—an interval we do not believe—is \([0.038, 0.041]\). The robust interval is twice as wide, being \([0.036, 0.042]\).

As we said, one correct way to fit this model is by random-effects regression. Here is the random-effects results:

```
. xtreg ln_wage age c.age#c.age tenure, re
```

```
Random-effects GLS regression Number of obs = 28101
Group variable: idcode Number of groups = 4699
R-sq: within = 0.1370 Obs per group: min = 1
between = 0.2154 avg = 6.0
overall = 0.1608 max = 15
Wald chi2(3) = 4717.05
corr(u_i, X) = 0 (assumed) Prob > chi2 = 0.0000

| ln_wage | Coef. | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|---------|-------|-----------|-------|------|---------------------|
| age     | .0568296 | .0026958 | 21.08 | 0.000 | .0515459 - .0621132 |
| c.age#c.age | -.0007566 | .0000447 | -16.93 | 0.000 | -.0008844 - .000669 |
| tenure  | .0260135 | .0007477 | 34.79 | 0.000 | .0245481 - .0274789 |
| _cons   | .6136792 | .0394611 | 15.55 | 0.000 | .5363368 - .6910216 |

Robust regression estimated the 95% interval \([0.036, 0.042]\), and `xtreg` (see [XT] xtreg) estimates \([0.025, 0.027]\). Which is better? The random-effects regression estimator assumes a lot. We can check some of these assumptions by performing a Hausman test. Using `estimates` (see [R] estimates store), we store the random-effects estimation results, and then we run the required fixed-effects regression to perform the test.
regress — Linear regression

We estimate the following regression:

```
xtreg ln_wage age c.age#c.age tenure, fe
```

Fixed-effects (within) regression

F test that all u_i=0:  F(4698, 23399) = 7.98  Prob > F = 0.0000

The Hausman test casts grave suspicions on the random-effects model we just fit, so we should be careful in interpreting those results.

Meanwhile, our robust regression results still stand, as long as we are careful about the interpretation. The correct interpretation is that, if the data collection were repeated (on women sampled the same way as in the original sample), and if we were to refit the model, 95% of the time we would expect the estimated coefficient on tenure to be in the range [0.036, 0.042].

Even with robust regression, we must be careful about going beyond that statement. Here the Hausman test is probably picking up something that differs within and between person, which would cast doubt on our robust regression model in terms of interpreting [0.036, 0.042] to contain the rate of return for keeping a job, economywide, for all women, without exception.
**Weighted regression**

`regress` can perform weighted and unweighted regression. We indicate the weight by specifying the `[weight]` qualifier. By default, `regress` assumes analytic weights; see the technical note below.

**Example 8: Using means as regression variables**

We have census data recording the death rate (`drate`) and median age (`medage`) for each state. The data also record the region of the country in which each state is located and the overall population of the state:

```
. use http://www.stata-press.com/data/r13/census9
(1980 Census data by state)
. describe
    obs:     50  1980 Census data by state
    vars:      6  6 Apr 2013 15:43
    size:   1,450

storage  display variable name   type   format   value label  variable label
          variable
state     str14  %-14s State
state2    str2   %-2s   Two-letter state abbreviation
drate     float  %9.0g Death Rate
pop       long   %12.0gc Population
medage    float  %9.2f Median age
region    byte   %-8.0g cenreg Census region
```

Sorted by:

We can use factor variables to include dummy variables for region. Because the variables in the regression reflect means rather than individual observations, the appropriate method of estimation is analytically weighted least squares (Davidson and MacKinnon 2004, 261–262), where the weight is total population:

```
. regress drate medage i.region [w=pop]
(analytic weights assumed)
(sum of wgt is 2.2591e+08)
```

```
Source | SS       df       MS

```

To weight the regression by population, we added the qualifier `[w=pop]` to the end of the `regress` command. Our qualifier was vague (we did not say `[aweight=pop]`), but unless told otherwise, Stata
assumes analytic weights for `regress`. Stata informed us that the sum of the weight is $2.2591 \times 10^8$; there were approximately 226 million people residing in the United States according to our 1980 data.

### Technical note

Once we fit a weighted regression, we can obtain the appropriately weighted variance–covariance matrix of the estimators using `estat vce` and perform appropriately weighted hypothesis tests using `test`.

In the weighted regression in example 8, we see that `4.region` is statistically significant but that `2.region` and `3.region` are not. We use `test` to test the joint significance of the region variables:

```
. test 2.region 3.region 4.region
   ( 1) 2.region = 0
   ( 2) 3.region = 0
   ( 3) 4.region = 0

F(  3,  45) =   9.84
Prob > F =  0.0000
```

The results indicate that the region variables are jointly significant.

`regress` also accepts frequency weights (`fweights`). Frequency weights are appropriate when the data do not reflect cell means, but instead represent replicated observations. Specifying `aweight`s or `fweight`s will not change the parameter estimates, but it will change the corresponding significance levels.

For instance, if we specified `[fweight=pop]` in the weighted regression example above—which would be statistically incorrect—Stata would treat the data as if the data represented 226 million independent observations on death rates and median age. The data most certainly do not represent that—they represent 50 observations on state averages.

With `aweight`s, Stata treats the number of observations on the process as the number of observations in the data. When we specify `fweight`s, Stata treats the number of observations as if it were equal to the sum of the weights; see `Methods and formulas` below.

### Technical note

A popular request on the help line is to describe the effect of specifying `[aweight=exp]` with `regress` in terms of transformation of the dependent and independent variables. The mechanical answer is that typing

```
. regress y x1 x2 [aweight=n]
```

is equivalent to fitting the model

$$y_j \sqrt{n_j} = \beta_0 \sqrt{n_j} + \beta_1 x_{1j} \sqrt{n_j} + \beta_2 x_{2j} \sqrt{n_j} + u_j \sqrt{n_j}$$

This regression will reproduce the coefficients and covariance matrix produced by the `aweight`ed `regress`. The mean squared errors (estimates of the variance of the residuals) will, however, be different. The transformed regression reports $s_t^2$, an estimate of $\text{Var}(u_j \sqrt{n_j})$. The `aweight`ed regression reports $s_a^2$, an estimate of $\text{Var}(u_j \sqrt{n_j} \sqrt{N/\sum_k n_k})$, where $N$ is the number of observations. Thus

$$s_a^2 = \frac{N}{\sum_k n_k} s_t^2 = \frac{s_t^2}{n}$$

(1)
The logic for this adjustment is as follows: Consider the model

\[ y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + u \]

Assume that, were this model fit on individuals, Var(\(u\)) = \(\sigma_u^2\), a constant. Assume that individual data are not available; what is available are averages \((\bar{y}_j, \bar{x}_{1j}, \bar{x}_{2j})\) for \(j = 1, \ldots, N\), and each average is calculated over \(n_j\) observations. Then it is still true that

\[ y_j = \beta_0 + \beta_1 x_{1j} + \beta_2 x_{2j} + u_j \]

where \(\bar{u}_j\) is the average of \(n_j\) mean 0, variance \(\sigma_u^2\) deviates and has variance \(\sigma_u^2/n_j\). Thus multiplying through by \(\sqrt{n_j}\) produces

\[ \bar{y}_j \sqrt{n_j} = \beta_0 \sqrt{n_j} + \beta_1 \bar{x}_{1j} \sqrt{n_j} + \beta_2 \bar{x}_{2j} \sqrt{n_j} + \bar{u}_j \sqrt{n_j} \]

and Var(\(\bar{u}_j \sqrt{n_j}\)) = \(\sigma_u^2\). The mean squared error, \(s_t^2\), reported by fitting this transformed regression is an estimate of \(\sigma_u^2\). The coefficients and covariance matrix could also be obtained by aweight regress. The only difference would be in the reported mean squared error, which from (1) is \(\sigma_u^2/n\). On average, each observation in the data reflects the averages calculated over \(n = \sum_k n_k/N\) individuals, and thus this reported mean squared error is the average variance of an observation in the dataset. We can retrieve the estimate of \(\sigma_u^2\) by multiplying the reported mean squared error by \(n\).

More generally, aweights are used to solve general heteroskedasticity problems. In these cases, we have the model

\[ y_j = \beta_0 + \beta_1 x_{1j} + \beta_2 x_{2j} + u_j \]

and the variance of \(u_j\) is thought to be proportional to \(a_j\). If the variance is proportional to \(a_j\), it is also proportional to \(\alpha a_j\), where \(\alpha\) is any positive constant. Not quite arbitrarily, but with no loss of generality, we could choose \(\alpha = \sum_k (1/a_k)/N\), the average value of the inverse of \(a_j\). We can then write Var(\(u_j\)) = \(k\alpha a_j \sigma^2\), where \(k\) is the constant of proportionality that is no longer a function of the scale of the weights.

Dividing this regression through by the \(\sqrt{a_j}\),

\[ y_j/\sqrt{a_j} = \beta_0/\sqrt{a_j} + \beta_1 x_{1j}/\sqrt{a_j} + \beta_2 x_{2j}/\sqrt{a_j} + u_j/\sqrt{a_j} \]

produces a model with Var(\(u_j/\sqrt{a_j}\)) = \(k\alpha \sigma^2\), which is the constant part of Var(\(u_j\)). This variance is a function of \(\alpha\), the average of the reciprocal weights; if the weights are scaled arbitrarily, then so is this variance.

We can also fit this model by typing

```
. regress y x1 x2 [aweights=1/a]
```

This input will produce the same estimates of the coefficients and covariance matrix; the reported mean squared error is, from (1), \(\{N/\sum_k (1/a_k)\}k\alpha \sigma^2 = k \sigma^2\). This variance is independent of the scale of \(a_j\).
### Instrumental variables and two-stage least-squares regression

An alternate syntax for `regress` can be used to produce instrumental-variables (two-stage least squares) estimates.

```
regress depvar [varlist1 [ (varlist2) ]] [ if ] [ in ] [ weight ] [, regress_options]
```

This syntax is used mainly by programmers developing estimators using the instrumental-variables estimates as intermediate results. `ivregress` is normally used to directly fit these models; see [R] `ivregress`.

With this syntax, `regress` fits a structural equation of `depvar` on `varlist1` using instrumental variables regression; `(varlist2)` indicates the list of instrumental variables. With the exception of `vce(hc2)` and `vce(hc3)`, all standard `regress` options are allowed.

### Video example

**Simple linear regression in Stata**

### Stored results

`regress` stores the following in `e()`:

- **Scalars**
  - `e(N)`: number of observations
  - `e(mss)`: model sum of squares
  - `e(df_m)`: model degrees of freedom
  - `e(rss)`: residual sum of squares
  - `e(df_r)`: residual degrees of freedom
  - `e(r2)`: $R^2$
  - `e(r2_a)`: adjusted $R^2$
  - `e(F)`: $F$ statistic
  - `e(rmse)`: root mean squared error
  - `e(ll)`: log likelihood under additional assumption of i.i.d. normal errors
  - `e(ll_0)`: log likelihood, constant-only model
  - `e(N_clust)`: number of clusters
  - `e(rank)`: rank of `e(V)`

- **Macros**
  - `e(cmd)`: `regress`
  - `e(cmdline)`: command as typed
  - `e(depvar)`: name of dependent variable
  - `e(model)`: `ols` or `iv`
  - `e(wtype)`: weight type
  - `e(wexp)`: weight expression
  - `e(title)`: title in estimation output when `vce()` is not `ols`
  - `e(clustvar)`: name of cluster variable
  - `e(vcetype)`: `vcetype` specified in `vce()`
  - `e(properties)`: `b V`
  - `e(estat_cmd)`: program used to implement `estat`
  - `e(predict)`: program used to implement `predict`
  - `e(marginsok)`: predictions allowed by `margins`
  - `e(asbalanced)`: factor variables `fvset` as `asbalanced`
  - `e(asobserved)`: factor variables `fvset` as `asobserved`

- **Matrices**
  - `e(b)`: coefficient vector
  - `e(V)`: variance–covariance matrix of the estimators
  - `e(V_modelbased)`: model-based variance

- **Functions**
  - `e(sample)`: marks estimation sample
Methods and formulas

Methods and formulas are presented under the following headings:

Coefficient estimation and ANOVA table
A general notation for the robust variance calculation
Robust calculation for regress

Coefficient estimation and ANOVA table

Variables printed in lowercase and not boldfaced (for example, $x$) are scalars. Variables printed in lowercase and boldfaced (for example, $x$) are column vectors. Variables printed in uppercase and boldfaced (for example, $X$) are matrices.

Let $v$ be a column vector of weights specified by the user. If no weights are specified, $v = 1$. Let $w$ be a column vector of normalized weights. If no weights are specified or if the user specified `fweight` or `iweight`, $w = v$. Otherwise, $w = \{v/(1'v)\}1'1$.

The number of observations, $n$, is defined as $1'w$. For `iweight`, this is truncated to an integer. The sum of the weights is $1'v$. Define $c = 1$ if there is a constant in the regression and zero otherwise. Define $k$ as the number of right-hand-side variables (including the constant).

Let $X$ denote the matrix of observations on the right-hand-side variables, $y$ the vector of observations on the left-hand-side variable, and $Z$ the matrix of observations on the instruments. If the user specifies no instruments, then $Z = X$. In the following formulas, if the user specifies weights, then $X'X$, $X'y$, $y'y$, $Z'Z$, $Z'X$, and $Z'y$ are replaced by $X'DX$, $X'Dy$, $y'Dy$, $Z'DZ$, $Z'DX$, and $Z'Dy$, respectively, where $D$ is a diagonal matrix whose diagonal elements are the elements of $w$. We suppress the $D$ below to simplify the notation.

If no instruments are specified, define $A$ as $X'X$ and $a$ as $X'y$. Otherwise, define $A$ as $X'Z(Z'Z)^{-1}(X'X)'$ and $a$ as $X'Z(Z'Z)^{-1}Z'y$.

The coefficient vector $b$ is defined as $A^{-1}a$. Although not shown in the notation, unless `hascons` is specified, $A$ and $a$ are accumulated in deviation form and the constant is calculated separately. This comment applies to all statistics listed below.

The total sum of squares, $TSS$, equals $y'y$ if there is no intercept and $y'y - \{(1'y)^2/n\}$ otherwise. The degrees of freedom is $n - c$.

The error sum of squares, $ESS$, is defined as $y'y - 2bX'y + b'X'Xb$ if there are instruments and as $y'y - b'X'y$ otherwise. The degrees of freedom is $n - k$.

The model sum of squares, $MSS$, equals $TSS - ESS$. The degrees of freedom is $k - c$.

The mean squared error, $s^2$, is defined as $ESS/(n - k)$. The root mean squared error is $s$, its square root.

The $F$ statistic with $k - c$ and $n - k$ degrees of freedom is defined as

$$F = \frac{MSS}{(k - c)s^2}$$

if no instruments are specified. If instruments are specified and $c = 1$, then $F$ is defined as

$$F = \frac{(b - c)'A(b - c)}{(k - 1)s^2}$$

where $c$ is a vector of $k - 1$ zeros and $k$th element $1'y/n$. Otherwise, $F$ is defined as “missing”. (Here you may use the `test` command to construct any $F$ test that you wish.)
The R-squared, $R^2$, is defined as $R^2 = 1 - \text{ESS}/\text{TSS}$.

The adjusted R-squared, $R_a^2$, is $1 - (1 - R^2)(n - c)/(n - k)$.

If vce(robust) is not specified, the conventional estimate of variance is $s^2A^{-1}$. The handling of vce(robust) is described below.

A general notation for the robust variance calculation

Put aside all context of linear regression and the notation that goes with it—we will return to it. First, we are going to establish a notation for describing robust variance calculations.

The calculation formula for the robust variance calculation is

$$\hat{V} = q_c \hat{V} \left( \sum_{k=1}^{M} u_k^{(G)} u_k^{(G)'} \right) \hat{V}$$

where

$$u_k^{(G)} = \sum_{j \in G_k} w_j u_j$$

$G_1, G_2, \ldots, G_M$ are the clusters specified by vce(cluster clustvar), and $w_j$ are the user-specified weights, normalized if aweights or pweights are specified and equal to 1 if no weights are specified.

For fweights without clusters, the variance formula is

$$\hat{V} = q_c \hat{V} \left( \sum_{j=1}^{N} w_j u'_j u_j \right) \hat{V}$$

which is the same as expanding the dataset and making the calculation on the unweighted data.

If vce(cluster clustvar) is not specified, $M = N$, and each cluster contains 1 observation. The inputs into this calculation are

- $\hat{V}$, which is typically a conventionally calculated variance matrix;
- $u_j$, $j = 1, \ldots, N$, a row vector of scores; and
- $q_c$, a constant finite-sample adjustment.

Thus we can now describe how estimators apply the robust calculation formula by defining $\hat{V}$, $u_j$, and $q_c$.

Two definitions are popular enough for $q_c$ to deserve a name. The regression-like formula for $q_c$ (Fuller et al. 1986) is

$$q_c = \frac{N - 1}{N - k} \frac{M}{M - 1}$$

where $M$ is the number of clusters and $N$ is the number of observations. For weights, $N$ refers to the sum of the weights if weights are frequency weights and the number of observations in the dataset (ignoring weights) in all other cases. Also note that, weighted or not, $M = N$ when vce(cluster clustvar) is not specified, and then $q_c = N/(N - k)$.

The asymptotic-like formula for $q_c$ is

$$q_c = \frac{M}{M - 1}$$

where $M = N$ if vce(cluster clustvar) is not specified.
See [U] 20.21 Obtaining robust variance estimates and [P] _robust for a discussion of the robust variance estimator and a development of these formulas.

Robust calculation for regress

For regress, $\hat{V} = A^{-1}$. The other terms are

No instruments, vce(robust), but not vce(hc2) or vce(hc3),

$u_j = (y_j - x_j b)x_j$

and $q_c$ is given by its regression-like definition.

No instruments, vce(hc2),

$u_j = \frac{1}{\sqrt{1-h_{jj}}}(y_j - x_j b)x_j$

where $q_c = 1$ and $h_{jj} = x_j(X'X)^{-1}x_j'$. 

No instruments, vce(hc3),

$u_j = \frac{1}{1-h_{jj}}(y_j - x_j b)x_j$

where $q_c = 1$ and $h_{jj} = x_j(X'X)^{-1}x_j'$. 

Instrumental variables,

$u_j = (y_j - x_j b)\hat{x}_j$

where $q_c$ is given by its regression-like definition, and

$\hat{x}_j' = Pz_j'$

where $P = (X'Z)(Z'Z)^{-1}$.

Acknowledgments

The robust estimate of variance was first implemented in Stata by Mead Over of the Center for Global Development, Dean Jolliffe of the World Bank, and Andrew Foster of the Department of Economics at Brown University (Over, Jolliffe, and Foster 1996).
The history of regression is long and complicated: the books by Stigler (1986) and Hald (1998) are devoted largely to the story. Legendre published first on least squares in 1805. Gauss published later in 1809, but he had the idea earlier. Gauss, and especially Laplace, tied least squares to a normal errors assumption. The idea of the normal distribution can itself be traced back to De Moivre in 1733. Laplace discussed a variety of other estimation methods and error assumptions over his long career, while linear models long predate either innovation. Most of this work was linked to problems in astronomy and geodesy.

A second wave of ideas started when Galton used graphical and descriptive methods on data bearing on heredity to develop what he called regression. His term reflects the common phenomenon that characteristics of offspring are positively correlated with those of parents but with regression slope such that offspring “regress toward the mean”. Galton’s work was rather intuitive: contributions from Pearson, Edgeworth, Yule, and others introduced more formal machinery, developed related ideas on correlation, and extended application into the biological and social sciences. So most of the elements of regression as we know it were in place by 1900.

Pierre-Simon Laplace (1749–1827) was born in Normandy and was early recognized as a remarkable mathematician. He weathered a changing political climate well enough to rise to Minister of the Interior under Napoleon in 1799 (although only for 6 weeks) and to be made a Marquis by Louis XVIII in 1817. He made many contributions to mathematics and physics, his two main interests being theoretical astronomy and probability theory (including statistics). Laplace transforms are named for him.

Adrien-Marie Legendre (1752–1833) was born in Paris (or possibly in Toulouse) and educated in mathematics and physics. He worked in number theory, geometry, differential equations, calculus, function theory, applied mathematics, and geodesy. The Legendre polynomials are named for him. His main contribution to statistics is as one of the discoverers of least squares. He died in poverty, having refused to bow to political pressures.

Johann Carl Friedrich Gauss (1777–1855) was born in Braunschweig (Brunswick), now in Germany. He studied there and at Göttingen. His doctoral dissertation at the University of Helmstedt was a discussion of the fundamental theorem of algebra. He made many fundamental contributions to geometry, number theory, algebra, real analysis, differential equations, numerical analysis, statistics, astronomy, optics, geodesy, mechanics, and magnetism. An outstanding genius, Gauss worked mostly in isolation in Göttingen.

Francis Galton (1822–1911) was born in Birmingham, England, into a well-to-do family with many connections: he and Charles Darwin were first cousins. After an unsuccessful foray into medicine, he became independently wealthy at the death of his father. Galton traveled widely in Europe, the Middle East, and Africa, and became celebrated as an explorer and geographer. His pioneering work on weather maps helped in the identification of anticyclones, which he named. From about 1865, most of his work was centered on quantitative problems in biology, anthropology, and psychology. In a sense, Galton (re)invented regression, and he certainly named it. Galton also promoted the normal distribution, correlation approaches, and the use of median and selected quantiles as descriptive statistics. He was knighted in 1909.

[U] 20 Estimation and postestimation commands
The following postestimation commands are of special interest after \texttt{regress}:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{dfbeta}</td>
<td>DFBETA influence statistics</td>
</tr>
<tr>
<td>\texttt{estat hettest}</td>
<td>tests for heteroskedasticity</td>
</tr>
<tr>
<td>\texttt{estat imtest}</td>
<td>information matrix test</td>
</tr>
<tr>
<td>\texttt{estat ovtest}</td>
<td>Ramsey regression specification-error test for omitted variables</td>
</tr>
<tr>
<td>\texttt{estat szroeter}</td>
<td>Szroeter’s rank test for heteroskedasticity</td>
</tr>
<tr>
<td>\texttt{estat vif}</td>
<td>variance inflation factors for the independent variables</td>
</tr>
<tr>
<td>\texttt{estat esize}</td>
<td>$\eta^2$ and $\omega^2$ effect sizes</td>
</tr>
</tbody>
</table>

These commands are not appropriate after the \texttt{svy} prefix.
The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>contrast</td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td>estat ic</td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td>estat summarize</td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td>estat vce</td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td>estat (svy)</td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td>estimates</td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td>forecast(^1)</td>
<td>dynamic forecasts and simulations</td>
</tr>
<tr>
<td>hausman</td>
<td>Hausman’s specification test</td>
</tr>
<tr>
<td>lincom</td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td>linktest</td>
<td>link test for model specification</td>
</tr>
<tr>
<td>lrtest(^2)</td>
<td>likelihood-ratio test</td>
</tr>
<tr>
<td>margins</td>
<td>marginal means, predictive margins, marginal effects, and average marginal effects</td>
</tr>
<tr>
<td>marginsplot</td>
<td>graph the results from margins (profile plots, interaction plots, etc.)</td>
</tr>
<tr>
<td>nlcom</td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td>predict</td>
<td>predictions, residuals, influence statistics, and other diagnostic measures</td>
</tr>
<tr>
<td>predictnl</td>
<td>point estimates, standard errors, testing, and inference for generalized predictions</td>
</tr>
<tr>
<td>pwcompare</td>
<td>pairwise comparisons of estimates</td>
</tr>
<tr>
<td>suest</td>
<td>seemingly unrelated estimation</td>
</tr>
<tr>
<td>test</td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td>testnl</td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

\(^1\) forecast is not appropriate with \textit{mi} or \textit{svy} estimation results.

\(^2\) lrtest is not appropriate with \textit{svy} estimation results.
Predictions

Syntax for predict

```
predict [ `type` ] `newvar` [ `if` ] [ `in` ] [ `, statistic` ]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>xb</code></td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td><code>residuals</code></td>
<td>residuals</td>
</tr>
<tr>
<td><code>score</code></td>
<td>score; equivalent to <code>residuals</code></td>
</tr>
<tr>
<td><code>rstandard</code></td>
<td>standardized residuals</td>
</tr>
<tr>
<td><code>rstudent</code></td>
<td>Studentized (jackknifed) residuals</td>
</tr>
<tr>
<td><code>cooksd</code></td>
<td>Cook’s distance</td>
</tr>
<tr>
<td><code>leverage</code> [ <code>hat</code> ]</td>
<td>leverage (diagonal elements of hat matrix)</td>
</tr>
<tr>
<td><code>pr</code> (<code>a</code>, <code>b</code>)</td>
<td>$\Pr(y_j \mid a &lt; y_j &lt; b)$</td>
</tr>
<tr>
<td><code>e</code> (<code>a</code>, <code>b</code>)</td>
<td>$E(y_j \mid a &lt; y_j &lt; b)$</td>
</tr>
<tr>
<td><code>ystar</code> (<code>a</code>, <code>b</code>)</td>
<td>$E(y^<em>_j), y^</em>_j = \max{a, \min(y_j, b)}$</td>
</tr>
<tr>
<td><code>* dfbeta</code> (<code>varname</code>)</td>
<td>DFBETA for <code>varname</code></td>
</tr>
<tr>
<td><code>* stdp</code></td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td><code>* stdf</code></td>
<td>standard error of the forecast</td>
</tr>
<tr>
<td><code>* stdr</code></td>
<td>standard error of the residual</td>
</tr>
<tr>
<td><code>* covratio</code></td>
<td>COVRATIO</td>

<tr>
<td><code>* welsch</code></td>
<td>Welsch distance</td>
</tr>
</tbody>
</table>

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when `if e(sample)` is not specified.

`rstandard`, `rstudent`, `cooksd`, `leverage`, `dfbeta()`, `stdp`, `stdf`, `covratio`, `dfits`, and `welsch` are not available if any `vce()` other than `vce(ols)` was specified with `regress`.

`xb`, `residuals`, `score`, and `stdp` are the only options allowed with `svy` estimation results.

where $a$ and $b$ may be numbers or variables; $a$ missing ($a \geq .$) means $-\infty$, and $b$ missing ($b \geq .$) means $+\infty$; see [U] 12.2.1 Missing values.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

- **Main**
  - `xb`, the default, calculates the linear prediction.
  - `residuals` calculates the residuals.
  - `score` is equivalent to `residuals` in linear regression.
rstandard calculates the standardized residuals.

rstudent calculates the Studentized (jackknifed) residuals.

cooksd calculates the Cook’s D influence statistic (Cook 1977).

leverage or hat calculates the diagonal elements of the projection (“hat”) matrix.

pr(a,b) calculates \( \Pr(a < x_j b + u_j < b) \), the probability that \( y_j | x_j \) would be observed in the interval \((a,b)\).

\( a \) and \( b \) may be specified as numbers or variable names; \( lb \) and \( ub \) are variable names;

\( \text{pr}(20,30) \) calculates \( \Pr(20 < x_j b + u_j < 30) \);

\( \text{pr}(lb,ub) \) calculates \( \Pr(lb < x_j b + u_j < ub) \); and

\( \text{pr}(20,ub) \) calculates \( \Pr(20 < x_j b + u_j < ub) \).

\( a \) missing \( (a \geq .) \) means \( -\infty \); \( \text{pr}(.,30) \) calculates \( \Pr(-\infty < x_j b + u_j < 30) \);

\( \text{pr}(lb,30) \) calculates \( \Pr(-\infty < x_j b + u_j < 30) \) in observations for which \( lb \geq . \)

and calculates \( \Pr(lb < x_j b + u_j < ub) \) elsewhere.

\( b \) missing \( (b \geq .) \) means \( +\infty \); \( \text{pr}(20,.) \) calculates \( \Pr(\infty > x_j b + u_j > 20) \);

\( \text{pr}(20,ub) \) calculates \( \Pr(\infty > x_j b + u_j > 20) \) in observations for which \( ub \geq . \)

and calculates \( \Pr(20 < x_j b + u_j < ub) \) elsewhere.

e(a,b) calculates \( E(x_j b + u_j | a < x_j b + u_j < b) \), the expected value of \( y_j | x_j \) conditional on \( y_j | x_j \) being in the interval \((a,b)\), meaning that \( y_j | x_j \) is truncated. \( a \) and \( b \) are specified as they are for \( \text{pr}(.) \).

ystar(a,b) calculates \( E(y_j^*) \), where \( y_j^* = a \) if \( x_j b + u_j \leq a \), \( y_j^* = b \) if \( x_j b + u_j \geq b \), and \( y_j^* = x_j b + u_j \) otherwise, meaning that \( y_j^* \) is censored. \( a \) and \( b \) are specified as they are for \( \text{pr}(.) \).

dfbeta(varname) calculates the DFbeta for \( varname \), the difference between the regression coefficient when the \( j \)th observation is included and excluded, said difference being scaled by the estimated standard error of the coefficient. \( varname \) must have been included among the regressors in the previously fitted model. The calculation is automatically restricted to the estimation subsample.

stdp calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

stdf calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by \( \text{stdf} \) are always larger than those produced by \( \text{stdp} \); see Methods and formulas.

stdr calculates the standard error of the residuals.

covratio calculates COVRATIO (Belsley, Kuh, and Welsch 1980), a measure of the influence of the \( j \)th observation based on considering the effect on the variance–covariance matrix of the estimates. The calculation is automatically restricted to the estimation subsample.

dfits calculates DFITS (Welsch and Kuh 1977) and attempts to summarize the information in the leverage versus residual-squared plot into one statistic. The calculation is automatically restricted to the estimation subsample.

welsch calculates Welsch distance (Welsch 1982) and is a variation on \( \text{dfits} \). The calculation is automatically restricted to the estimation subsample.
Remarks and examples for predict

Remarks are presented under the following headings:

- Terminology
- Fitted values and residuals
- Prediction standard errors
- Prediction with weighted data
- Leverage statistics
- Standardized and Studentized residuals
- DFITS, Cook’s Distance, and Welsch Distance
- COVRATIO

Terminology

Many of these commands concern identifying influential data in linear regression. This is, unfortunately, a field that is dominated by jargon, codified and partially begun by Belsley, Kuh, and Welsch (1980). In the words of Chatterjee and Hadi (1986, 416), “Belsley, Kuh, and Welsch’s book, Regression Diagnostics, was a very valuable contribution to the statistical literature, but it unleashed on an unsuspecting statistical community a computer speak (à la Orwell), the likes of which we have never seen.” Things have only gotten worse since then. Chatterjee and Hadi’s (1986, 1988) own attempts to clean up the jargon did not improve matters (see Hoaglin and Kempthorne [1986], Velleman [1986], and Welsch [1986]). We apologize for the jargon, and for our contribution to the jargon in the form of inelegant command names, we apologize most of all.

Model sensitivity refers to how estimates are affected by subsets of our data. Imagine data on $y$ and $x$, and assume that the data are to be fit by the regression $y_i = \alpha + \beta x_i + \epsilon_i$. The regression estimates of $\alpha$ and $\beta$ are $a$ and $b$, respectively. Now imagine that the estimated $a$ and $b$ would be different if a small portion of the dataset, perhaps even one observation, were deleted. As a data analyst, you would like to think that you are summarizing tendencies that apply to all the data, but you have just been told that the model you fit is unduly influenced by one point or just a few points and that, as a matter of fact, there is another model that applies to the rest of the data—a model that you have ignored. The search for subsets of the data that, if deleted, would change the results markedly is a predominant theme of this entry.

There are three key issues in identifying model sensitivity to individual observations, which go by the names residuals, leverage, and influence. In our $y_i = a + bx_i + \epsilon_i$ regression, the residuals are, of course, $e_i$—they reveal how much our fitted value $\hat{y}_i = a + bx_i$ differs from the observed $y_i$. A point $(x_i, y_i)$ with a corresponding large residual is called an outlier. Say that you are interested in outliers because you somehow think that such points will exert undue influence on your estimates. Your feelings are generally right, but there are exceptions. A point might have a huge residual and yet not affect the estimated $b$ at all. Nevertheless, studying observations with large residuals almost always pays off.

$(x_i, y_i)$ can be an outlier in another way—just as $y_i$ can be far from $\hat{y}_i$, $x_i$ can be far from the center of mass of the other $x$’s. Such an “outlier” should interest you just as much as the more traditional outliers. Picture a scatterplot of $y$ against $x$ with thousands of points in some sort of mass at the lower left of the graph and one point at the upper right of the graph. Now run a regression line through the points—the regression line will come close to the point at the upper right of the graph and may in fact, go through it. That is, this isolated point will not appear as an outlier as measured by residuals because its residual will be small. Yet this point might have a dramatic effect on our resulting estimates in the sense that, were you to delete the point, the estimates would change markedly. Such a point is said to have high leverage. Just as with traditional outliers, a high leverage point does not necessarily have an undue effect on regression estimates, but if it does not, it is more the exception than the rule.
Now all this is a most unsatisfactory state of affairs. Points with large residuals may, but need
not, have a large effect on our results, and points with small residuals may still have a large effect.
Points with high leverage may, but need not, have a large effect on our results, and points with low
leverage may still have a large effect. Can you not identify the influential points and simply have the
computer list them for you? You can, but you will have to define what you mean by “influential”.

“Influential” is defined with respect to some statistic. For instance, you might ask which points in
your data have a large effect on your estimated $a$, which points have a large effect on your estimated
$b$, which points have a large effect on your estimated standard error of $b$, and so on, but do not be
surprised when the answers to these questions are different. In any case, obtaining such measures
is not difficult—all you have to do is fit the regression excluding each observation one at a time
and record the statistic of interest which, in the day of the modern computer, is not too onerous.
Moreover, you can save considerable computer time by doing algebra ahead of time and working
out formulas that will calculate the same answers as if you ran each of the regressions. (Ignore the
question of pairs of observations that, together, exert undue influence, and triples, and so on, which
remains largely unsolved and for which the brute force fit-every-possible-regression procedure is not
a viable alternative.)

Fitted values and residuals

Typing `predict newvar` with no options creates `newvar` containing the fitted values. Typing
`predict newvar, resid` creates `newvar` containing the residuals.

Example 1

Continuing with example 1 from [R] `regress`, we wish to fit the following model:

\[
mpg = \beta_0 + \beta_1 \text{weight} + \beta_2 \text{foreign} + \epsilon
\]

. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. regress mpg weight foreign

Source                        SS       df    MS
------------------------------+-------------------+-------------------
Model                   1619.2877   2  809.643849         F(  2,  71) =  69.75
Residual                824.171761  71  11.608053  Prob > F =      0.0000
------------------------------+-------------------+-------------------
Total                  2443.45946  73  33.4720474        R-squared =    0.6627
                        Number of obs =    74
                        Adj R-squared =    0.6532
                        Root MSE =    3.4071

mpg                       Coef.   Std. Err.     t    P>|t|    [95% Conf. Interval]
------------------------------+-------------------+-------------------+-------------------
weight                  -0.0065879    0.0006371  -10.34  0.000    -0.0078583   -0.0053175
foreign                   -1.650029    1.075994   -1.53  0.130    -3.7955    .4954422
_cons                     41.6797     2.165547    19.25  0.000     37.36172    45.99768

That done, we can now obtain the predicted values from the regression. We will store them in a new
variable called `pmpg` by typing `predict pmpg`. Because `predict` produces no output, we will follow
that by summarizing our predicted and observed values.
Example 2: Out-of-sample predictions

We can just as easily obtain predicted values from the model by using a wholly different dataset from the one on which the model was fit. The only requirement is that the data have the necessary variables, which here are weight and foreign.

Using the data on two new cars (the Pontiac Sunbird and the Volvo 260) from the newautos.dta dataset, we can obtain out-of-sample predictions (or forecasts) by typing

```
use http://www.stata-press.com/data/r13/newautos, clear
(predict pmpg (option xb assumed; fitted values)
.list, divider
```

<table>
<thead>
<tr>
<th>make</th>
<th>weight</th>
<th>foreign</th>
<th>pmpg</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pont. Sunbird</td>
<td>2690</td>
<td>Domestic</td>
<td>23.95829</td>
</tr>
<tr>
<td>Volvo 260</td>
<td>3170</td>
<td>Foreign</td>
<td>19.14607</td>
</tr>
</tbody>
</table>

The Pontiac Sunbird has a predicted mileage rating of 23.96 mpg, whereas the Volvo 260 has a predicted rating of 19.15 mpg. In comparison, the actual mileage ratings are 24 for the Pontiac and 17 for the Volvo.

Prediction standard errors

`predict` can calculate the standard error of the forecast (`stdf` option), the standard error of the prediction (`stdp` option), and the standard error of the residual (`stdr` option). It is easy to confuse `stdf` and `stdp` because both are often called the prediction error. Consider the prediction \( \hat{y}_j = x_j b \), where \( b \) is the estimated coefficient (column) vector and \( x_j \) is a (row) vector of independent variables for which you want the prediction. First, \( \hat{y}_j \) has a variance due to the variance of the estimated coefficient vector \( b \),

\[
\text{Var}(\hat{y}_j) = \text{Var}(x_j b) = s^2 h_j
\]

where \( h_j = x_j (X'X)^{-1} x_j' \) and \( s^2 \) is the mean squared error of the regression. Do not panic over the algebra—just remember that \( \text{Var}(\hat{y}_j) = s^2 h_j \), whatever \( s^2 \) and \( h_j \) are. `stdp` calculates this quantity. This is the error in the prediction due to the uncertainty about \( b \).

If you are about to hand this number out as your forecast, however, there is another error. According to your model, the true value of \( y_j \) is given by

\[
y_j = x_j b + \epsilon_j = \hat{y}_j + \epsilon_j
\]
and thus the $\text{Var}(y_j) = \text{Var}(\hat{y}_j) + \text{Var}(\epsilon_j) = s^2 h_j + s^2$, which is the square of stdf. stdf, then, is the sum of the error in the prediction plus the residual error.

stdr has to do with an analysis-of-variance decomposition of $s^2$, the estimated variance of $y$. The standard error of the prediction is $s^2 h_j$, and therefore $s^2 h_j + s^2 (1 - h_j) = s^2$ decomposes $s^2$ into the prediction and residual variances.

### Example 3: standard error of the forecast

Returning to our model of mpg on weight and foreign, we previously predicted the mileage rating for the Pontiac Sunbird and Volvo 260 as 23.96 and 19.15 mpg, respectively. We now want to put a standard error around our forecast. Remember, the data for these two cars were in newautos.dta:

```
. use http://www.stata-press.com/data/r13/newautos, clear
(New Automobile Models)
. predict pmpg
(option xb assumed; fitted values)
. predict se_pmpg, stdf
. list, divider
```

<table>
<thead>
<tr>
<th>make</th>
<th>weight</th>
<th>foreign</th>
<th>pmpg</th>
<th>se_pmpg</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pont. Sunbird</td>
<td>2690</td>
<td>Domestic</td>
<td>23.95829</td>
<td>3.462791</td>
</tr>
<tr>
<td>Volvo 260</td>
<td>3170</td>
<td>Foreign</td>
<td>19.14607</td>

Thus an approximate 95% confidence interval for the mileage rating of the Volvo 260 is $19.15 \pm 2 \cdot 3.53 = [12.09, 26.21]$.

### Prediction with weighted data

predict can be used after frequency-weighted (fweight) estimation, just as it is used after unweighted estimation. The technical note below concerns the use of predict after analytically weighted (aweight) estimation.

#### Technical note

After analytically weighted estimation, predict is willing to calculate only the prediction (no options), residual (residual option), standard error of the prediction (stdp option), and diagonal elements of the projection matrix (hat option). Moreover, the results produced by hat need to be adjusted, as will be described. For analytically weighted estimation, the standard error of the forecast and residuals, the standardized and Studentized residuals, and Cook’s $D$ are not statistically well-defined concepts.
Leverage statistics

In addition to providing fitted values and the associated standard errors, the predict command can also be used to generate various statistics used to detect the influence of individual observations. This section provides a brief introduction to leverage (hat) statistics, and some of the following subsections discuss other influence statistics produced by predict.

Example 4: diagonal elements of projection matrix

The diagonal elements of the projection matrix, obtained by the hat option, are a measure of distance in explanatory variable space. leverage is a synonym for hat.

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. regress mpg weight foreign 
(output omitted)
. predict xdist, hat
. summarize xdist, detail
```

```
Leverage
Percentiles          Smallest
1%  .0192325          .0192325
5%  .0192686          .0192366
10% .0193448          .019241    Obs    74
25% .0220291          .0192686   Sum of Wgt. 74
50% .0383797          Obs                   .0405405
    Largest           Std. Dev.     .0207624
75% .0494002          .0880814
90% .0693432          .099715      Variance    .0004311
95% .0880814          .099715      Skewness    1.159745
99% .1003283          .1003283     Kurtosis    4.083313
```

Some 5% of our sample has an xdist measure in excess of 0.08. Let’s force them to reveal their identities:

```
. list foreign make mpg if xdist>.08, divider
```

```
  foreign | make     mpg  
-----------|---------|-------
     24.   | Domestic| Ford Fiesta | 28
     27.   | Domestic| Linc. Mark V | 12
     43.   | Domestic| Plym. Champ | 34
     64.   | Foreign | Peugeot 604 | 14
```

To understand why these cars are on this list, we must remember that the explanatory variables in our model are weight and foreign and that xdist measures distance in this metric. The Ford Fiesta and the Plymouth Champ are the two lightest domestic cars in our data. The Lincolns are the two heaviest domestic cars, and the Peugeot is the heaviest foreign car.

See lvr2plot in [R] regress postestimation diagnostic plots for information on a leverage-versus-squared-residual plot.
Standardized and Studentized residuals

The terms standardized and Studentized residuals have meant different things to different authors. In Stata, `predict` defines the standardized residual as \( \hat{e}_i = e_i / (s \sqrt{1 - h_i}) \) and the Studentized residual as \( r_i = e_i / (s(i) \sqrt{1 - h_i}) \), where \( s(i) \) is the root mean squared error of a regression with the \( i \)th observation removed. Stata’s definition of the Studentized residual is the same as the one given in Bollen and Jackman (1990, 264) and is what Chatterjee and Hadi (1988, 74) call the “externally Studentized” residual. Stata’s “standardized” residual is the same as what Chatterjee and Hadi (1988, 74) call the “internally Studentized” residual.

Standardized and Studentized residuals are attempts to adjust residuals for their standard errors. Although the \( e_i \) theoretical residuals are homoskedastic by assumption (that is, they all have the same variance), the calculated \( e_i \) are not. In fact,

\[
\text{Var}(e_i) = \sigma^2 (1 - h_i)
\]

where \( h_i \) are the leverage measures obtained from the diagonal elements of hat matrix. Thus observations with the greatest leverage have corresponding residuals with the smallest variance.

Standardized residuals use the root mean squared error of the regression for \( \sigma \). Studentized residuals use the root mean squared error of a regression omitting the observation in question for \( \sigma \). In general, Studentized residuals are preferable to standardized residuals for purposes of outlier identification. Studentized residuals can be interpreted as the \( t \) statistic for testing the significance of a dummy variable equal to 1 in the observation in question and 0 elsewhere (Belsley, Kuh, and Welsch 1980). Such a dummy variable would effectively absorb the observation and so remove its influence in determining the other coefficients in the model. Caution must be exercised here, however, because of the simultaneous testing problem. You cannot simply list the residuals that would be individually significant at the 5% level—their joint significance would be far less (their joint significance level would be far greater).

Example 5: standardized and Studentized residuals

In the Terminology section of Remarks and examples for `predict`, we distinguished residuals from leverage and speculated on the impact of an observation with a small residual but large leverage. If we adjust the residuals for their standard errors, however, the adjusted residual would be (relatively) larger and perhaps large enough so that we could simply examine the adjusted residuals. Taking our price on weight and foreign##c.mpg model from example 1 of [R] regress postestimation diagnostic plots, we can obtain the in-sample standardized and Studentized residuals by typing

```
. use http://www.stata-press.com/data/r13/auto, clear
   (1978 Automobile Data)
. regress price weight foreign##c.mpg
   (output omitted)
. predict esta if e(sample), rstandard
. predict estu if e(sample), rstudent
```
In the *lvr2plot* section of [R] *regress postestimation diagnostic plots*, we discovered that the VW Diesel has the highest leverage in our data, but a corresponding small residual. The standardized and Studentized residuals for the VW Diesel are

```
. list make price esta estu if make=="VW Diesel"

<table>
<thead>
<tr>
<th>make</th>
<th>price</th>
<th>esta</th>
<th>estu</th>
</tr>
</thead>
<tbody>
<tr>
<td>VW Diesel</td>
<td>5,397</td>
<td>.6142691</td>
<td>.6114758</td>
</tr>
</tbody>
</table>
```

The Studentized residual of 0.611 can be interpreted as the $t$ statistic for including a dummy variable for VW Diesel in our regression. Such a variable would not be significant.

**DFITS, Cook’s Distance, and Welsch Distance**

DFITS (Welsch and Kuh 1977), Cook’s Distance (Cook 1977), and Welsch Distance (Welsch 1982) are three attempts to summarize the information in the leverage versus residual-squared plot into one statistic. That is, the goal is to create an index that is affected by the size of the residuals—outliers—and the size of $h_i$—leverage. Viewed mechanically, one way to write DFITS (Bollen and Jackman 1990, 265) is

$$DFITS_i = r_i \sqrt{\frac{h_i}{1-h_i}}$$

where $r_i$ are the Studentized residuals. Thus large residuals increase the value of DFITS, as do large values of $h_i$. Viewed more traditionally, DFITS is a scaled difference between predicted values for the $i$th case when the regression is fit with and without the $i$th observation, hence the name.

The mechanical relationship between DFITS and Cook’s Distance, $D_i$ (Bollen and Jackman 1990, 266), is

$$D_i = \frac{1}{k} \frac{s_{(i)}^2}{s^2} DFITS_i^2$$

where $k$ is the number of variables (including the constant) in the regression, $s$ is the root mean squared error of the regression, and $s_{(i)}$ is the root mean squared error when the $i$th observation is omitted. Viewed more traditionally, $D_i$ is a scaled measure of the distance between the coefficient vectors when the $i$th observation is omitted.
