Cross-referencing the documentation

When reading this manual, you will find references to other Stata manuals. For example,

[U] 26 Overview of Stata estimation commands
[XT] xtabond
[D] reshape

The first example is a reference to chapter 26, *Overview of Stata estimation commands*, in the *User's Guide*; the second is a reference to the *xtabond* entry in the *Longitudinal-Data/Panel-Data Reference Manual*; and the third is a reference to the *reshape* entry in the *Data Management Reference Manual*.

All the manuals in the Stata Documentation have a shorthand notation:

[GSM] Getting Started with Stata for Mac
[GSU] Getting Started with Stata for Unix
[GSW] Getting Started with Stata for Windows
[U] Stata User’s Guide
[R] Stata Base Reference Manual
[XT] Stata Longitudinal-Data/Panel-Data Reference Manual
[MI] Stata Multiple-Imputation Reference Manual
[PSS] Stata Power and Sample-Size Reference Manual
[SVY] Stata Survey Data Reference Manual
[I] Stata Glossary and Index
This entry describes the organization of the reference manuals.

The complete list of reference manuals is as follows:

[R]  Stata Base Reference Manual
[XT] Stata Longitudinal-Data/Panel-Data Reference Manual
[M]  Stata Multiple-Imputation Reference Manual
[PSS] Stata Power and Sample-Size Reference Manual
[SVY] Stata Survey Data Reference Manual
[I]   Stata Glossary and Index

When we refer to “reference manuals”, we mean all manuals listed above.

When we refer to the specialty manuals, we mean all the manuals listed above except [R] and [I].
Arrangement of the reference manuals

Each manual contains the following sections:

- **Contents.**
  A table of contents can be found at the beginning of each manual.

- **Cross-referencing the documentation.**
  This entry lists all the manuals and explains how they are cross-referenced.

- **Introduction.**
  This entry—usually called intro—provides an overview of the manual. In the specialty manuals, this introduction suggests entries that you might want to read first and provides information about new features.

  Each specialty manual contains an overview of the commands described in it.

- **Entries.**
  Entries are arranged in alphabetical order. Most entries describe Stata commands, but some entries discuss concepts, and others provide overviews.

  Entries that describe estimation commands are followed by an entry discussing postestimation commands that are available for use after the estimation command. For example, the `xtlogit` entry in the `[XT]` manual is followed by the `xtlogit postestimation` entry.

- **Index.**
  An index can be found at the end of each manual.

  The *Glossary and Index*, [1], contains a subject table of contents for all the reference manuals and the *User’s Guide*, a combined acronym glossary, a combined glossary, a vignette index, a combined author index, and a combined subject index for all the manuals.

  To find information and commands quickly, use Stata’s `search` command; see [R] `search` (see the entry `search` in the [R] manual).

Arrangement of each entry

Entries in the Stata reference manuals, except the [M] and [SEM] manuals, generally contain the following sections, which are explained below:

- **Syntax**
- **Menu**
- **Description**
- **Options**
- **Remarks and examples**
- **Stored results**
- **Methods and formulas**
- **References**
- **Also see**

**Syntax**

A command’s syntax diagram shows how to type the command, indicates all possible options, and gives the minimal allowed abbreviations for all the items in the command. For instance, the syntax diagram for the `summarize` command is
**summarize [varlist] [if] [in] [weight] [ , options]**

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Main</strong></td>
<td></td>
</tr>
<tr>
<td><strong>detail</strong></td>
<td>display additional statistics</td>
</tr>
<tr>
<td><strong>meanonly</strong></td>
<td>suppress the display; calculate only the mean; programmer’s option</td>
</tr>
<tr>
<td><strong>format</strong></td>
<td>use variable’s display format</td>
</tr>
<tr>
<td><strong>separator(#)</strong></td>
<td>draw separator line after every # variables; default is separator(5)</td>
</tr>
<tr>
<td><strong>display_options</strong></td>
<td>control spacing and base and empty cells</td>
</tr>
</tbody>
</table>

*varlist* may contain factor variables; see [U] 11.4.3 Factor variables.

*varlist* may contain time-series operators; see [U] 11.4.4 Time-series varlists.

*by* is allowed; see [D] by.

aweights, fweights, and iweights are allowed. However, iweights may not be used with the detail option; see [U] 11.1.6 weight.

Items in the typewriter-style font should be typed exactly as they appear in the diagram, although they may be abbreviated. **Underlining** indicates the shortest abbreviations where abbreviations are allowed. For instance, *summarize* may be abbreviated *su*, *sum*, *summ*, etc., or it may be spelled out completely. Items in the typewriter font that are not underlined may not be abbreviated.

Square brackets denote optional items. In the syntax diagram above, *varlist*, *if*, *in*, *weight*, and the *options* are optional.

The *options* are listed in a table immediately following the diagram, along with a brief description of each.

Items typed in italics represent arguments for which you are to substitute variable names, observation numbers, and the like.

The diagrams use the following symbols:

- # Indicates a literal number, for example, 5; see [U] 12.2 Numbers.
- [ ] Anything enclosed in brackets is optional.
- { } At least one of the items enclosed in braces must appear.
- | The vertical bar separates alternatives.
- %fmt Any Stata format, for example, %8.2f; see [U] 12.5 Formats: Controlling how data are displayed.
- depvar The dependent variable in an estimation command; see [U] 20 Estimation and postestimation commands.
- exp Any algebraic expression, for example, (5+myvar)/2; see [U] 13 Functions and expressions.
- filename Any filename; see [U] 11.6 Filenaming conventions.
- indepvars The independent variables in an estimation command; see [U] 20 Estimation and postestimation commands.
- newvar A variable that will be created by the current command; see [U] 11.4.2 Lists of new variables.
- numlist A list of numbers; see [U] 11.1.8 numlist.
- oldvar A previously created variable; see [U] 11.4.1 Lists of existing variables.
- options A list of options; see [U] 11.1.7 options.
**range**  
An observation range, for example, 5/20; see [U] 11.1.4 in range.

**"string"**  
Any string of characters enclosed in double quotes; see [U] 12.4 Strings.

**varlist**  
A list of variable names; see [U] 11.4 varlists. If varlist allows factor variables, a note to that effect will be shown below the syntax diagram; see [U] 11.4.3 Factor variables. If varlist allows time-series operators, a note to that effect will be shown below the syntax diagram; see [U] 11.4.4 Time-series varlists.

**varname**  
A variable name; see [U] 11.3 Naming conventions.

**weight**  
A \([\text{weighttype}]=\exp\) modifier; see [U] 11.1.6 weight and [U] 20.23 Weighted estimation.

**xvar**  
The variable to be displayed on the horizontal axis.

**yvar**  
The variable to be displayed on the vertical axis.

The **Syntax** section will indicate whether factor variables or time-series operators may be used with a command. **summarize** allows factor variables and time-series operators.

If a command allows prefix commands, this will be indicated immediately following the table of options. **summarize** allows by.

If a command allows weights, the types of weights allowed will be specified, with the default weight listed first. **summarize** allows **aweights**, **fweights**, and **iweights**, and if the type of weight is not specified, the default is **aweights**.

**Menu**

A menu indicates how the dialog box for the command may be accessed using the menu system.

**Description**

Following the syntax diagram is a brief description of the purpose of the command.

**Options**

If the command allows any options, they are explained here, and for dialog users the location of the options in the dialog is indicated. For instance, in the **logistic** entry in this manual, the **Options** section looks like this:

```
Model
SE/Robust
Reporting
Maximization
```
Remarks and examples

The explanations under Description and Options are exceedingly brief and technical; they are designed to provide a quick summary. The remarks explain in English what the preceding technical jargon means. Examples are used to illustrate the command.

Stored results

Commands are classified as e-class, r-class, s-class, or n-class, according to whether they store calculated results in $e()$, $r()$, $s()$, or not at all. These results can then be used in subroutines by other programs (ado-files). Such stored results are documented here; see [U] 18.8 Accessing results calculated by other programs and [U] 18.9 Accessing results calculated by estimation commands.

Methods and formulas

The techniques and formulas used in obtaining the results are described here as tersely and technically as possible.

References

Published sources are listed that either were directly referenced in the preceding text or might be of interest.

Other manual entries relating to this entry are listed that might also interest you.

Elizabeth L. (“Betty”) Scott (1917–1988) was an astronomer and mathematician trained at the University of California at Berkeley. She published her first paper when she was just 22 years old, and her work was focused on comets for much of her early academic career.

During World War II, Scott began working at the statistical laboratory at Berkeley, which had recently been established by Jerzy Neyman, sparking what would be a long and fruitful collaboration with him. After the war, she shifted her focus toward mathematics and statistics, partly because of limited career opportunities as an astronomer, though she still applied her research to astronomical topics. For example, in 1949 she published a paper using statistical techniques to analyze the distribution of binary star systems. She also published papers examining the distribution of galaxies, and she is the name behind the “Scott effect”, which helps determine the distances to galaxies. Later in her career, Scott applied her statistical knowledge to problems associated with ozone depletion and its effects on the incidence of skin cancer as well as weather modification. She was also a champion of equality for women graduate students and faculty.

Among Scott’s many awards and accomplishments, she was elected an honorary fellow of the Royal Statistical Society and was a fellow of the American Association for the Advancement of Science. In 1992, the Committee of Presidents of Statistical Societies established the Elizabeth L. Scott Award, a biannual award to recognize those who have strived to enhance the status of women within the statistics profession.

<th>Description</th>
<th>Options</th>
<th>Remarks and examples</th>
</tr>
</thead>
<tbody>
<tr>
<td>adoupdate [pkglist] [, options]</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

- **options**
  - **update**
    - perform update; default is to list packages that have updates, but not to update them
  - **all**
    - include packages that might have updates; default is to list or update only packages that are known to have updates
  - **ssconly**
    - check only packages obtained from SSC; default is to check all installed packages
  - **dir(dir)**
    - check packages installed in dir; default is to check those installed in PLUS
  - **verbose**
    - provide output to assist in debugging network problems

**Description**

User-written additions to Stata are called packages. These packages can add remarkable abilities to Stata. Packages are found and installed by using `ssc`, `search`, and `net`; see [R] `ssc`, [R] `search`, and [R] `net`.

User-written packages are updated by their developers, just as official Stata software is updated by StataCorp.

To determine whether your official Stata software is up to date, and to update it if it is not, you use `update`; see [R] `update`.

To determine whether your user-written additions are up to date, and to update them if they are not, you use `adoupdate`.

**Options**

- **update** specifies that packages with updates be updated. The default is simply to list the packages that could be updated without actually performing the update.

  The first time you adoupdate, do not specify this option. Once you see adoupdate work, you will be more comfortable with it. Then type

    . adoupdate, update

  The packages that can be updated will be listed and updated.

- **all** is rarely specified. Sometimes, adoupdate cannot determine whether a package you previously installed has been updated. adoupdate can determine that the package is still available over the web but is unsure whether the package has changed. Usually, the package has not changed, but if you want to be certain that you are using the latest version, reinstall from the source.
Specifying all does this. Typing

```
    . adoupdate, all
```

adds such packages to the displayed list as needing updating but does not update them. Typing

```
    . adoupdate, update all
```

lists such packages and updates them.

ssconly is a popular option. Many packages are available from the Statistical Software Components (SSC) archive—often called the Boston College Archive—which is provided at http://repec.org. Many users find most of what they want there. See [R] ssc for more information on the SSC.

ssconly specifies that adoupdate check only packages obtained from that source. Specifying this option is popular because SSC always provides distribution dates, and so adoupdate can be certain whether an update exists.

dir(dir) specifies which installed packages be checked. The default is dir(PLUS), and that is probably correct. If you are responsible for maintaining a large system, however, you may have previously installed packages in dir(SITE), where they are shared across users. See [P] sysdir for an explanation of these directory codewords. You may also specify an actual directory name, such as C:\mydir.

verbose is specified when you suspect network problems. It provides more detailed output that may help you diagnose the problem.

## Remarks and examples

Do not confuse adoupdate with update. Use adoupdate to update user-written files. Use update to update the components (including ado-files) of the official Stata software. To use either command, you must be connected to the Internet.

Remarks are presented under the following headings:

- **Using adoupdate**
- **Possible problem the first time you run adoupdate and the solution**
- **Notes for developers**

### Using adoupdate

The first time you try adoupdate, type

```
    . adoupdate
```

That is, do not specify the update option. adoupdate without update produces a report but does not update any files. The first time you run adoupdate, you may see messages such as

```
    . adoupdate
    (note: package utx was installed more than once; older copy removed)
    (remaining output omitted)
```

Having the same packages installed multiple times is common; adoupdate cleans that up.

The second time you run adoupdate, pick one package to update. Suppose that the report indicates that package st0008 has an update available. Type

```
    . adoupdate st0008, update
```

You can specify one or many packages after the adoupdate command. You can even use wildcards such as st* to mean all packages that start with st or st*8 to mean all packages that start with st and end with 8. You can do that with or without the update option.
Finally, you can let `adoupdate` update all your user-written additions:

```
.adoupdate, update
```

**Possible problem the first time you run adoupdate and the solution**

The first time you run `adoupdate`, you might get many duplicate messages:

```
.adoupdate
(note: package ___ installed more than once; older copy removed)
(note: package ___ installed more than once; older copy removed)
(note: package ___ installed more than once; older copy removed)
...
(note: package ___ installed more than once; older copy removed)
(remaining output omitted)
```

Some users have hundreds of duplicates. You might even see the same package name repeated more than once:

```
(note: package stylus installed more than once; older copy removed)
(note: package stylus installed more than once; older copy removed)
```

That means that the package was duplicated twice.

Stata tolerates duplicates, and you did nothing wrong when you previously installed and updated packages. `adoupdate`, however, needs the duplicates removed, mainly so that it does not keep checking the same files.

The solution is to just let `adoupdate` run. `adoupdate` will run faster next time, when there are no (or just a few) duplicates.

**Notes for developers**

`adoupdate` reports whether an installed package is up to date by comparing its distribution date with that of the package available over the web.

If you are distributing software, include the line
```
.d Distribution-Date: date
```
somewhere in your `.pkg` file. The capitalization of `Distribution-Date` does not matter, but include the hyphen and the colon as shown. Code the date in either of two formats:

- all numeric: `yyyyMMdd`, for example, 20120701
- Stata standard: `ddMONyyyy`, for example, 01ju12012

**Stored results**

`adoupdate` stores the following in `r()`:

- **Macros**
  - `r(pkglist)` a space-separated list of package names that need updating (`update` not specified) or that were updated (`update` specified)

ameans — Arithmetic, geometric, and harmonic means

Syntax

ameans [ varlist ] [ if ] [ in ] [ weight ] [ , options ]

Syntax Menu Description Options

Remarks and examples Stored results Methods and formulas Acknowledgments

References Also see

Syntax

Menu

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Arith./geometric/harmonic means

Description

ameans computes the arithmetic, geometric, and harmonic means, with their corresponding confidence intervals, for each variable in varlist or for all the variables in the data if varlist is not specified. gmeans and hmeans are synonyms for ameans.

If you simply want arithmetic means and corresponding confidence intervals, see [R] ci.

Options

Main

| add(#) | add # to each variable in varlist |
| only | add # only to variables with nonpositive values |
| level(#) | set confidence level; default is level(95) |

by is allowed; see [D] by.
aweights and fweights are allowed; see [U] 11.1.6 weight.
Remarks and examples

Example 1

We have a dataset containing 8 observations on a variable named \( x \). The eight values are 5, 4, -4, -5, 0, 0, \( \text{missing} \), and 7.

```
. ameans x
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Type</th>
<th>Obs</th>
<th>Mean</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>Arithmetic</td>
<td>7</td>
<td>1</td>
<td>-3.204405 5.204405</td>
</tr>
<tr>
<td></td>
<td>Geometric</td>
<td>3</td>
<td>5.192494</td>
<td>2.57899 10.45448</td>
</tr>
<tr>
<td></td>
<td>Harmonic</td>
<td>3</td>
<td>5.060241</td>
<td>3.023008 15.5179</td>
</tr>
</tbody>
</table>

```
. ameans x, add(5)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Type</th>
<th>Obs</th>
<th>Mean</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>Arithmetic</td>
<td>7</td>
<td>6</td>
<td>1.795595 10.2044 *</td>
</tr>
<tr>
<td></td>
<td>Geometric</td>
<td>6</td>
<td>5.477226</td>
<td>2.1096 14.22071 *</td>
</tr>
<tr>
<td></td>
<td>Harmonic</td>
<td>6</td>
<td>3.540984</td>
<td>. . . *</td>
</tr>
</tbody>
</table>

(*) 5 was added to the variables prior to calculating the results. Missing values in confidence intervals for harmonic mean indicate that confidence interval is undefined for corresponding variables. Consult Reference Manual for details.

The number of observations displayed for the arithmetic mean is the number of nonmissing observations. The number of observations displayed for the geometric and harmonic means is the number of nonmissing, positive observations. Specifying the `add(5)` option produces 3 more positive observations. The confidence interval for the harmonic mean is not reported; see Methods and formulas below.

Video example

Descriptive statistics in Stata

Stored results

`ameans` stores the following in `r()`:

Scalars
- `r(N)` number of nonmissing observations; used for arithmetic mean
- `r(N_pos)` number of nonmissing positive observations; used for geometric and harmonic means
- `r(mean)` arithmetic mean
- `r(lb)` lower bound of confidence interval for arithmetic mean
- `r(ub)` upper bound of confidence interval for arithmetic mean
- `r(Var)` variance of untransformed data
- `r(mean_g)` geometric mean
- `r(lb_g)` lower bound of confidence interval for geometric mean
- `r(ub_g)` upper bound of confidence interval for geometric mean
- `r(Var_g)` variance of `ln(x)`
- `r(mean_h)` harmonic mean
- `r(lb_h)` lower bound of confidence interval for harmonic mean
- `r(ub_h)` upper bound of confidence interval for harmonic mean
- `r(Var_h)` variance of `1/x`
Methods and formulas

When restricted to the same set of values (that is, to positive values), the arithmetic mean ($\bar{x}$) is greater than or equal to the geometric mean, which in turn is greater than or equal to the harmonic mean. Equality holds only if all values within a sample are equal to a positive constant.

The arithmetic mean and its confidence interval are identical to those provided by ci; see [R] ci.

To compute the geometric mean, `ameans` first creates $u_j = \ln x_j$ for all positive $x_j$. The arithmetic mean of the $u_j$ and its confidence interval are then computed as in ci. Let $\bar{u}$ be the resulting mean, and let $[L, U]$ be the corresponding confidence interval. The geometric mean is then $\exp(\bar{u})$, and its confidence interval is $[\exp(L), \exp(U)]$.

The same procedure is followed for the harmonic mean, except that then $u_j = 1/x_j$. The harmonic mean is then $1/\bar{u}$, and its confidence interval is $[1/U, 1/L]$ if $L$ is greater than zero. If $L$ is not greater than zero, this confidence interval is not defined, and missing values are reported.

When weights are specified, `ameans` applies the weights to the transformed values, $u_j = \ln x_j$ and $u_j = 1/x_j$, respectively, when computing the geometric and harmonic means. For details on how the weights are used to compute the mean and variance of the $u_j$, see [R] summarize. Without weights, the formula for the geometric mean reduces to

$$\exp\left\{\frac{1}{n} \sum_j \ln(x_j)\right\}$$

Without weights, the formula for the harmonic mean is

$$\frac{n}{\sum_j \frac{1}{x_j}}$$

Acknowledgments

This improved version of `ameans` is based on the `gmci` command (Carlin, Vidmar, and Ramalheira 1998) and was written by John Carlin of the Murdoch Children’s Research Institute and the University of Melbourne; Suzanna Vidmar of the University of Melbourne; and Carlos Ramalheira of Coimbra University Hospital, Portugal.

### Syntax

```plaintext
anova varname [termlist] [if] [in] [weight] [, options]
```

where `termlist` is a factor-variable list (see [U] 11.4.3 Factor variables) with the following additional features:

- Variables are assumed to be categorical; use the `c.` factor-variable operator to override this.
- The `|` symbol (indicating nesting) may be used in place of the `#` symbol (indicating interaction).
- The `/` symbol is allowed after a term and indicates that the following term is the error term for the preceding terms.

<table>
<thead>
<tr>

</tr>
<tr>
<td><code>dropemptycells</code></td>
<td>drop empty cells from the design matrix</td>
</tr>
</tbody>
</table>

**Adv. model**

- `bse(term)` — between-subjects error term in repeated-measures ANOVA
- `bseunit(varname)` — variable representing lowest unit in the between-subjects error term
- `grouping(varname)` — grouping variable for computing pooled covariance matrix

Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap. aweights are not allowed with the jackknife prefix; see [R] jackknife.

```plaintext
aweight s and fweight s are allowed; see [U] 11.1.6 weight.
```

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

### Menu

Statistics > Linear models and related > ANOVA/MANOVA > Analysis of variance and covariance

### Description

The `anova` command fits analysis-of-variance (ANOVA) and analysis-of-covariance (ANCOVA) models for balanced and unbalanced designs, including designs with missing cells; for repeated-measures ANOVA; and for factorial, nested, or mixed designs.
The `regress` command (see [R] regress) will display the coefficients, standard errors, etc., of the regression model underlying the last run of `anova`.

If you want to fit one-way ANOVA models, you may find the `oneway` or `loneway` command more convenient; see [R] oneway and [R] loneway. If you are interested in MANOVA or MANCOVA, see [MV] manova.

### Options

- `repeated(varlist)` indicates the names of the categorical variables in the terms that are to be treated as repeated-measures variables in a repeated-measures ANOVA or ANCOVA.
- `partial` presents the ANOVA table using partial (or marginal) sums of squares. This setting is the default. Also see the `sequential` option.
- `sequential` presents the ANOVA table using sequential sums of squares.
- `noconstant` suppresses the constant term (intercept) from the ANOVA or regression model.
- `dropemptycells` drops empty cells from the design matrix. If `c(emptycells)` is set to `keep` (see [R] set emptycells), this option temporarily resets it to `drop` before running the ANOVA model. If `c(emptycells)` is already set to `drop`, this option does nothing.

- `bse(term)` indicates the between-subjects error term in a repeated-measures ANOVA. This option is needed only in the rare case when the `anova` command cannot automatically determine the between-subjects error term.
- `bseunit(varname)` indicates the variable representing the lowest unit in the between-subjects error term in a repeated-measures ANOVA. This option is rarely needed because the `anova` command automatically selects the first variable listed in the between-subjects error term as the default for this option.
- `grouping(varname)` indicates a variable that determines which observations are grouped together in computing the covariance matrices that will be pooled and used in a repeated-measures ANOVA. This option is rarely needed because the `anova` command automatically selects the combination of all variables except the first (or as specified in the `bseunit()` option) in the between-subjects error term as the default for grouping observations.

### Remarks and examples

Remarks are presented under the following headings:

- Introduction
- One-way ANOVA
- Two-way ANOVA
- N-way ANOVA
- Weighted data
- ANCOVA
- Nested designs
- Mixed designs
- Latin-square designs
- Repeated-measures ANOVA
- Video examples
Introduction

*anova* uses least squares to fit the linear models known as ANOVA or ANCOVA (henceforth referred to simply as ANOVA models).

If your interest is in one-way ANOVA, you may find the *oneway* command to be more convenient; see [R] oneway.

Structural equation modeling provides a more general framework for fitting ANOVA models; see the *Stata Structural Equation Modeling Reference Manual*.

ANOVA was pioneered by Fisher. It features prominently in his texts on statistical methods and his design of experiments (1925, 1935). Many books discuss ANOVA; see, for instance, Altman (1991); van Belle et al. (2004); Cobb (1998); Snedecor and Cochran (1989); or Winer, Brown, and Michels (1991). For a classic source, see Scheffé (1959). Kennedy and Gentle (1980) discuss ANOVA’s computing problems. Edwards (1985) is concerned primarily with the relationship between multiple regression and ANOVA. Acok (2014, chap. 9) illustrates his discussion with Stata output. Repeated-measures ANOVA is discussed in Winer, Brown, and Michels (1991); Kuehl (2000); and Milliken and Johnson (2009). Pioneering work in repeated-measures ANOVA can be found in Box (1954); Geisser and Greenhouse (1958); Huynh and Feldt (1976); and Huynh (1978). For a Stata-specific discussion of ANOVA contrasts, see Mitchell (2012, chap. 7–9).

One-way ANOVA

*anova*, entered without options, performs and reports standard ANOVA. For instance, to perform a one-way layout of a variable called *endog* on *exog*, you would type *anova endog exog*.

➤ Example 1: One-way ANOVA

We run an experiment varying the amount of fertilizer used in growing apple trees. We test four concentrations, using each concentration in three groves of 12 trees each. Later in the year, we measure the average weight of the fruit.

If all had gone well, we would have had 3 observations on the average weight for each of the four concentrations. Instead, two of the groves were mistakenly leveled by a confused man on a large bulldozer. We are left with the following data:

```
. use http://www.stata-press.com/data/r13/apple
   (Apple trees)
. list, abbrev(10) sepby(treatment)
    +-----------+-----------------+----------+
   | treatment |    weight |        |   
   |           |          |        |   
   | 1.        |   117.5  |   113.8|   
   | 2.        |    104.4 |   48.9 |   
   | 3.        |    70.4  |   86.9 |   
   | 4.        |    87.7  |   67.3 |   
   +-----------+-----------------+----------+
```

---

<td>9</td>
<td>643.237333</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

We find significant (at better than the 1% level) differences among the four concentrations.

Although the output is a usual ANOVA table, let’s run through it anyway. Above the table is a summary of the underlying regression. The model was fit on 10 observations, and the root mean squared error (Root MSE) is 9.07. The \( R^2 \) for the model is 0.9147, and the adjusted \( R^2 \) is 0.8721.

The first line of the table summarizes the model. The sum of squares (Partial SS) for the model is 5295.5 with 3 degrees of freedom (df). This line results in a mean square (MS) of 5295.5/3 \( \approx \) 1765.2. The corresponding \( F \) statistic is 21.46 and has a significance level of 0.0013. Thus the model appears to be significant at the 0.13% level.

The next line summarizes the first (and only) term in the model, treatment. Because there is only one term, the line is identical to that for the overall model.

The third line summarizes the residual. The residual sum of squares is 493.59 with 6 degrees of freedom, resulting in a mean squared error of 82.27. The square root of this latter number is reported as the Root MSE.

The model plus the residual sum of squares equals the total sum of squares, which is reported as 5789.1 in the last line of the table. This is the total sum of squares of weight after removal of the mean. Similarly, the model plus the residual degrees of freedom sum to the total degrees of freedom, 9. Remember that there are 10 observations. Subtracting 1 for the mean, we are left with 9 total degrees of freedom.

⚠️ Technical note

Rather than using the `anova` command, we could have performed this analysis by using the `oneway` command. Example 1 in [R] `oneway` repeats this same analysis. You may wish to compare the output.

Type `regress` to see the underlying regression model corresponding to an ANOVA model fit using the `anova` command.

➤ Example 2: Regression table from a one-way ANOVA

Returning to the apple tree experiment, we found that the fertilizer concentration appears to significantly affect the average weight of the fruit. Although that finding is interesting, we next want to know which concentration appears to grow the heaviest fruit. One way to find out is by examining the underlying regression coefficients.

See [R] regress for an explanation of how to read this table. The baselevels option of regress displays a row indicating the base category for our categorical variable, treatment. In summary, we find that concentration 1, the base (omitted) group, produces significantly heavier fruits than concentration 2, 3, and 4; concentration 2 produces the lightest fruits; and concentrations 3 and 4 appear to be roughly equivalent.

Example 3: ANOVA replay

We previously typed anova weight treatment to produce and display the ANOVA table for our apple tree experiment. Typing regress displays the regression coefficients. We can redisplay the ANOVA table by typing anova without arguments:

. anova

Two-way ANOVA

You can include multiple explanatory variables with the anova command, and you can specify interactions by placing ‘#’ between the variable names. For instance, typing anova y a b performs a two-way layout of y on a and b. Typing anova y a b a#b performs a full two-way factorial layout. The shorthand anova y a##b does the same.

With the default partial sums of squares, when you specify interacted terms, the order of the terms does not matter. Typing anova y a b a#b is the same as typing anova y b a b#a.
Example 4: Two-way factorial ANOVA

The classic two-way factorial ANOVA problem, at least as far as computer manuals are concerned, is a two-way ANOVA design from Afifi and Azen (1979).

Fifty-eight patients, each suffering from one of three different diseases, were randomly assigned to one of four different drug treatments, and the change in their systolic blood pressure was recorded. Here are the data:

<table>
<thead>
<tr>
<th>Drug 1</th>
<th>Disease 1</th>
<th>Disease 2</th>
<th>Disease 3</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>42, 44, 36</td>

</tr>
</tbody>
</table>

Let's assume that we have entered these data into Stata and stored the data as systolic.dta. Below we use the data, list the first 10 observations, summarize the variables, and tabulate the control variables:

```
. use http://www.stata-press.com/data/r13/systolic
(Systolic Blood Pressure Data)
. list in 1/10
    +-----------------+-----------------+-----------------+-----------------+
   | drug | disease | systolic   |                |
   +-----------------+-----------------+-----------------+-----------------+
    1. | 1     | 1         | 42             |
    2. | 1     | 1         | 44             |
    3. | 1     | 1         | 36             |
    4. | 1     | 1         | 13             |

    7. | 1     | 2         | 33             |
    8. | 1     | 2         | 26             |
    9. | 1     | 2         | 33             |
   10. | 1     | 2         | 21             |
. summarize
  +-----------------+--------+----------+----------+-------+-------+
  | Variable | Obs  | Mean    | Std. Dev.| Min   | Max   |
  +-----------------+--------+----------+----------+-------+-------+
  | drug           | 58     | 2.5      | 1.158493 | 1     | 4     |
  | disease        | 58     | 2.017241 | .8269873 | 1     | 3     |
  | systolic        | 58     | 18.87931 | 12.80087 | –6    | 44    |
. tabulate drug disease
  +-----------------+-----------------+-----------------+-----------------+
  | Drug Used | Patient's Disease |                |                |
  +-----------------+-----------------+-----------------+-----------------+
   | 1     | 6     | 4         | 5     | 15    |
   | 2     | 5     | 4         | 6     | 15    |
   | 3     | 3     | 5         | 4     | 12    |
   | 4     | 5     | 6         | 5     | 16    |
  +-----------------+-----------------+-----------------+-----------------+
  | Total    | 19    | 19        | 20    | 58    |
```
Each observation in our data corresponds to one patient, and for each patient we record drug, disease, and the increase in the systolic blood pressure, systolic. The tabulation reveals that the data are not balanced—there are not equal numbers of patients in each drug–disease cell. Stata does not require that the data be balanced. We can perform a two-way factorial ANOVA by typing

```
  . anova systolic drug disease drug#disease
```

```
Number of obs = 58  R-squared = 0.4560
Root MSE = 10.5096  Adj R-squared = 0.3259

Source | Partial SS  df      MS   F     Prob > F
-------------|-------------|--------|------|------|---------------------
Model       | 4259.33851  11  387.212591 | 3.51 | 0.0013
  drug      | 2997.47186  3  999.157287 | 9.05 | 0.0001
  disease   | 415.873046  2  207.936523 | 1.88 | 0.1637
  drug#disease | 707.266259  6  117.87771  | 1.07 | 0.3958
Residual    | 5080.81667  46  110.452536
Total       | 9340.15517  57  163.862371

```

Although Stata’s `table` command does not perform ANOVA, it can produce useful summary tables of your data (see [R] `table`):

```
  . table drug disease, c(mean systolic) row col f(%8.2f)
```

```
<table>
<thead>
<tr>
<th>Drug Used</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>29.33</td>
<td>28.25</td>
<td>20.40</td>
<td>26.07</td>
</tr>
<tr>
<td>2</td>
<td>28.00</td>
<td>33.50</td>
<td>18.17</td>
<td>25.53</td>
</tr>
<tr>
<td>3</td>
<td>16.33</td>
<td>4.40</td>
<td>8.50</td>
<td>8.75</td>
</tr>
<tr>
<td>4</td>
<td>13.60</td>
<td>12.83</td>
<td>14.20</td>
<td>13.50</td>
</tr>
<tr>
<td>Total</td>
<td>22.79</td>
<td>18.21</td>
<td>15.80</td>
<td>18.88</td>
</tr>
</tbody>
</table>
```

These are simple means and are not influenced by our `anova` model. More useful is the `margins` command (see [R] `margins`) that provides marginal means and adjusted predictions. Because drug is the only significant factor in our ANOVA, we now examine the adjusted marginal means for drug.

```
  . margins drug, asbalanced
```

```
Expression : Linear prediction, predict()
at : drug (asbalanced)
  disease (asbalanced)

|    | Margin | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|----|--------|-----------|------|------|----------------------|
|    |        |           |      |      |                      |
| drug |        |           |      |      |                      |
| 1   | 25.994444 | 2.751008 | 9.45 | 0.000 | 20.45695 | 31.53194 |
| 2   | 26.55556  | 2.751008 | 9.65 | 0.000 | 21.01806 | 32.09305 |
| 3   | 9.744444  | 3.100558 | 3.14 | 0.003 | 3.503344 | 15.98554 |
| 4   | 13.54444  | 2.637123 | 5.14 | 0.000 | 8.236191 | 18.8527 |
```

These adjusted marginal predictions are not equal to the simple drug means (see the total column from the `table` command); they are based upon predictions from our ANOVA model. The `asbalanced` option of `margins` corresponds with the interpretation of the $F$ statistic produced by ANOVA—each cell is given equal weight regardless of its sample size (see the following three technical notes). You
can omit the *asbalanced* option and obtain predictive margins that take into account the unequal sample sizes of the cells.

```
.margins drug
Predictive margins                                      Number of obs =  58
Expression : Linear prediction, predict()
```

| Marginal Delta-method | Margin | Std. Err. | t | P>|t| | [95% Conf. Interval] |
|-----------------------|--------|-----------|---|------|---------------------|
| drug                  |        |           |   |      |                     |
| 1                     | 25.89799 | 2.750533  | 9.42 | 0.000 | 20.36145 - 31.43452 |
| 2                     | 26.41092 | 2.742762  | 9.63 | 0.000 | 20.89003 - 31.93181 |
| 3                     | 9.722989 | 3.099185  | 3.14 | 0.003 | 3.484652 - 15.96132 |
| 4                     | 13.55575 | 2.640602  | 5.13 | 0.000 | 8.24049 - 18.871    |

> Technical note

How do you interpret the significance of terms like *drug* and *disease* in unbalanced data? If you are familiar with SAS, the sums of squares and the $F$ statistic reported by Stata correspond to SAS type III sums of squares. (Stata can also calculate sequential sums of squares, but we will postpone that topic for now.)

Let's think in terms of the following table:

<table>
<thead>
<tr>
<th>Drug</th>
<th>Disease 1</th>
<th>Disease 2</th>
<th>Disease 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>$\mu_{11}$</td>
<td>$\mu_{12}$</td>
<td>$\mu_{13}$</td>
</tr>
<tr>
<td>2</td>
<td>$\mu_{21}$</td>
<td>$\mu_{22}$</td>
<td>$\mu_{23}$</td>
</tr>
<tr>
<td>3</td>
<td>$\mu_{31}$</td>
<td>$\mu_{32}$</td>
<td>$\mu_{33}$</td>
</tr>
<tr>
<td>4</td>
<td>$\mu_{41}$</td>
<td>$\mu_{42}$</td>
<td>$\mu_{43}$</td>
</tr>
</tbody>
</table>

In this table, $\mu_{ij}$ is the mean increase in systolic blood pressure associated with drug $i$ and disease $j$, while $\mu_i$ is the mean for drug $i$, $\mu_j$ is the mean for disease $j$, and $\mu_\cdot$ is the overall mean.

If the data are balanced, meaning that there are equal numbers of observations going into the calculation of each mean $\mu_{ij}$, the row means, $\mu_i$, are given by

$$
\mu_i = \frac{\mu_{i1} + \mu_{i2} + \mu_{i3}}{3}
$$

In our case, the data are not balanced, but we define the $\mu_i$ according to that formula anyway. The test for the main effect of drug is the test that

$$
\mu_1 = \mu_2 = \mu_3 = \mu_4.
$$

To be absolutely clear, the $F$ test of the term *drug*, called the *main effect* of drug, is formally equivalent to the test of the three constraints:
\[
\frac{\mu_{11} + \mu_{12} + \mu_{13}}{3} = \frac{\mu_{21} + \mu_{22} + \mu_{23}}{3} \\
\frac{\mu_{11} + \mu_{12} + \mu_{13}}{3} = \frac{\mu_{31} + \mu_{32} + \mu_{33}}{3} \\
\frac{\mu_{11} + \mu_{12} + \mu_{13}}{3} = \frac{\mu_{41} + \mu_{42} + \mu_{43}}{3}
\]

In our data, we obtain a significant $F$ statistic of 9.05 and thus reject those constraints.

**Technical note**

Stata can display the symbolic form underlying the test statistics it presents, as well as display other test statistics and their symbolic forms; see *Obtaining symbolic forms* in [R] *anova postestimation*. Here is the result of requesting the symbolic form for the main effect of `drug` in our data:

```
.test drug, symbolic
drug
  1  -(r2+r3+r4)
  2  r2
  3  r3
  4  r4
disease
  1  0
  2  0
  3  0
drug#disease
  1  1  -1/3 (r2+r3+r4)
  1  2  -1/3 (r2+r3+r4)
  1  3  -1/3 (r2+r3+r4)
  2  1  1/3 r2
  2  2  1/3 r2
  2  3  1/3 r2
  3  1  1/3 r3
  3  2  1/3 r3
  3  3  1/3 r3
  4  1  1/3 r4
  4  2  1/3 r4
  4  3  1/3 r4
_cons  0
```

This says exactly what we said in the previous technical note.

**Technical note**

Saying that there is no main effect of a variable is not the same as saying that it has no effect at all. Stata’s ability to perform ANOVA on unbalanced data can easily be put to ill use.

For example, consider the following table of the probability of surviving a bout with one of two diseases according to the drug administered to you:
If you have disease 1 and are administered drug 1, you live. If you have disease 2 and are administered drug 2, you live. In all other cases, you die.

This table has no main effects of either drug or disease, although there is a large interaction effect. You might now be tempted to reason that because there is only an interaction effect, you would be indifferent between the two drugs in the absence of knowledge about which disease infects you. Given an equal chance of having either disease, you reason that it does not matter which drug is administered to you—either way, your chances of surviving are 0.5.

You may not, however, have an equal chance of having either disease. If you knew that disease 1 was 100 times more likely to occur in the population, and if you knew that you had one of the two diseases, you would express a strong preference for receiving drug 1.

When you calculate the significance of main effects on unbalanced data, you must ask yourself why the data are unbalanced. If the data are unbalanced for random reasons and you are making predictions for a balanced population, the test of the main effect makes perfect sense. If, however, the data are unbalanced because the underlying populations are unbalanced and you are making predictions for such unbalanced populations, the test of the main effect may be practically—if not statistically—meaningless.

Example 5: ANOVA with missing cells

Stata can perform ANOVA not only on unbalanced populations, but also on populations that are so unbalanced that entire cells are missing. For instance, using our systolic blood pressure data, let’s refit the model eliminating the drug 1–disease 1 cell. Because `anova` follows the same syntax as all other Stata commands, we can explicitly specify the data to be used by typing the `if` qualifier at the end of the `anova` command. Here we want to use the data that are not for drug 1 and disease 1:

```
. anova systolic drug##disease if !(drug==1 & disease==1)
```

```
Number of obs = 52  R-squared = 0.4545
Root MSE = 10.1615  Adj R-squared = 0.3215

Source                  Partial SS  df       MS        F        Prob > F
Model                    3527.95897  10  352.795897  3.42  0.0025
  drug                    2686.57832   3  895.526107  8.67  0.0001
  disease                 327.792598  2   163.896299  1.59  0.2168
  drug#disease            703.007602  5   140.60152  1.36  0.2586
Residual                 4233.48333  41  103.255691
Total                    7761.44231  51  152.185143
```

Here we used `drug##disease` as a shorthand for `drug disease drug#disease`. 
The test of the main effect of drug in the presence of missing cells is more complicated than that for unbalanced data. Our underlying tableau now has the following form:

<table>
<thead>
<tr>
<th></th>
<th>Disease 1</th>
<th>Disease 2</th>
<th>Disease 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>Drug 1</td>
<td>$\mu_{12}$</td>
<td>$\mu_{13}$</td>
<td></td>
</tr>
<tr>
<td>Drug 2</td>
<td>$\mu_{21}$</td>
<td>$\mu_{22}$</td>
<td>$\mu_{23}$</td>
</tr>
<tr>
<td>Drug 3</td>
<td>$\mu_{31}$</td>
<td>$\mu_{32}$</td>
<td>$\mu_{33}$</td>
</tr>
<tr>
<td>Drug 4</td>
<td>$\mu_{41}$</td>
<td>$\mu_{42}$</td>
<td>$\mu_{43}$</td>
</tr>
</tbody>
</table>

The hole in the drug 1–disease 1 cell indicates that the mean is unobserved. Considering the main effect of drug, the test is unchanged for the rows in which all the cells are defined:

$$\mu_2 = \mu_3 = \mu_4.$$

The first row, however, requires special attention. Here we want the average outcome for drug 1, which is averaged only over diseases 2 and 3, to be equal to the average values of all other drugs averaged over those same two diseases:

$$\frac{\mu_{12} + \mu_{13}}{2} = \frac{(\mu_{22} + \mu_{23})}{3}/2 + \frac{(\mu_{32} + \mu_{33})}{3}/2 + \frac{(\mu_{42} + \mu_{43})}{3}/2$$

Thus the test contains three constraints:

$$\frac{\mu_{21} + \mu_{22} + \mu_{23}}{3} = \frac{\mu_{31} + \mu_{32} + \mu_{33}}{3}$$

$$\frac{\mu_{21} + \mu_{22} + \mu_{23}}{3} = \frac{\mu_{41} + \mu_{42} + \mu_{43}}{3}$$

$$\frac{\mu_{12} + \mu_{13}}{2} = \frac{\mu_{22} + \mu_{23} + \mu_{32} + \mu_{33} + \mu_{42} + \mu_{43}}{6}$$

Stata can calculate two types of sums of squares, *partial* and *sequential*. If you do not specify which sums of squares to calculate, Stata calculates partial sums of squares. The technical notes above have gone into great detail about the definition and use of partial sums of squares. Use the *sequential* option to obtain sequential sums of squares.

Before we illustrate sequential sums of squares, consider one more feature of the partial sums. If you know how such things are calculated, you may worry that the terms must be specified in some particular order, that Stata would balk or, even worse, produce different results if you typed, say, `anova drug#disease drug disease` rather than `anova drug disease drug#disease`. We assure you that is not the case.

When you type a model, Stata internally reorganizes the terms, forms the cross-product matrix, inverts it, converts the result to an upper-Hermite form, and then performs the hypothesis tests. As a final touch, Stata reports the results in the same order that you typed the terms.
Example 6: Sequential sums of squares

We wish to estimate the effects on systolic blood pressure of drug and disease by using sequential sums of squares. We want to introduce disease first, then drug, and finally, the interaction of drug and disease:

```
    . anova systolic disease drug disease#drug, sequential
```

```
                      Number of obs = 58                  R-squared = 0.4560
                      Root MSE = 10.5096                  Adj R-squared = 0.3259
                  Source         | Seq. SS  df    MS     F     Prob > F
                      Model         | 4259.33851 11 387.212591 3.51  0.0013
                      disease      | 488.639383  2 244.319691  2.21  0.1210
                      drug         | 3063.43286  3 1021.14429  9.25  0.0001
                      disease#drug | 707.266259  6 117.87771  1.07  0.3958
                      Residual     | 5080.81667 46 110.452536
                      Total        | 9340.15517 57 163.862371
```

The $F$ statistic on disease is now 2.21. When we fit this same model by using partial sums of squares, the statistic was 1.88.

N-way ANOVA

You may include high-order interaction terms, such as a third-order interaction between the variables A, B, and C, by typing A#B#C.

Example 7: Three-way factorial ANOVA

We wish to determine the operating conditions that maximize yield for a manufacturing process. There are three temperature settings, two chemical supply companies, and two mixing methods under investigation. Three observations are obtained for each combination of these three factors.

```

Here our ANOVA is balanced (each cell has the same number of observations), and we obtain the same values as in the table above (but with additional information such as confidence intervals) by using the `margins` command. Because our ANOVA is balanced, using the `asbalanced` option with `margins` would not produce different results. We request the predictive margins for the two terms that appear significant in our ANOVA: `temperature#method` and `method`.
We decide to use the folding method of mixing and a high temperature in our manufacturing process.

Weighted data

Like all estimation commands, anova can produce estimates on weighted data. See [U] 11.1.6 weight for details on specifying the weight.

Example 8: Three-way factorial ANOVA on grouped data

We wish to investigate the prevalence of byssinosis, a form of pneumoconiosis that can afflict workers exposed to cotton dust. We have data on 5,419 workers in a large cotton mill. We know whether each worker smokes, his or her race, and the dustiness of the work area. The variables are

- **smokes**: smoker or nonsmoker in the last five years
- **race**: white or other
- **workplace**: 1 (most dusty), 2 (less dusty), 3 (least dusty)

We wish to fit an ANOVA model explaining the prevalence of byssinosis according to a full factorial model of smokes, race, and workplace.

The data are unbalanced. Moreover, although we have data on 5,419 workers, the data are grouped according to the explanatory variables, along with some other variables, resulting in 72 observations. For each observation, we know the number of workers in the group (pop), the prevalence of byssinosis (prob), and the values of the three explanatory variables. Thus we wish to fit a three-way factorial model on grouped data.

We begin by showing a bit of the data, which are from Higgins and Koch (1977).

<td>.152439</td>
</tr>
<tr>
<td>yes</td>
<td>other</td>
<td>less</td>
<td>88</td>
<td>0</td>
</tr>
</tbody>
</table>

The first observation in the data represents a group of 40 white workers who smoke and work in a “most” dusty work area. Of those 40 workers, 7.5% have byssinosis. The second observation represents a group of 74 white workers who also smoke but who work in a “less” dusty environment. None of those workers has byssinosis.

Almost every Stata command allows weights. Here we want to weight the data by pop. We can, for instance, make a table of the number of workers by their smoking status and race:

. tabulate smokes race [fw=pop]

<table>
<thead>
<tr>
<th>Smokes</th>
<th>Race</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>other</td>
<td>white</td>
</tr>
<tr>
<td>no</td>
<td>799</td>
<td>1,431</td>
</tr>
<tr>
<td>yes</td>
<td>1,104</td>
<td>2,085</td>
</tr>
</tbody>
</table>

The [fw=pop] at the end of the tabulate command tells Stata to count each observation as representing pop persons. When making the tally, tabulate treats the first observation as representing 40 workers, the second as representing 74 workers, and so on.

Similarly, we can make a table of the dustiness of the workplace:
We can discover the average incidence of byssinosis among these workers by typing:

```
. summarize prob [fw=pop]
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>prob</td>
<td>5419</td>
<td>.0304484</td>
<td>.0567373</td>
<td>0</td>
<td>.287037</td>
</tr>
</tbody>
</table>

We discover that 3.04% of these workers have byssinosis. Across all cells, the byssinosis rates vary from 0 to 28.7%. Just to prove that there might be something here, let’s obtain the average incidence rates according to the dustiness of the workplace:

```
. table workplace smokes race [fw=pop], c(mean prob)
```

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>Race and Smokes</th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>

</tbody>
</table>

Of course, if we want to see the underlying regression, we could type `regress`.  

Above we examined simple means of the cells of `workplace#smokes#race`. Our ANOVA shows `workplace`, `smokes`, and their interaction as being the only significant factors in our model. We now examine the predictive marginal mean byssinosis rates for these terms.
Smoking combined with the most dusty workplace produces the highest byssinosis rates.

Ronald Aylmer Fisher (1890–1962) (Sir Ronald from 1952) studied mathematics at Cambridge. Even before he finished his studies, he had published on statistics. He worked as a statistician at Rothamsted Experimental Station (1919–1933), as professor of eugenics at University College London (1933–1943), as professor of genetics at Cambridge (1943–1957), and in retirement at the CSIRO Division of Mathematical Statistics in Adelaide. His many fundamental and applied contributions to statistics and genetics mark him as one of the greatest statisticians of all time, including original work on tests of significance, distribution theory, theory of estimation, fiducial inference, and design of experiments.

**ANCOVA**

You can include multiple explanatory variables with the `anova` command, but unless you explicitly state otherwise by using the `c.` factor-variable operator, all the variables are interpreted as categorical variables. Using the `c.` operator, you can designate variables as continuous and thus perform ANCOVA.

### Example 9: ANCOVA (ANOVA with a continuous covariate)

We have census data recording the death rate (`drate`) and median age (`age`) for each state. The dataset also includes the region of the country in which each state is located (`region`):

```

</tbody>
</table>
```
\textbf{. use} \texttt{http://www.stata-press.com/data/r13/census2} \\
(1980 Census data by state) \\
\textbf{. summarize drate age region} \\
\begin{tabular}{lcccc} 
\hline
Variable & Obs & Mean & Std. Dev. & Min & Max \\
\hline
drate & 50 & 84.3 & 13.07318 & 40 & 107 \\
age & 50 & 29.5 & 1.752549 & 24 & 35 \\
region & 50 & 2.66 & 1.061574 & 1 & 4 \\
\hline
\end{tabular}

\textit{age} is coded in integral years from 24 to 35, and \textit{region} is coded from 1 to 4, with 1 standing for the Northeast, 2 for the North Central, 3 for the South, and 4 for the West.

When we examine the data more closely, we discover large differences in the death rate across regions of the country:

\textbf{. tabulate region, summarize(drate)}

\begin{tabular}{lcccc} 
\hline
Census region & Summary of Death Rate & \\
& Mean & Std. Dev. & Freq. & \\
\hline
NE & 93.444444 & 7.0553368 & 9 \\
N Cntrl & 88.916667 & 5.5833899 & 12 \\
South & 88.3125 & 8.5457104 & 16 \\
West & 68.769231 & 13.342625 & 13 \\
\hline
Total & 84.3 & 13.073185 & 50 \\
\hline
\end{tabular}

Naturally, we wonder if these differences might not be explained by differences in the median ages of the populations. To find out, we fit a regression model (via \texttt{anova}) of \textit{drate} on \textit{region} and \textit{age}. In the \texttt{anova} example below, we treat \textit{age} as a categorical variable.

\textbf{. anova drate region age} \\
\begin{tabular}{lcccc} 
\hline
Source & Partial SS & df & MS & F & Prob > F \\
\hline
Model & 6638.86529 & 11 & 603.533208 & 13.21 & 0.0000 \\
region & 1320.00973 & 3 & 440.003244 & 9.63 & 0.0001 \\
age & 2237.24937 & 8 & 279.656171 & 6.12 & 0.0000 \\
Residual & 1735.63471 & 38 & 45.6745977 & & \\
\hline
Total & 8374.5 & 49 & 170.908163 & & \\
\hline
\end{tabular}

We have the answer to our question: differences in median ages do not eliminate the differences in death rates across the four regions. The ANOVA table summarizes the two terms in the model, \textit{region} and \textit{age}. The \textit{region} term contains 3 degrees of freedom, and the \textit{age} term contains 8 degrees of freedom. Both are significant at better than the 1% level.

The \textit{age} term contains 8 degrees of freedom. Because we did not explicitly indicate that \textit{age} was to be treated as a continuous variable, it was treated as \textit{categorical}, meaning that unique coefficients were estimated for each level of age. The only clue of this labeling is that the number of degrees of freedom associated with the \textit{age} term exceeds 1. The labeling becomes more obvious if we review the regression coefficients:
The `regress` command displayed the `anova` model as a regression table. We used the `baselevels` option to display the dropped level (or base) for each term.

If we want to treat `age` as a continuous variable, we must prepend `c.` to `age` in our `anova`.

```
. anova drate region c.age
Number of obs = 50 R-squared = 0.7203
Root MSE = 7.21483 Adj R-squared = 0.6954
```

The `age` term now has 1 degree of freedom. The regression coefficients are
Although we started analyzing these data to explain the regional differences in death rate, let’s focus on the effect of age for a moment. In our first model, each level of age had a unique death rate associated with it. For instance, the predicted death rate in a north central state with a median age of 28 was

\[0.44 + 12.66 + 68.37 \approx 81.47\]

whereas the predicted death rate from our current model is

\[1.79 + 3.92 \times 28 - 28.60 \approx 82.95\]

Our previous model had an $R^2$ of 0.7927, whereas our current model has an $R^2$ of 0.7203. This “small” loss of predictive power accompanies a gain of 7 degrees of freedom, so we suspect that the continuous-age model is as good as the discrete-age model.

**Technical note**

There is enough information in the two ANOVA tables to attach a statistical significance to our suspicion that the loss of predictive power is offset by the savings in degrees of freedom. Because the continuous-age model is nested within the discrete-age model, we can perform a standard Chow test. For those of us who know such formulas off the top of our heads, the $F$ statistic is

\[
\frac{(2342.41746 - 1735.63471)/7}{45.6745977} = 1.90
\]

There is, however, a better way.

We can find out whether our continuous model is as good as our discrete model by putting age in the model twice: once as a continuous variable and once as a categorical variable. The categorical variable will then measure deviations around the straight line implied by the continuous variable, and the $F$ test for the significance of the categorical variable will test whether those deviations are jointly zero.
**Example 10: Interaction of continuous and categorical variables**

In our census data, we still find significant differences across the regions after controlling for the median age of the population. We might now wonder whether the regional differences are differences in level— independent of age—or are instead differences in the regional effects of age. Just as we can interact categorical variables with other categorical variables, we can interact categorical variables with continuous variables.

```plaintext
.anova drate region c.age region#c.age
```

The `region#c.age` term in our model measures the differences in slopes across the regions. We cannot reject the null hypothesis that there are no such differences. The `region` effect is now “insignificant”. This status does not mean that there are no regional differences in death rates because each test is a marginal or partial test. Here, with `region#c.age` included in the model, `region` is being tested at the point where `age` is zero. Apart from this value not existing in the dataset, it is also a long way from the mean value of `age`, so the test of `region` at this point is meaningless (although it is valid if you acknowledge what is being tested).

To obtain a more sensible test of `region`, we can subtract the mean from the `age` variable and use this in the model.

```plaintext
. quietly summarize age
. generate mage = age - r(mean)
```
region is significant when tested at the mean of the age variable.

Remember that we can specify interactions by typing `varname#varname`. We have seen examples of interacting categorical variables with categorical variables and, in the examples above, a categorical variable (region) with a continuous variable (age or mage).

We can also interact continuous variables with continuous variables. To include an age^2 term in our model, we could type `c.age#c.age`. If we also wanted to interact the categorical variable region with the age^2 term, we could type `region#c.age#c.age` (or even `c.age#region#c.age`).

## Nested designs

In addition to specifying interaction terms, nested terms can also be specified in an ANOVA. A vertical bar is used to indicate nesting: `A|B` is read as A nested within B. A|B|C is read as A nested within B, which is nested within C. A|B#C is read as A is nested within the interaction of B and C. A#B|C is read as the interaction of A and B, which is nested within C.

Different error terms can be specified for different parts of the model. The forward slash is used to indicate that the next term in the model is the error term for what precedes it. For instance, `anova y A / B|A` indicates that the F test for A is to be tested by using the mean square from B|A in the denominator. Error terms (terms following the slash) are generally not tested unless they are themselves followed by a slash. Residual error is the default error term.

For example, consider `A / B / C`, where A, B, and C may be arbitrarily complex terms. Then `anova` will report A tested by B and B tested by C. If we add one more slash on the end to form `A / B / C /`, then `anova` will also report C tested by the residual error.

### Example 11: Simple nested ANOVA

We have collected data from a manufacturer that is evaluating which of five different brands of machinery to buy to perform a particular function in an assembly line. Twenty assembly-line employees were selected at random for training on these machines, with four employees assigned to learn a particular machine. The output from each employee (operator) on the brand of machine for which he trained was measured during four trial periods. In this example, the operator is nested within machine. Because of sickness and employee resignations, the final data are not balanced. The following table gives the mean output and sample size for each machine and operator combination.
Assuming that operator is random (that is, we wish to infer to the larger population of possible operators) and machine is fixed (that is, only these five machines are of interest), the typical test for machine uses operator nested within machine as the error term. operator nested within machine can be tested by residual error. Our earlier warning concerning designs with either unplanned missing cells or unbalanced cell sizes, or both, also applies to interpreting the ANOVA results from this unbalanced nested example.

The results indicate that the machines are not all equal and that there are significant differences between operators.
Example 12: ANOVA with multiple levels of nesting

Your company builds and operates sewage treatment facilities. You want to compare two particulate solutions during the particulate reduction step of the sewage treatment process. For each solution, two area managers are randomly selected to implement and oversee the change to the new treatment process in two of their randomly chosen facilities. Two workers at each of these facilities are trained to operate the new process. A measure of particulate reduction is recorded at various times during the month at each facility for each worker. The data are described below.

```
. use http://www.stata-press.com/data/r13/sewage
(Sewage treatment)
. describe
Contains data from http://www.stata-press.com/data/r13/sewage.dta
obs: 64 Sewage treatment
vars: 5 9 May 2013 12:43
size: 320

storage  display value
variable name type format label variable label

particulate byte %9.0g particulate reduction
solution byte %9.0g 2 particulate solutions
manager byte %9.0g 2 managers per solution
facility byte %9.0g 2 facilities per manager
worker byte %9.0g 2 workers per facility

Sorted by: solution manager facility worker
```

You want to determine if the two particulate solutions provide significantly different particulate reduction. You would also like to know if manager, facility, and worker are significant effects. solution is a fixed factor, whereas manager, facility, and worker are random factors.

In the following `anova` command, we use abbreviations for the variable names, which can sometimes make long ANOVA model statements easier to read.

```
. anova particulate s / m|s / f|m|s / w|f|m|s /, dropemptycells

Number of obs = 64 R-squared = 0.6338
Root MSE = 12.7445 Adj R-squared = 0.5194

Source Partial SS   df   MS         F      Prob > F

          worker|facility|manager|solution  3064.9375  4  766.234375  2.57   0.1193
          solution  3064.9375  4  766.234375  2.57   0.1193
          worker|facility|solution  2386.625  8  298.328125  1.84   0.0931
          manager|solution  2386.625  8  298.328125  1.84   0.0931
          Residual  7796.25  48  162.421875
          Total  21289.8594  63  337.934276
```

While solution is not declared significant at the 5% significance level, it is near enough to that threshold to warrant further investigation (see example 3 in [R] `anova postestimation` for a continuation of the analysis of these data).

Technical note

Why did we use the `dropemptycells` option with the previous `anova`? By default, Stata retains empty cells when building the design matrix and currently treats | and # the same in how it determines the possible number of cells. Retaining empty cells in an ANOVA with nested terms can cause your design matrix to become too large. In example 12, there are $1024 = 2 \times 4 \times 8 \times 16$ cells that are considered possible for the `worker|facility|manager|solution` term because the worker, facility, and manager variables are uniquely numbered. With the `dropemptycells` option, the `worker|facility|manager|solution` term requires just 16 columns in the design matrix (corresponding to the 16 unique workers).

Why did we not use the `dropemptycells` option in example 11, where `operator` is nested in `machine`? If you look at the table presented at the beginning of that example, you will see that `operator` is compactly instead of uniquely numbered (you need both `operator` number and `machine` number to determine the `operator`). Here the `dropemptycells` option would have only reduced our design matrix from 26 columns down to 24 columns (because there were only 3 operators instead of 4 for `machines` 3 and 5).

We suggest that you specify `dropemptycells` when there are nested terms in your ANOVA. You could also use the `set emptycells drop` command to accomplish the same thing; see [R] `set`.

Mixed designs

An ANOVA can consist of both nested and crossed terms. A split-plot ANOVA design provides an example.

Example 13: Split-plot ANOVA

Two reading programs and three skill-enhancement techniques are under investigation. Ten classes of first-grade students were randomly assigned so that five classes were taught with one reading program and another five classes were taught with the other. The 30 students in each class were divided into six groups with 5 students each. Within each class, the six groups were divided randomly so that each of the three skill-enhancement techniques was taught to two of the groups within each class. At the end of the school year, a reading assessment test was administered to all the students. In this split-plot ANOVA, the whole-plot treatment is the two reading programs, and the split-plot treatment is the three skill-enhancement techniques.

In this split-plot ANOVA, the error term for program is class nested within program. The error term for skill and the program by skill interaction is the class by skill interaction nested within program. Other terms are also involved in the model and can be seen below.

Our anova command is too long to fit on one line of this manual. Where we have chosen to break the command into multiple lines is arbitrary. If we were typing this command into Stata, we would just type along and let Stata automatically wrap across lines, as necessary.

```
. anova score prog / class|prog skill prog#skill / class#skill|prog /
> group|class#skill|prog /, dropemptycells
```

. marginsplot, plot2opts(lp(dash) m(D)) plot3opts(lp(dot) m(T))
Variables that uniquely identify margins: program skill

. margins, within(program)
Predictive margins Number of obs = 300
Expression : Linear prediction, predict()
within : program
Empty cells : reweight

|                  | Delta-method | Margin | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|------------------|--------------|--------|-----------|-------|------|----------------------|
| program          |              |        |           |       |      |                      |
| 1                |              | 60.85333 | 1.194273  | 50.95 | 0.000| 58.50074 63.20593    |
| 2                |              | 53.11333 | 1.194273  | 44.47 | 0.000| 50.76074 55.46593    |

Because our ANOVA involves nested terms, we used the within() option of margins; see [R] margins.

skill 2 produces a low score when combined with program 1 and a high score when combined with program 2, demonstrating the interaction between the reading program and the skill-enhancement
You might conclude that the first reading program and the first skill-enhancement technique perform best when combined. However, notice the overlapping confidence interval for the first reading program and the third skill-enhancement technique.

**Technical note**

There are several valid ways to write complicated anova terms. In the reading experiment example (example 13), we had a term $\text{group|class#skill|program}$. This term can be read as group nested within both class and skill and further nested within program. You can also write this term as $\text{group|class#skill#program}$ or $\text{group|program#class#skill}$ or $\text{group|skill#class|program}$, etc. All variations will produce the same result. Some people prefer having only one ‘|’ in a term and would use $\text{group|class#skill#program}$, which is read as group nested within class, skill, and program.

Gertrude Mary Cox (1900–1978) was born on a farm near Dayton, Iowa. Initially intending to become superintendent of an orphanage, she enrolled at Iowa State College. There she majored in mathematics and attained the college’s first Master’s degree in statistics. After working on her PhD in psychological statistics for two years at the University of California–Berkeley, she decided to go back to Iowa State to work with George W. Snedecor. There she pursued her interest in and taught a course in design of experiments. That work led to her collaboration with W. G. Cochran, which produced a classic text. In 1940, when Snedecor shared with her his list of men he was nominating to head the statistics department at North Carolina State College, she wanted to know why she had not been included. He added her name, she won the position, and she built an outstanding department at North Carolina State. Cox retired early so she could work at the Research Triangle Institute in North Carolina. She consulted widely, served as editor of *Biometrics*, and was elected to the National Academy of Sciences.

**Latin-square designs**

You can use anova to analyze a Latin-square design. Consider the following example, published in Snedecor and Cochran (1989).

**Example 14: Latin-square ANOVA**

Data from a Latin-square design are as follows:

<table>
<thead>
<tr>
<th>Row</th>
<th>Column 1</th>
<th>Column 2</th>
<th>Column 3</th>
<th>Column 4</th>
<th>Column 5</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>257(B)</td>
<td>230(E)</td>
<td>279(A)</td>
<td>287(C)</td>
<td>202(D)</td>
</tr>
<tr>
<td>2</td>
<td>245(D)</td>
<td>283(A)</td>
<td>245(E)</td>
<td>280(B)</td>
<td>260(C)</td>
</tr>
<tr>
<td>3</td>
<td>182(E)</td>
<td>252(B)</td>
<td>280(C)</td>
<td>246(D)</td>
<td>250(A)</td>
</tr>
<tr>
<td>4</td>
<td>203(A)</td>
<td>204(C)</td>
<td>227(D)</td>
<td>193(E)</td>
<td>259(B)</td>
</tr>
<tr>
<td>5</td>
<td>231(C)</td>
<td>271(D)</td>
<td>266(B)</td>
<td>334(A)</td>
<td>338(E)</td>
</tr>
</tbody>
</table>
In Stata, the data might appear as follows:

```
. use http://www.stata-press.com/data/r13/latinsq
. list

<table>
<thead>
<tr>
<th>row</th>
<th>c1</th>
<th>c2</th>
<th>c3</th>

</tr>
<tr>
<td>5.</td>
<td>5</td>
<td>231</td>
<td>271</td>
<td>266</td>
<td>334</td>
</tr>
</tbody>
</table>
```

Before `anova` can be used on these data, the data must be organized so that the outcome measurement is in one column. `reshape` is inadequate for this task because there is information about the treatments in the sequence of these observations. `pkshape` is designed to reshape this type of data; see `[R] pkshape`.

```
. pkshape row row c1-c5, order(beacd daebc ebcda acdeb cdbae)

These methods will work with any type of Latin-square design, including those with replicated measurements. For more information, see [R] pk, [R] pkcross, and [R] pkshape.

Repeated-measures ANOVA

One approach for analyzing repeated-measures data is to use multivariate ANOVA (MANOVA); see [MV] manova. In this approach, the data are placed in wide form (see [D] reshape), and the repeated measures enter the MANOVA as dependent variables.

A second approach for analyzing repeated measures is to use anova. However, one of the underlying assumptions for the F tests in ANOVA is independence of observations. In a repeated-measures design, this assumption is almost certainly violated or is at least suspect. In a repeated-measures ANOVA, the subjects (or whatever the experimental units are called) are observed for each level of one or more of the other categorical variables in the model. These variables are called the repeated-measure variables. Observations from the same subject are likely to be correlated.

The approach used in repeated-measures ANOVA to correct for this lack of independence is to apply a correction to the degrees of freedom of the F test for terms in the model that involve repeated measures. This correction factor, $\epsilon$, lies between the reciprocal of the degrees of freedom for the repeated term and 1. Box (1954) provided the pioneering work in this area. Milliken and Johnson (2009) refer to the lower bound of this correction factor as Box’s conservative correction factor. Winer, Brown, and Michels (1991) call it simply the conservative correction factor.

Geisser and Greenhouse (1958) provide an estimate for the correction factor called the Greenhouse–Geisser $\epsilon$. This value is estimated from the data. Huynh and Feldt (1976) show that the Greenhouse–Geisser $\epsilon$ tends to be conservatively biased. They provide a revised correction factor called the Huynh–Feldt $\epsilon$. When the Huynh–Feldt $\epsilon$ exceeds 1, it is set to 1. Thus there is a natural ordering for these correction factors:

Box’s conservative $\epsilon \leq$ Greenhouse–Geisser $\epsilon \leq$ Huynh–Feldt $\epsilon \leq 1$

A correction factor of 1 is the same as no correction.

anova with the repeated() option computes these correction factors and displays the revised test results in a table that follows the standard ANOVA table. In the resulting table, H-F stands for Huynh–Feldt, G-G stands for Greenhouse–Geisser, and Box stands for Box’s conservative $\epsilon$. 
Example 15: Repeated-measures ANOVA

This example is taken from table 4.3 of Winer, Brown, and Michels (1991). The reaction time for five subjects each tested with four drugs was recorded in the variable `score`. Here is a table of the data (see `[P] tabdisp` if you are unfamiliar with `tabdisp`):

```
. use http://www.stata-press.com/data/r13/t43, clear
   (T4.3 -- Winer, Brown, Michels)
. tabdisp person drug, cellvar(score)

<table>
<thead>
<tr>
<th>person</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>30</td>
<td>28</td>
<td>16</td>
<td>34</td>
</tr>
<tr>
<td>2</td>
<td>14</td>
<td>18</td>
<td>10</td>
<td>22</td>
</tr>
<tr>
<td>3</td>
<td>24</td>
<td>20</td>
<td>18</td>
<td>30</td>
</tr>
<tr>
<td>4</td>
<td>38</td>
<td>34</td>
<td>20</td>
<td>44</td>
</tr>
<tr>
<td>5</td>
<td>26</td>
<td>28</td>
<td>14</td>
<td>30</td>
</tr>
</tbody>
</table>
```

drug is the repeated variable in this simple repeated-measures ANOVA example. The ANOVA is specified as follows:

```
. anova score person drug, repeated(drug)
```

```
Number of obs = 20  R-squared = 0.9244
Root MSE = 3.06594  Adj R-squared = 0.8803

Source     Partial SS   df  MS      F    Prob > F
----------   ---------   ---  ----      ----  :req
Model       1379.00      7  197 20.96    0.0000
person      680.80       4  170.2 18.11    0.0001
drug        698.20       3 232.73 24.76    0.0000
Residual    112.80      12   9.4          
Total       1491.80     19  78.52

Between-subjects error term: person
Levels: 5          (4 df)
Lowest b.s.e. variable: person
Repeated variable: drug

Huynh-Feldt epsilon = 1.0789
*Huynh-Feldt epsilon reset to 1.0000
Greenhouse-Geisser epsilon = 0.6049
Box's conservative epsilon = 0.3333

```

Here the Huynh–Feldt $\epsilon$ is 1.0789, which is larger than 1. It is reset to 1, which is the same as making no adjustment to the standard test computed in the main ANOVA table. The Greenhouse–Geisser $\epsilon$ is 0.6049, and its associated $p$-value is computed from an $F$ ratio of 24.76 using $1.8147(=3\epsilon)$ and $7.2588(=12\epsilon)$ degrees of freedom. Box’s conservative $\epsilon$ is set equal to the reciprocal of the degrees of freedom for the repeated term. Here it is 1/3, so Box’s conservative test is computed using 1 and 4 degrees of freedom for the observed $F$ ratio of 24.76.
Even for Box’s conservative ε, drug is significant with a $p$-value of 0.0076. The following table gives the predictive marginal mean score (that is, response time) for each of the four drugs:

```
. margins drug
Predictive margins Number of obs = 20
Expression : Linear prediction, predict()

<table>
<thead>
<tr>
<th></th>
<th>Delta-method</th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Margin</td>
<td>Std. Err.</td>
<td>t</td>
<td>P&gt;</td>
<td>t</td>
</tr>
<tr>
<td>drug</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>1</td>
<td>26.4</td>
<td>1.371131</td>
<td>19.25</td>
<td>0.000</td>
<td>23.41256</td>
</tr>
<tr>
<td>2</td>
<td>25.6</td>
<td>1.371131</td>
<td>18.67</td>
<td>0.000</td>
<td>22.61256</td>
</tr>
<tr>
<td>3</td>
<td>15.6</td>
<td>1.371131</td>
<td>11.38</td>
<td>0.000</td>
<td>12.61256</td>
</tr>
<tr>
<td>4</td>
<td>32</td>
<td>1.371131</td>
<td>23.34</td>
<td>0.000</td>
<td>29.01256</td>
</tr>
</tbody>
</table>
```

The ANOVA table for this example provides an $F$ test for person, but you should ignore it. An appropriate test for person would require replication (that is, multiple measurements for person and drug combinations). Also, without replication there is no test available for investigating the interaction between person and drug.

Example 16: Repeated-measures ANOVA with nesting

Table 7.7 of Winer, Brown, and Michels (1991) provides another repeated-measures ANOVA example. There are four dial shapes and two methods for calibrating dials. Subjects are nested within calibration method, and an accuracy score is obtained. The data are shown below.

```
. use http://www.stata-press.com/data/r13/t77
    (T7.7 -- Winer, Brown, Michels)
. tabdisp shape subject calib, cell(score)

<table>
<thead>
<tr>
<th>4 dial shapes</th>
<th>2 methods for calibrating dials and subject nested in calib</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>1 2 3 1 2 3 1 2 3 1 2 3</td>
</tr>
<tr>
<td>1</td>
<td>0 3 4 4 5 7</td>
</tr>
<tr>
<td>2</td>
<td>0 1 3 2 4 5</td>
</tr>
<tr>
<td>3</td>
<td>5 5 6 7 6 8</td>
</tr>
<tr>
<td>4</td>
<td>3 4 2 8 6 9</td>
</tr>
</tbody>
</table>
```

The calibration method and dial shapes are fixed factors, whereas subjects are random. The appropriate test for calibration method uses the nested subject term as the error term. Both the dial shape and the interaction between dial shape and calibration method are tested with the dial shape by subject interaction nested within calibration method. Here we drop this term from the `anova` command, and it becomes residual error. The dial shape is the repeated variable because each subject is tested with all four dial shapes. Here is the `anova` command that produces the desired results:
The repeated-measure $\epsilon$ corrections are applied to any terms that are tested in the main ANOVA table and have the repeated variable in the term. These $\epsilon$ corrections are given in a table below the main ANOVA table. Here the repeated-measures tests for shape and calib#shape are presented.

Calibration method is significant, as is dial shape. The interaction between calibration method and dial shape is not significant. The repeated-measure $\epsilon$ corrections do not change these conclusions, but they do change the significance level for the tests on shape and calib#shape. Here, though, unlike in the example 15, the Huynh–Feldt $\epsilon$ is less than 1.

Here are the predictive marginal mean scores for calibration method and dial shapes. Because the interaction was not significant, we request only the calib and shape predictive margins.

```
. margins, within(calib)
Predictive margins Number of obs =  24
Expression : Linear prediction, predict()
within : calib
Empty cells : reweight

</table>
```
Technical note

The computation of the Greenhouse–Geisser and Huynh–Feldt epsilons in a repeated-measures ANOVA requires the number of levels and degrees of freedom for the between-subjects error term, as well as a value computed from a pooled covariance matrix. The observations are grouped based on all but the lowest-level variable in the between-subjects error term. The covariance over the repeated variables is computed for each resulting group, and then these covariance matrices are pooled. The dimension of the pooled covariance matrix is the number of levels of the repeated variable (or combination of levels for multiple repeated variables). In example 16, there are four levels of the repeated variable (shape), so the resulting covariance matrix is $4 \times 4$.

The `anova` command automatically attempts to determine the between-subjects error term and the lowest-level variable in the between-subjects error term to group the observations for computation of the pooled covariance matrix. `anova` issues an error message indicating that the `bse()` or `bseunit()` option is required when `anova` cannot determine them. You may override the default selections of `anova` by specifying the `bse()`, `bseunit()`, or `grouping()` option. The term specified in the `bse()` option must be a term in the ANOVA model.

The default selection for the between-subjects error term (the `bse()` option) is the interaction of the nonrepeated categorical variables in the ANOVA model. The first variable listed in the between-subjects error term is automatically selected as the lowest-level variable in the between-subjects error term but can be overridden with the `bseunit(varname)` option. `varname` is often a term, such as subject or subsample within subject, and is most often listed first in the term because of the nesting notation of ANOVA. This term makes sense in most repeated-measures ANOVA designs when the terms of the model are written in standard form. For instance, in example 16, there were three categorical variables (subject, calib, and shape), with shape being the repeated variable. Here `anova` looked for a term involving only subject and calib to determine the between-subjects error term. It found `subject|calib` as the term with six levels and 4 degrees of freedom. `anova` then picked `subject` as the default for the `bseunit()` option (the lowest variable in the between-subjects error term) because it was listed first in the term.

The grouping of observations proceeds, based on the different combinations of values of the variables in the between-subjects error term, excluding the lowest level variable (as found by default or as specified with the `bseunit()` option). You may specify the `grouping()` option to change the default grouping used in computing the pooled covariance matrix.

The between-subjects error term, number of levels, degrees of freedom, lowest variable in the term, and grouping information are presented after the main ANOVA table and before the rest of the repeated-measures output.
Example 17: Repeated-measures ANOVA with two repeated variables

Data with two repeated variables are given in table 7.13 of Winer, Brown, and Michels (1991). The accuracy scores of subjects making adjustments to three dials during three different periods are recorded. Three subjects are exposed to a certain noise background level, whereas a different set of three subjects is exposed to a different noise background level. Here is a table of accuracy scores for the noise, subject, period, and dial variables:

```stata
use http://www.stata-press.com/data/r13/t713
(T7.13 -- Winer, Brown, Michels)
tabdisp subject dial period, by(noise) cell(score) stubwidth(11)
```

| noise background and subject nested in noise | 10 minute time periods and dial
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>

For each repeated variable and for each combination of interactions of repeated variables, there are different $\epsilon$ correction values. The `anova` command produces tables for each applicable combination.

The two most significant factors in this model appear to be dial and period. The noise by period interaction may also be significant, depending on the correction factor you use. Below is a table of predictive margins for the accuracy score for dial, period, and noise by period.

```
.margins, within(dial)
Predictive margins
Expression : Linear prediction, predict()
within : dial
Empty cells : reweight

 Delta-method
  MARGIN  Std. Err.   t    P>|t|    [95% Conf. Interval]
  dial
    1  37.38889 .6643478 56.28 0.000  35.98053  38.79724
    2  42.22222 .6643478 63.55 0.000  40.81387  43.63058
    3  53.22222 .6643478 80.11 0.000  51.81387  54.63058

.margins, within(period)
Predictive margins
Expression : Linear prediction, predict()
within : period
Empty cells : reweight

 Delta-method
  MARGIN  Std. Err.   t    P>|t|    [95% Conf. Interval]
  period
    1  54.33333 .6643478 81.78 0.000  52.92498  55.74169
    2   44.5  .6643478 66.98 0.000  43.09165  45.90835
    3   34   .6643478 51.18 0.000  32.59165  35.40835
```
Dial shape 3 produces the highest score, and scores decrease over the periods.

Example 17 had two repeated-measurement variables. Up to four repeated-measurement variables may be specified in the \texttt{anova} command.

Analysis of covariance in Stata

Two-way ANOVA in Stata
Stored results

`anova` stores the following in `e()`:

**Scalars**
- `e(N)` number of observations
- `e(mss)` model sum of squares
- `e(df_m)` model degrees of freedom
- `e(rss)` residual sum of squares
- `e(df_r)` residual degrees of freedom
- `e(r2)` $R^2$
- `e(r2_a)` adjusted $R^2$
- `e(F)` $F$ statistic
- `e(rmse)` root mean squared error
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(ss_#)` sum of squares for term #
- `e(df_#)` numerator degrees of freedom for term #
- `e(ssdenom_#)` denominator sum of squares for term # (when using nonresidual error)
- `e(dfdenom_#)` denominator degrees of freedom for term # (when using nonresidual error)
- `e(F_#)` $F$ statistic for term # (if computed)
- `e(N_bse)` number of levels of the between-subjects error term
- `e(df_bse)` degrees of freedom for the between-subjects error term
- `e(box#)` Box’s conservative epsilon for a particular combination of repeated variables (repeated() only)
- `e(gg#)` Greenhouse–Geisser epsilon for a particular combination of repeated variables (repeated() only)
- `e(hf#)` Huynh–Feldt epsilon for a particular combination of repeated variables (repeated() only)
- `e(rank)` rank of `e(V)`

**Macros**
- `e(cmd)` `anova`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(varnames)` names of the right-hand-side variables
- `e(term_#)` term #
- `e(errorterm_#)` error term for term # (when using nonresidual error)
- `e(sstype)` type of sum of squares; sequential or partial
- `e(repvars)` names of repeated variables (repeated() only)
- `e(repvar#)` names of repeated variables for a particular combination of repeated variables (repeated() only)
- `e(model)` ols
- `e(vtype)` weight type
- `e(wexp)` weight expression
- `e(properties)` `b V`  
- `e(estat_cmd)` program used to implement `estat`
- `e(predict)` program used to implement `predict`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

**Matrices**
- `e(b)` coefficient vector
- `e(V)` variance–covariance matrix of the estimators
- `e(Srep)` covariance matrix based on repeated measures (repeated() only)

**Functions**
- `e(sample)` marks estimation sample

**Special-interest postestimation commands**

In addition to the common estat commands (see [R] estat), estat hettest, estat imtest, estat ovtest, estat szroeter, and estat vif are also available. dfbeta is also available. The syntax for dfbeta and these estat commands is the same as after regress; see [R] regress postestimation.

For information on the plot commands, see [R] regress postestimation diagnostic plots.

In addition to the standard syntax of test (see [R] test), test after anova has three additionally allowed syntaxes; see below. test performs Wald tests of expressions involving the coefficients of the underlying regression model. Simple and composite linear hypotheses are possible.

**Syntax for predict**

predict after anova follows the same syntax as predict after regress and can provide predictions, residuals, standardized residuals, Studentized residuals, the standard error of the residuals, the standard error of the prediction, the diagonal elements of the projection (hat) matrix, and Cook’s D. See [R] regress postestimation for details.
Syntax for test after anova

In addition to the standard syntax of test (see [R] test), test after anova also allows the following:

\[
\text{test, test(matname) [ mtest[(opt)] matvlc(matname)]} \quad \text{syntax a}
\]
\[
\text{test, showorder} \quad \text{syntax b}
\]
\[
\text{test [ term [ term ... ] ] [ / term [ term ... ] ] [, symbolic]} \quad \text{syntax c}
\]

syntax a  test expression involving the coefficients of the underlying regression model; you provide information as a matrix
syntax b  show underlying order of design matrix, which is useful when constructing matname argument of the test() option
syntax c  test effects and show symbolic forms

Menu for test after anova

Statistics > Linear models and related > ANOVA/MANOVA > Test linear hypotheses after anova

Options for test after anova

\text{test(matname)} is required with syntax a of test. The rows of matname specify linear combinations of the underlying design matrix of the ANOVA that are to be jointly tested. The columns correspond to the underlying design matrix (including the constant if it has not been suppressed). The column and row names of matname are ignored.

A listing of the constraints imposed by the test() option is presented before the table containing the tests. You should examine this table to verify that you have applied the linear combinations you desired. Typing test, showorder allows you to examine the ordering of the columns for the design matrix from the ANOVA.

\text{mtest[(opt)]} specifies that tests are performed for each condition separately. \text{opt} specifies the method for adjusting \textit{p}-values for multiple testing. Valid values for \text{opt} are

\begin{verbatim}
bonferroni  Bonferroni’s method
holm       Holm’s method
sidak      Šidák’s method
noadjust   no adjustment is to be made
\end{verbatim}

Specifying mtest with no argument is equivalent to mtest(noadjust).

\text{matvlc(matname)}, a programmer’s option, saves the variance–covariance matrix of the linear combinations involved in the suite of tests. For the test \( \text{Lb} = \text{c} \), what is returned in matname is \( \text{LVL}' \), where \( \text{V} \) is the estimated variance–covariance matrix of \text{b}.

\text{showorder} causes test to list the definition of each column in the design matrix. showorder is not allowed with any other option.

\text{symbolic} requests the symbolic form of the test rather than the test statistic. When this option is specified with no terms (\text{test, symbolic}), the symbolic form of the estimable functions is displayed.
Remarks and examples

Remarks are presented under the following headings:

- Testing effects
- Obtaining symbolic forms
- Testing coefficients and contrasts of margins
- Video example

See examples 4, 7, 8, 13, 15, 16, and 17 in [R] anova for examples that use the margins command.

Testing effects

After fitting a model using anova, you can test for the significance of effects in the ANOVA table, as well as for effects that are not reported in the ANOVA table, by using the test or contrast command. You follow test or contrast by the list of effects that you wish to test. By default, these commands use the residual mean squared error in the denominator of the $F$ ratio. You can specify other error terms by using the slash notation, just as you would with anova. See [R] contrast for details on this command.

Example 1: Testing effects

Recall our byssinosis example (example 8) in [R] anova:

```
. anova prob workplace smokes race workplace#smokes workplace#race smokes#race
    > workplace#smokes#race [aweight=pop]
    (sum of wgt is  5.4190e+03)
```

<table>

<td>64</td>
<td>.003268817</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

We can easily obtain a test on a particular term from the ANOVA table. Here are two examples:

```
. test smokes
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>smokes</td>
<td>.013030812</td>
<td>1</td>
<td>.013030812</td>
<td>19.42</td>
<td>0.0001</td>
</tr>
<tr>
<td>Residual</td>
<td>.035557766</td>
<td>53</td>
<td>.000670901</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

```
. test smokes#race
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>smokes#race</td>
<td>.001662874</td>
<td>1</td>
<td>.001662874</td>
<td>2.48</td>
<td>0.1214</td>
</tr>
<tr>
<td>Residual</td>
<td>.035557766</td>
<td>53</td>
<td>.000670901</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Both of these tests use residual error by default and agree with the ANOVA table produced earlier.
We could have performed these same tests with *contrast*:

```
. contrast smokes
Contrasts of marginal linear predictions
Margins : asbalanced
          df  F   P>F
smokes    1 19.42 0.0001
Denominator          53

. contrast smokes#race
Contrasts of marginal linear predictions
Margins : asbalanced
          df  F   P>F
smokes#race  1  2.48 0.1214
Denominator          53
```

## Technical note

After *anova*, you can use the `/` syntax in *test* or *contrast* to perform tests with a variety of non-$\sigma^2$ error structures. However, in most unbalanced models, the mean squares are not independent and do not have equal expectations under the null hypothesis. Also, be warned that you assume responsibility for the validity of the test statistic.

### Example 2: Testing effects with different error terms

We return to the nested ANOVA example (example 11) in [R] *anova*, where five brands of machinery were compared in an assembly line. We can obtain appropriate tests for the nested terms using *test*, even if we had run the *anova* command without initially indicating the proper error terms.

```
. use http://www.stata-press.com/data/r13/machine
  (machine data)
. anova output machine / operator|machine /
Number of obs =  57  R-squared = 0.8661
Root MSE = 1.47089  Adj R-squared = 0.8077
Source       Partial SS   df       MS      F     Prob > F
Model         545.822288  17  32.1071934  14.84  0.0000
machine       430.980792   4 107.745198  13.82  0.0001
operator|machine 101.353804  13  7.79644648
operator|machine 101.353804  13  7.79644648  3.60  0.0009
Residual        84.3766582  39  2.16350406
Total          630.198947  56 11.2535526
```

- Technical note

- Example 2: Testing effects with different error terms
In this ANOVA table, machine is tested with residual error. With this particular nested design, the appropriate error term for testing machine is operator nested within machine, which is easily obtained from test.

```
. test machine / operator|machine

Source | Partial SS  | df | MS       | F        | Prob > F
------ | ----------- | ---- | -------- | -------- |-----------
machine | 430.980792  | 4   | 107.745198 | 13.82    | 0.0001
operator|machine     | 101.353804 | 13  | 7.79644648 |          |           
```

This result from test matches what we obtained from our anova command.

Example 3: Pooling terms when testing effects

The other nested ANOVA example (example 12) in [R] anova was based on the sewage data. The ANOVA table is presented here again. As before, we will use abbreviations of variable names in typing the commands.

```
. use http://www.stata-press.com/data/r13/sewage
(Sewage treatment)
. anova particulate s / m|s / f|m|s / w|f|m|s /, dropemptycells
```

```
Number of obs = 64  R-squared = 0.6338
Root MSE = 12.7445  Adj R-squared = 0.5194
Source | Partial SS  | df | MS       | F        | Prob > F
------ | ----------- | ---- | -------- | -------- |-----------
Model  | 13493.6094  | 15  | 899.573958 | 5.54     | 0.0000
solution | 7203.76563  | 1   | 7203.76563 | 17.19    | 0.0536
manager|solution  | 838.28125  | 2   | 419.140625 | 0.55     | 0.6166
facility|manager|solution | 3064.9375  | 4   | 766.234375 |          |           
facility|manager|solution | 3064.9375  | 4   | 766.234375 | 2.57     | 0.1193
worker|facility|manager|solution | 2386.625  | 8   | 298.328125 | 1.84     | 0.0931
worker|facility|manager|solution | 2386.625  | 8   | 298.328125 | 1.84     | 0.0931
Residual | 7796.25   | 48  | 162.421875 |          |           
Total   | 21289.8594 | 63  | 337.934276 |          |           
```

In practice, it is often beneficial to pool nonsignificant nested terms to increase the power of tests on remaining terms. One rule of thumb is to allow the pooling of a term whose $p$-value is larger than 0.25. In this sewage example, the $p$-value for the test of manager is 0.6166. This value indicates that the manager effect is negligible and might be ignored. Currently, solution is tested by manager|solution, which has only 2 degrees of freedom. If we pool the manager and facility terms and use this pooled estimate as the error term for solution, we would have a term with 6 degrees of freedom.

Below are two tests: a test of solution with the pooled manager and facility terms and a test of this pooled term by worker.
In the first test, we included two terms after the forward slash (m|s and f|m|s). test after anova allows multiple terms both before and after the slash. The terms before the slash are combined and are then tested by the combined terms that follow the slash (or residual error if no slash is present).

The p-value for solution using the pooled term is 0.0159. Originally, it was 0.0536. The increase in the power of the test is due to the increase in degrees of freedom for the pooled error term.

We can get identical results if we drop manager from the anova model. (This dataset has unique numbers for each facility so that there is no confusion of facilities when manager is dropped.)
Example 4: Obtaining overall significance of a term using contrast

In example 10 of [R] anova, we fit the model anova drate region c.mage region#c.mage. Now we use the contrast command to test for the overall significance of region.

```
. contrast region region#c.mage, overall
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>region</td>
<td>3</td>
<td>7.40</td>
<td>0.0004</td>
</tr>
<tr>
<td>region#c.mage</td>
<td>3</td>
<td>0.86</td>
<td>0.4689</td>
</tr>
<tr>
<td>Overall</td>
<td>6</td>
<td>5.65</td>
<td>0.0002</td>
</tr>
</tbody>
</table>
```

The overall $F$ statistic associated with the `region` and `region#c.mage` terms is 5.65, and it is significant at the 0.02% level.

In the ANOVA output, the `region` term, by itself, had a sum of squares of 1166.15, which, based on 3 degrees of freedom, yielded an $F$ statistic of 7.40 and a significance level of 0.0004. This is the same test that is reported by `contrast` in the row labeled `region`. Likewise, the test from the ANOVA output for the `region#c.mage` term is reproduced in the second row of the `contrast` output.

Obtaining symbolic forms

test can produce the symbolic form of the estimable functions and symbolic forms for particular tests.

Example 5: Symbolic form of the estimable functions

After fitting an ANOVA model, we type `test, symbolic` to obtain the symbolic form of the estimable functions. For instance, returning to our blood pressure data introduced in example 4 of [R] anova, let’s begin by reestimating `systolic` on `drug`, `disease`, and `drug#disease`:

```
. use http://www.stata-press.com/data/r13/systolic, clear
    (Systolic Blood Pressure Data)
. anova systolic drug disease drug#disease
```

The ANOVA table:

```
Number of obs = 58           R-squared = 0.4560
Root MSE      = 10.5096       Adj R-squared = 0.3259
Source        | Partial SS | df | MS      | F     | Prob > F
------------|------------|----|---------|-------|----------
Model        | 4259.33851 | 11 | 387.212591 | 3.51 | 0.0013
            | 2997.47186 | 3  | 999.157287 | 9.05 | 0.0001
            | 415.873046 | 2  | 207.936523  | 1.88 | 0.1637
            | 707.266259 | 6  | 117.87771  | 1.07 | 0.3958
            | 5080.81667 | 46 | 110.452536 |
Residual     |            |    |          |       |          |
Total        | 9340.15517 | 57 | 163.862371 |
```

test can produce the symbolic form of the estimable functions and symbolic forms for particular tests.
To obtain the symbolic form of the estimable functions, type

```
.test, symbolic
drug
  1  -(r2+r3+r4-r0)
  2  r2
  3  r3
  4  r4
disease
  1  -(r6+r7-r0)
  2  r6
  3  r7
drug#disease
  1 1  -(r2+r3+r4+r6+r7-r12-r13-r15-r16-r18-r19-r0)
  1 2  r6  -(r12+r15+r18)
  1 3  r7  -(r13+r16+r19)
  2 1  r2  -(r12+r13)
  2 2  r12
  2 3  r13
  3 1  r3  -(r15+r16)
  3 2  r15
  3 3  r16
  4 1  r4  -(r18+r19)
  4 2  r18
  4 3  r19
_cons  r0
```

Example 6: Symbolic form for a particular test

To obtain the symbolic form for a particular test, we type `test term [term ...], symbolic`. For instance, the symbolic form for the test of the main effect of drug is

```
.test drug, symbolic
drug
  1  -(r2+r3+r4)
  2  r2
  3  r3
  4  r4
disease
  1  0
  2  0
  3  0
drug#disease
  1  1  -1/3 (r2+r3+r4)
  1  2  -1/3 (r2+r3+r4)
  1  3  -1/3 (r2+r3+r4)
  2  1  1/3 r2
  2  2  1/3 r2
  2  3  1/3 r2
  3  1  1/3 r3
  3  2  1/3 r3
  3  3  1/3 r3
  4  1  1/3 r4
  4  2  1/3 r4
  4  3  1/3 r4
_cons  r0
```
If we omit the symbolic option, we instead see the result of the test:

```
.test drug
```

<table>
<thead>

</table>

Testing coefficients and contrasts of margins

The `test` command allows you to perform tests directly on the coefficients of the underlying regression model. For instance, the coefficient on the third drug and the second disease is referred to as 3.drug#2.disease. This could also be written as i3.drug#i2.disease, or `_b[3.drug#2.disease]`, or even `_coef[i3.drug#i2.disease]`; see [U] 13.5 Accessing coefficients and standard errors.

Example 7: Testing linear combinations of coefficients

Let's begin by testing whether the coefficient on the third drug is equal to the coefficient on the fourth in our blood pressure data. We have already fit the model `anova systolic drug##disease` (equivalent to `anova systolic drug disease drug#disease`), and you can see the results of that estimation in example 5. Even though we have performed many tasks since we fit the model, Stata still remembers, and we can perform tests at any time.

```
.test 3.drug = 4.drug
   ( 1) 3.drug - 4.drug = 0
   F(  1,  46) = 0.13
   Prob > F = 0.7234
```

We find that the two coefficients are not significantly different, at least at any significance level smaller than 73%.

For more complex tests, the `contrast` command often provides a more concise way to specify the test we are interested in and prevents us from having to write the tests in terms of the regression coefficients. With `contrast`, we instead specify our tests in terms of differences in the marginal means for the levels of a particular factor. For example, if we want to compare the third and fourth drugs, we can test the difference in the mean impact on systolic blood pressure separately for each disease using the `@` operator. We also use the reverse adjacent operator, `ar_.`, to compare the fourth level of drug with the previous level.
. contrast ar4.drug@disease

Contrasts of marginal linear predictions

Margins : asbalanced

<table>

<td>(4 vs 3) 3</td>
<td>5.7</td>
<td>7.050081</td>
<td>-8.491077 19.89108</td>
</tr>
</tbody>
</table>

None of the individual contrasts shows significant differences between the third drug and the fourth drug. Likewise, the overall $F$ statistic is 0.85, which is hardly significant. We cannot reject the hypothesis that the third drug has the same effect as the fourth drug.

Technical note

Alternatively, we could have specified these tests based on the coefficients of the underlying regression model using the `test` command. We would have needed to perform tests on the coefficients for drug and for the coefficients on drug interacted with disease in order to test for differences in the means mentioned above. To do this, we start with our previous `test` command:

```
. test 3.drug = 4.drug
```

Notice that the $F$ statistic for this test is equivalent to the test labeled (4 vs 3) 1 in the contrast output. Let’s now add the constraint that the coefficient on the third drug interacted with the third disease is equal to the coefficient on the fourth drug, again interacted with the third disease. We do that by typing the new constraint and adding the `accumulate` option:

```
. test 3.drug#3.disease = 4.drug#3.disease, accumulate
   ( 1)  3.drug - 4.drug = 0
   ( 2)  3.drug#3.disease - 4.drug#3.disease = 0
F(  2,  46) =  0.39
Prob > F =  0.6791
```

So far, our test includes the equality of the two drug coefficients, along with the equality of the two drug coefficients when interacted with the third disease. Now we add two more equations, one for each of the remaining two diseases:
. test 3.drug#2.disease = 4.drug#2.disease, accumulate
  ( 1)  3.drug - 4.drug = 0
  ( 2)  3.drug#3.disease - 4.drug#3.disease = 0
  ( 3)  3.drug#2.disease - 4.drug#2.disease = 0
      F(  3,  46) =  0.85
      Prob > F =  0.4761
.
. test 3.drug#1.disease = 4.drug#1.disease, accumulate
  ( 1)  3.drug - 4.drug = 0
  ( 2)  3.drug#3.disease - 4.drug#3.disease = 0
  ( 3)  3.drug#2.disease - 4.drug#2.disease = 0
  ( 4)  3o.drug#1b.disease - 4o.drug#1b.disease = 0
      Constraint 4 dropped
      F(  3,  46) =  0.85
      Prob > F =  0.4761

The overall $F$ statistic reproduces the one from the joint test in the `contrast` output.

You may notice that we also got the message “Constraint 4 dropped”. For the technically inclined, this constraint was unnecessary, given the normalization of the model. If we specify all the constraints involved in our test or use `contrast`, we need not worry about the normalization because Stata handles this automatically.

The `test()` option of `test` provides another alternative for testing coefficients. Instead of spelling out each coefficient involved in the test, a matrix representing the test provides the needed information. `test, showorder` shows the order of the terms in the ANOVA corresponding to the order of the columns for the matrix argument of `test()`.

Example 8: Another way to test linear combinations of coefficients

We repeat the last test of example 7 above with the `test()` option. First, we view the definition and order of the columns underlying the ANOVA performed on the systolic data.
. test, showorder

Order of columns in the design matrix
1: (drug==1)
2: (drug==2)
3: (drug==3)
4: (drug==4)
5: (disease==1)
6: (disease==2)
7: (disease==3)
8: (drug==1)*(disease==1)
9: (drug==1)*(disease==2)
10: (drug==1)*(disease==3)
11: (drug==2)*(disease==1)
12: (drug==2)*(disease==2)
13: (drug==2)*(disease==3)
14: (drug==3)*(disease==1)
15: (drug==3)*(disease==2)
16: (drug==3)*(disease==3)
17: (drug==4)*(disease==1)
18: (drug==4)*(disease==2)
19: (drug==4)*(disease==3)
20: _cons

Columns 1–4 correspond to the four levels of drug. Columns 5–7 correspond to the three levels of disease. Columns 8–19 correspond to the interaction of drug and disease. The last column corresponds to _cons, the constant in the model.

We construct the matrix dr3vs4 with the same four constraints as the last test shown in example 7 and then use the test(dr3vs4) option to perform the test.

. matrix dr3vs4 = (0,0,1,-1, 0,0,0, 0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,
               > 0,0,0, 0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,
               > 0,0,0, 0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,
               > 0,0,0, 0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,
               > 0,0,0, 0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0)

. test, test(dr3vs4)
( 1) 3.drug - 4.drug = 0
( 2) 3.drug#3.disease - 4.drug#3.disease = 0
( 3) 3.drug#2.disease - 4.drug#2.disease = 0
( 4) 3o.drug#1b.disease - 4o.drug#1b.disease = 0
Constraint 4 dropped
F(  3,  46) = 0.85
Prob > F = 0.4761

Here the effort involved with spelling out the coefficients is similar to that of constructing a matrix and using it in the test() option. When the test involving coefficients is more complicated, the test() option may be more convenient than specifying the coefficients directly in test. However, as previously demonstrated, contrast may provide an even simpler method for testing the same hypothesis.

After fitting an ANOVA model, various contrasts (1-degree-of-freedom tests comparing different levels of a categorical variable) are often of interest. contrast can perform each 1-degree-of-freedom test in addition to the combined test, even in cases in which the contrasts do not correspond to one of the contrast operators.
Example 9: Testing particular contrasts of interest

Rencher and Schaalje (2008) illustrate 1-degree-of-freedom contrasts for an ANOVA comparing the net weight of cans filled by five machines (labeled A–E). The data were originally obtained from Ostle and Mensing (1975). Rencher and Schaalje use a cell-means ANOVA model approach for this problem. We could do the same by using the noconstant option of anova; see [R] anova. Instead, we obtain the same results by using the standard overparameterized ANOVA approach (that is, we keep the constant in the model).

The four 1-degree-of-freedom tests of interest among the five machines are A and D versus B, C, and E; B and E versus C; A versus D; and B versus E. We can specify these tests as user-defined contrasts by placing the corresponding contrast coefficients into positions related to the five levels of machine as described in *User-defined contrasts* of [R] contrast.
. contrast {machine 3 -2 -2 3 -2}
> {machine 0 1 -2 0 1}

contrast produces a 1-degree-of-freedom test for each of the specified contrasts as well as a joint test. We included the noeffects option so that the table displaying the values of the individual contrasts with their confidence intervals was suppressed.

The significance values above are not adjusted for multiple comparisons. We could have produced the Bonferroni-adjusted significance values by using the mcompare(bonferroni) option.

. contrast {machine 3 -2 -2 3 -2}
> {machine 0 1 -2 0 1}

We can use the `p.` contrast operator to obtain the 1-degree-of-freedom tests for the linear and quadratic effects of \( A \) and \( B \).

Contrasts of marginal linear predictions

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>1</td>
<td>212.65</td>
<td>0.0000</td>
</tr>
<tr>
<td>(linear)</td>
<td>1</td>
<td>70.88</td>
<td>0.0000</td>
</tr>
<tr>
<td>(quadratic)</td>
<td>2</td>
<td>141.77</td>
<td>0.0000</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>26.17</td>
<td>0.0000</td>
</tr>
<tr>
<td>B</td>
<td>1</td>
<td>26.17</td>
<td>0.0000</td>
</tr>
<tr>
<td>(linear)</td>
<td>1</td>
<td>27.51</td>
<td>0.0000</td>
</tr>
<tr>
<td>(quadratic)</td>
<td>2</td>
<td>26.84</td>
<td>0.0000</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>26.84</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

All the above tests appear to be significant. In addition to presenting the 1-degree-of-freedom tests, the combined tests for \( A \) and \( B \) are produced and agree with the original ANOVA results.

Now we explore the interaction between \( A \) and \( B \).

. contrast p.A#p1.B, noeffects

Contrasts of marginal linear predictions

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>A#B</td>
<td>1</td>
<td>17.71</td>
<td>0.0003</td>

<td>0.07</td>
<td>0.7893</td>
</tr>
<tr>
<td>(linear) (quadratic)</td>
<td>2</td>
<td>8.89</td>
<td>0.0011</td>
</tr>
</tbody>
</table>

The 2-degrees-of-freedom test of the interaction of \( A \) with the linear components of \( B \) is significant at the 0.0011 level. But, when we examine the two 1-degree-of-freedom tests that compose this result,
the significance is due to the linear A by linear B contrast (significance level of 0.0003). A significance value of 0.7893 for the quadratic A by linear B indicates that this factor is not significant for these data.

```
. contrast p.A#p2.B, noeffects

*absorb(varname) is required.

indepvars may contain factor variables; see [U] 11.4.3 Factor variables.

depvar and indepvars may contain time-series operators; see [U] 11.4.4 Time-series varlists.

bootstrap, by, fp, jackknife, mi estimate, rolling, and statsby are allowed; see [U] 11.1.10 Prefix commands.

vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

aweights are not allowed with the jackknife prefix; see [R] jackknife.

aweights, fweights, and pweights are allowed; see [U] 11.1.6 weight.

coefflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Menu

Statistics > Linear models and related > Other > Linear regression absorbing one cat. variable

Description

areg fits a linear regression absorbing one categorical factor. areg is designed for datasets with many groups, but not a number of groups that increases with the sample size. See the xtreg, fe command in [XT] xtreg for an estimator that handles the case in which the number of groups increases with the sample size.
Options

**Model**

`absorb(varname)` specifies the categorical variable, which is to be included in the regression as if it were specified by dummy variables. `absorb()` is required.

**SE/Robust**

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`ols`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see `[R] vce_option`.

`vce(ols)`, the default, uses the standard variance estimator for ordinary least-squares regression. Exercise caution when using the `vce(cluster clustvar)` option with `areg`. The effective number of degrees of freedom for the robust variance estimator is \( n_g - 1 \), where \( n_g \) is the number of clusters. Thus the number of levels of the `absorb()` variable should not exceed the number of clusters.

**Reporting**

`level(#)`; see `[R] estimation options`.

`display_options`: `nomomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fwrap(#)`, `fwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see `[R] estimation options`.

The following option is available with `areg` but is not shown in the dialog box:

`coeflegend`; see `[R] estimation options`.

Remarks and examples

Suppose that you have a regression model that includes among the explanatory variables a large number, \( k \), of mutually exclusive and exhaustive dummies:

\[
y = X\beta + d_1\gamma_1 + d_2\gamma_2 + \cdots + d_k\gamma_k + \epsilon
\]

For instance, the dummy variables, \( d_i \), might indicate countries in the world or states of the United States. One solution would be to fit the model with `regress`, but this solution is possible only if \( k \) is small enough so that the total number of variables (the number of columns of \( X \) plus the number of \( d_i \)'s plus one for \( y \)) is sufficiently small—meaning less than `matsize` (see `[R] matsize`). For problems with more variables than the largest possible value of `matsize` (100 for Small Stata, 800 for Stata/IC, and 11,000 for Stata/SE and Stata/MP), `regress` will not work. `areg` provides a way of obtaining estimates of \( \beta \)—but not the \( \gamma_i \)'s—in these cases. The effects of the dummy variables are said to be absorbed.

> **Example 1**

So that we can compare the results produced by `areg` with Stata’s other regression commands, we will fit a model in which \( k \) is small. `areg`’s real use, however, is when \( k \) is large.

In our automobile data, we have a variable called `rep78` that is coded 1, 2, 3, 4, and 5, where 1 means poor and 5 means excellent. Let’s assume that we wish to fit a regression of `mpg` on `weight`, `gear_ratio`, and `rep78` (parameterized as a set of dummies).
. use http://www.stata-press.com/data/r13/auto2
(1978 Automobile Data)
. regress mpg weight gear_ratio b5.rep78

| rep78  | F(4, 62) = 1.117 | 0.356 | (5 categories) |

Both `regress` and `areg` display the same $R^2$ values, root mean squared error, and—for weight and gear_ratio—the same parameter estimates, standard errors, $t$ statistics, significance levels, and confidence intervals. `areg`, however, does not report the coefficients for rep78, and, in fact, they are not even calculated. This computational trick makes the problem manageable when $k$ is large. `areg` reports a test that the coefficients associated with rep78 are jointly zero. Here this test has a significance level of 35.6%. This $F$ test for rep78 is the same that we would obtain after `regress` if we were to specify `test 1.rep78 2.rep78 3.rep78 4.rep78`; see [R] `test`.

The model $F$ tests reported by `regress` and `areg` also differ. The `regress` command reports a test that all coefficients except that of the constant are equal to zero; thus, the dummies are included in this test. The `areg` output shows a test that all coefficients excluding the dummies and the constant are equal to zero. This is the same test that can be obtained after `regress` by typing `test weight gear_ratio`.  

areg is designed for datasets with many groups, but not a number that grows with the sample size. Consider two different samples from the U.S. population. In the first sample, we have 10,000 individuals and we want to include an indicator for each of the 50 states, whereas in the second sample we have 3 observations on each of 10,000 individuals and we want to include an indicator for each individual. areg was designed for datasets similar to the first sample in which we have a fixed number of groups, the 50 states. In the second sample, the number of groups, which is the number of individuals, grows as we include more individuals in the sample. For an estimator designed to handle the case in which the number of groups grows with the sample size, see the xtreg, fe command in [XT] xtreg.

Although the point estimates produced by areg and xtreg, fe are the same, the estimated VCEs differ when vce(cluster clustvar) is specified because the commands make different assumptions about whether the number of groups increases with the sample size.

---

Technical note

The intercept reported by areg deserves some explanation because, given \( k \) mutually exclusive and exhaustive dummies, it is arbitrary. areg identifies the model by choosing the intercept that makes the prediction calculated at the means of the independent variables equal to the mean of the dependent variable: \( \bar{Y} = \bar{x} \hat{\beta} \).

```
. predict yhat
(option xb assumed; fitted values)
. summarize mpg yhat if rep78 != .
```

<table>
<thead>
<tr>
<th></th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>69</td>
<td>21.28986</td>
<td>5.866408</td>
<td>12</td>
<td>41</td>
</tr>
<tr>
<td>yhat</td>
<td>69</td>
<td>21.28986</td>
<td>4.383224</td>
<td>11.58643</td>
<td>28.07367</td>
</tr>
</tbody>
</table>

We had to include if rep78 < . in our summarize command because we have missing values in our data. areg automatically dropped those missing values (as it should) in forming the estimates, but predict with the xb option will make predictions for cases with missing rep78 because it does not know that rep78 is really part of our model.

These predicted values do not include the absorbed effects (that is, the \( d_i \gamma_i \)). For predicted values that include these effects, use the xbd option of predict (see [R] areg postestimation) or see [XT] xtreg.

---

Example 2

areg, vce(robust) is a Huberized version of areg; see [P] _robust. Just as areg is equivalent to using regress with dummies, areg, vce(robust) is equivalent to using regress, vce(robust) with dummies. You can use areg, vce(robust) when you expect heteroskedastic or nonnormal errors. areg, vce(robust), like ordinary regression, assumes that the observations are independent, unless the vce(cluster clustvar) option is specified. If the vce(cluster clustvar) option is specified, this independence assumption is relaxed and only the clusters identified by equal values of clustvar are assumed to be independent.
Assume that we were to collect data by randomly sampling 10,000 doctors (from 100 hospitals) and then sampling 10 patients of each doctor, yielding a total dataset of 100,000 patients in a cluster sample. If in some regression we wished to include effects of the hospitals to which the doctors belonged, we would want to include a dummy variable for each hospital, adding 100 variables to our model. `areg` could fit this model by

```
. areg depvar patient_vars, absorb(hospital) vce(cluster doctor)
```

### Stored results

`areg` stores the following in `e()`:

**Scalars**

- `e(N)` number of observations
- `e(tss)` total sum of squares
- `e(df_m)` model degrees of freedom
- `e(rss)` residual sum of squares
- `e(df_r)` residual degrees of freedom
- `e(r2)` $R^2$
- `e(r2_a)` adjusted $R^2$
- `e(df_a)` degrees of freedom for absorbed effect
- `e(rmse)` root mean squared error
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(N_clust)` number of clusters
- `e(F)` $F$ statistic
- `e(F_absorb)` $F$ statistic for absorbed effect (when `vce(robust)` is not specified)
- `e(rank)` rank of `e(V)`

**Macros**

- `e(cmd)` `areg`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(absvar)` name of `absorb` variable
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(vce)` `vcetype` specified in `vce()`
- `e(vcetype)` `vcetype` specified in `vce()`
- `e(datasignature)` the checksum
- `e(datasignaturevars)` variables used in calculation of checksum
- `e(properties)` `b` `V`
- `e(predict)` program used to implement `predict`
- `e(footnote)` program used to implement the footnote display
- `e(marginsnotok)` predictions disallowed by `margins`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

**Matrices**

- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

**Functions**

- `e(sample)` marks estimation sample
areg — Linear regression with a large dummy-variable set 79

Methods and formulas

areg begins by recalculating depvar and indepvars to have mean 0 within the groups specified by absorb(). The overall mean of each variable is then added back in. The adjusted depvar is then regressed on the adjusted indepvars with regress, yielding the coefficient estimates. The degrees of freedom of the variance–covariance matrix of the coefficients is then adjusted to account for the absorbed variables—this calculation yields the same results (up to numerical roundoff error) as if the matrix had been calculated directly by the formulas given in [R] regress.

areg with vce(robust) or vce(cluster clustvar) works similarly, calling _robust after regress to produce the Huber/White/sandwich estimator of the variance or its clustered version. See [P] _robust, particularly Introduction and Methods and formulas. The model $F$ test uses the robust variance estimates. There is, however, no simple computational means of obtaining a robust test of the absorbed dummies; thus this test is not displayed when the vce(robust) or vce(cluster clustvar) option is specified.

The number of groups specified in absorb() are included in the degrees of freedom used in the finite-sample adjustment of the cluster–robust VCE estimator. This statement is only valid if the number of groups is small relative to the sample size. (Technically, the number of groups must remain fixed as the sample size grows.) For an estimator that allows the number of groups to grow with the sample size, see the xtreg, fe command in [XT] xtreg.

</tr>
</tbody>
</table>

Unstarred statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when if e(sample) is not specified.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

- **Main**:
  - \( xb \), the default, calculates the prediction of \( x_j \beta \), the fitted values, by using the average effect of the absorbed variable. Also see \( xbd \) below.
  - \( stdp \) calculates the standard error of \( x_j \beta \).
  - \( d_{\text{residuals}} \) calculates \( y_j - x_j \beta \), which are the residuals plus the effect of the absorbed variable.
  - \( xbd \) calculates \( x_j \beta + d_{\text{absorbvar}} \), which are the fitted values including the individual effects of the absorbed variable.
  - \( d \) calculates \( d_{\text{absorbvar}} \), the individual coefficients for the absorbed variable.
  - \( \text{residuals} \) calculates the residuals, that is, \( y_j - (x_j \beta + d_{\text{absorbvar}}) \).
  - \( \text{score} \) is a synonym for \( \text{residuals} \).

Remarks and examples

> Example 1

Continuing with example 1 of [R] areg, we refit the model with robust standard errors and then obtain linear predictions and standard errors for those linear predictions.

. use http://www.stata-press.com/data/r13/auto2
(1978 Automobile Data)
We can obtain the same linear predictions by fitting the model with \texttt{xtreg, fe}, but we would first need to specify the panel structure by using \texttt{xtset}.

\begin{verbatim}
. xtset rep78
     panel variable:  rep78 (unbalanced)
. xtreg mpg weight gear_ratio, fe vce(robust)
     (output omitted)
. predict xb_xt
     (option xb assumed; fitted values)
. predict stdp_xt, stdp
. summarize xb_ar xb_xt stdp*
     Variable |        Obs       Mean    Std. Dev.      Min      Max
-------------+---------------------------------------------
       xb_ar |         74 21.36805 4.286788 11.58643 28.07367
       xb_xt |         74 21.36805 4.286788 11.58643 28.07367
       stdp_ar |         74 .7105649 .1933936 .4270821 1.245179
       stdp_xt |         74 .8155919 .4826332 .0826999 1.709786
\end{verbatim}

The predicted \( xb \) values above are the same for \texttt{areg} and \texttt{xtreg, fe}, but the standard errors for those linear predictions are different. The assumptions for these two estimators lead to different formulations for their standard errors. The robust variance estimates with \texttt{areg} are equivalent to the robust variance estimates using \texttt{regress}, including the panel dummies. The consistent robust variance estimates with \texttt{xtreg} are equivalent to those obtained by specifying \texttt{vce(cluster panelvar)} with that estimation command. For a theoretical discussion, see Wooldridge (2013), Stock and Watson (2008), and Arellano (2003); also see the technical note after example 3 of \cite{XT_xtreg}.

\section*{Example 2}

We would like to use \texttt{linktest} to check whether the dependent variable for our model is correctly specified:

\begin{verbatim}
. use http://www.stata-press.com/data/r13/auto2, clear
     (1978 Automobile Data)
. areg mpg weight gear_ratio, absorb(rep78)
     (output omitted)
. linktest, absorb(rep78)
     Linear regression, absorbing indicators

          Number of obs = 69
          F(  2,   62) = 46.50
          Prob > F    = 0.0000
          R-squared   = 0.6939
          Adj R-squared = 0.6643
          Root MSE    = 3.3990

     Coef.    Std. Err.     t    P>|t|     [95% Conf. Interval]
-------------+---------------------------------------------
      mpg |           _hat   -.9305602   .9537856   -0.98   0.333    -2.83715  .9760302
         .hat |         .0462785   .0227219    2.04   0.046     .0008582   .0916989
      mpg |          _hatsq   19.24899   9.725618    1.98   0.052    -.1922457  38.69022
      mpg |          _cons
     rep78 |           F( 4, 62) = 1.278   0.288   (5 categories)
\end{verbatim}
The squared residuals are significant in the regression for mpg on the linear and squared residuals; therefore, the test indicates that our dependent variable does not seem to be well specified. Let’s transform the dependent variable into energy consumption, gallons per mile, fit the alternative model, and check the link test again.

```
. generate gpm = 1/mpg
. areg gpm weight gear_ratio, absorb(rep78)
(output omitted)
. linktest, absorb(rep78)
```

**Linear regression, absorbing indicators**

| Coef. | Std. Err. | t | P>|t| | [95% Conf. Interval] |
|-------|-----------|---|------|-------------------|
| _hat  | .2842582  | .7109124 | 0.40 | 0.691 | -1.136835 1.705352 |
| _hatsq| 6.956965  | 6.862439 | 1.01 | 0.315 | -6.760855 20.67478 |
| _cons | .0175457  | .0178251 | 0.98 | 0.329 | -.0180862 .0531777 |

```
. linktest, absorb(rep78)
```

**Linear regression, absorbing indicators**

| Coef. | Std. Err. | t | P>|t| | [95% Conf. Interval] |
|-------|-----------|---|------|-------------------|
| _hat  | .2842582  | .7109124 | 0.40 | 0.691 | -1.136835 1.705352 |
| _hatsq| 6.956965  | 6.862439 | 1.01 | 0.315 | -6.760855 20.67478 |
| _cons | .0175457  | .0178251 | 0.98 | 0.329 | -.0180862 .0531777 |
| rep78 | F(4, 62) = 0.065 | 0.992 | (5 categories) |

The link test supports the use of the transformed dependent variable.

*case(\text{varname}) and alternatives(\text{varname}) are required.

bootstrap, by, fp, jackknife, statsby, and xi are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

fweights, iweights, and pweights are allowed (see [U] 11.1.6 weight), but they are interpreted to apply to cases as a whole, not to individual observations. See Use of weights in [R] clogit.

coefflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
asclogit — Alternative-specific conditional logit (McFadden’s choice) model

Menu
Statistics > Categorical outcomes > Alternative-specific conditional logit

Description

asclogit fits McFadden’s choice model, which is a specific case of the more general conditional logistic regression model (McFadden 1974). asclogit requires multiple observations for each case (individual or decision), where each observation represents an alternative that may be chosen. The cases are identified by the variable specified in the case() option, whereas the alternatives are identified by the variable specified in the alternatives() option. The outcome or chosen alternative is identified by a value of 1 in depvar, whereas zeros indicate the alternatives that were not chosen. There can be multiple alternatives chosen for each case.

asclogit allows two types of independent variables: alternative-specific variables and case-specific variables. Alternative-specific variables vary across both cases and alternatives and are specified in indepvars. Case-specific variables vary only across cases and are specified in the casevars() option.

See [R] clogit for a more general application of conditional logistic regression. For example, clogit would be used when you have grouped data where each observation in a group may be a different individual, but all individuals in a group have a common characteristic. You may use clogit to obtain the same estimates as asclogit by specifying the case() variable as the group() variable in clogit and generating variables that interact the casevars() in asclogit with each alternative (in the form of an indicator variable), excluding the interaction variable associated with the base alternative. asclogit takes care of this data management burden for you. Also, for clogit, each record (row in your data) is an observation, whereas in asclogit each case, consisting of several records (the alternatives) in your data, is an observation. This last point is important because asclogit will drop observations, by default, in a casewise fashion. That is, if there is at least one missing value in any of the variables for each record of a case, the entire case is dropped from estimation. To use alternativewise deletion, specify the altwise option and only the records with missing values will be dropped from estimation.

Options

Model

\[ case(\text{varname}) \]

specifies the numeric variable that identifies each case. case() is required and must be integer valued.

\[ \text{alternatives(\text{varname})} \]

specifies the variable that identifies the alternatives for each case. The number of alternatives can vary with each case; the maximum number of alternatives cannot exceed the limits of tabulate oneway; see [R] tabulate oneway. alternatives() is required and may be a numeric or a string variable.

\[ \text{casevars(\text{varlist})} \]

specifies the case-specific numeric variables. These are variables that are constant for each case. If there are a maximum of \( J \) alternatives, there will be \( J - 1 \) sets of coefficients associated with the casevars().

\[ \text{basealternative(\# | \textbf{lbl} | \textit{str})} \]

specifies the alternative that normalizes the latent-variable location (the level of utility). The base alternative may be specified as a number, label, or string depending on the storage type of the variable indicating alternatives. The default is the alternative with the highest frequency.

If vce(bootstrap) or vce(jackknife) is specified, you must specify the base alternative. This is to ensure that the same model is fit with each call to asclogit.
noconstant suppresses the $J - 1$ alternative-specific constant terms.

altwise specifies that alternativewise deletion be used when marking out observations due to missing values in your variables. The default is to use casewise deletion; that is, the entire group of observations making up a case is deleted if any missing values are encountered. This option does not apply to observations that are marked out by the if or in qualifier or the by prefix.

offset(varname), constraints(numlist | matname), collinear; see [R] estimation options.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#) ; see [R] estimation options.

or reports the estimated coefficients transformed to odds ratios, that is, $e^b$ rather than $b$. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. or may be specified at estimation or when replaying previously estimated results.

noheader prevents the coefficient table header from being displayed.

nocnsreport; see [R] estimation options.

display_options: cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), atol tolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

 technique(bhhh) is not allowed.

The initial estimates must be specified as from(matname [, copy]), where matname is the matrix containing the initial estimates and the copy option specifies that only the position of each element in matname is relevant. If copy is not specified, the column stripe of matname identifies the estimates.

The following option is available with asclogit but is not shown in the dialog box:

coeflegend; see [R] estimation options.

Remarks and examples

asclogit fits McFadden’s choice model (McFadden [1974]; for a brief introduction, see Greene [2012, sec. 18.2] or Cameron and Trivedi [2010, sec. 15.5]). In this model, we have a set of unordered alternatives indexed by $1, 2, \ldots, J$. Let $y_{ij}, j = 1, \ldots, J$, be an indicator variable for the alternative actually chosen by the $i$th individual (case). That is, $y_{ij} = 1$ if individual $i$ chose alternative $j$ and $y_{ij} = 0$ otherwise. The independent variables come in two forms: alternative specific and case
specific. Alternative-specific variables vary among the alternatives (as well as cases), and case-specific variables vary only among cases. Assume that we have \( p \) alternative-specific variables so that for case \( i \) we have a \( J \times p \) matrix, \( \mathbf{X}_i \). Further, assume that we have \( q \) case-specific variables so that we have a \( 1 \times q \) vector \( \mathbf{z}_i \) for case \( i \). Our random-utility model can then be expressed as

\[
\mathbf{u}_i = \mathbf{X}_i \beta + (\mathbf{z}_i \mathbf{A})' + \epsilon_i
\]

Here \( \beta \) is a \( p \times 1 \) vector of alternative-specific regression coefficients and \( \mathbf{A} = (\alpha_1, \ldots, \alpha_J) \) is a \( q \times J \) matrix of case-specific regression coefficients. The elements of the \( J \times 1 \) vector \( \epsilon_i \) are independent Type I (Gumbel-type) extreme-value random variables with mean \( \gamma \) (the Euler–Mascheroni constant, approximately 0.577) and variance \( \pi^2/6 \). We must fix one of the \( \alpha_j \) to the constant vector to normalize the location. We set \( \alpha_k = 0 \), where \( k \) is specified by the \texttt{basealternative()} option. The vector \( \mathbf{u}_i \) quantifies the utility that the individual gains from the \( J \) alternatives. The alternative chosen by individual \( i \) is the one that maximizes utility.

Example 1

We have data on 295 consumers and their choice of automobile. Each consumer chose among an American, Japanese, or European car; the variable \texttt{car} indicates the nationality of the car for each alternative. We want to explore the relationship between the choice of \texttt{car} to the consumer’s sex (variable \texttt{sex}) and income (variable \texttt{income} in thousands of dollars). We also have information on the number of dealerships of each nationality in the consumer’s city in the variable \texttt{dealer} that we want to include as a regressor. We assume that consumers’ preferences are influenced by the number of dealerships in an area but that the number of dealerships is not influenced by consumer preferences (which we admit is a rather strong assumption). The variable \texttt{dealer} is an alternative-specific variable (\( \mathbf{X}_i \) is a \( 3 \times 1 \) vector in our previous notation), and \texttt{sex} and \texttt{income} are case-specific variables (\( \mathbf{z}_i \) is a \( 1 \times 2 \) vector). Each consumer’s chosen car is indicated by the variable \texttt{choice}.

Let’s list some of the data.

```
. use http://www.stata-press.com/data/r13/choice
. list id car choice dealer sex income in 1/12, sepby(id)
```

<table>
<thead>

We see, for example, that the first consumer, a male earning $46,700 per year, chose to purchase a European car even though there are more American and Japanese car dealers in his area. The fourth consumer, a female earning $49,200 per year, purchased a Japanese car.
We now fit our model.

These results indicate that men (sex = 1) are less likely to pick a Japanese car over an American car than women (odds ratio 0.59) but that men are more likely to choose a European car over an American car (odds ratio 1.77). Raising a person’s income increases the likelihood that he or she
purchases a Japanese or European car; interestingly, the effect of higher income is about the same for these two types of cars.

Daniel Little McFadden was born in 1937 in North Carolina. He studied physics, psychology, and economics at the University of Minnesota and has taught economics at Pittsburgh, Berkeley, MIT, and the University of Southern California. His contributions to logit models were triggered by a student’s project on freeway routing decisions, and his work consistently links economic theory and applied problems. In 2000, he shared the Nobel Prize in Economics with James J. Heckman.

---

**Technical note**

McFadden’s choice model is related to multinomial logistic regression (see [R] mlogit). If all the independent variables are case specific, then the two models are identical. We verify this supposition by running the previous example without the alternative-specific variable, dealer.

```
.asclogit choice, case(id) alternatives(car) casevars(sex income) nolog
```

To run mlogit, we must rearrange the dataset. mlogit requires a dependent variable that indicates the choice—1, 2, or 3—for each individual. We will use car as our dependent variable for those observations that represent the choice actually chosen.
. keep if choice == 1  
(590 observations deleted)

The results are the same except for the model statistic: asclogit uses a Wald test and mlogit uses a likelihood-ratio test. If you prefer the likelihood-ratio test, you can fit the constant-only model for asclogit followed by the full model and use [R] `lrtest`. The following example will carry this out.

. use http://www.stata-press.com/data/r13/choice, clear  
. asclogit choice, case(id) alternatives(car)  
. estimates store null  
. asclogit choice, case(id) alternatives(car) casevars(sex income)  
. lrtest null .

Technical note

We force you to explicitly identify the case-specific variables in the `casevars()` option to ensure that the program behaves as you expect. For example, an `if` or `in` qualifier may drop observations in such a way that (what was expected to be) an alternative-specific variable turns into a case-specific variable. Here you would probably want `asclogit` to terminate instead of interacting the variable with the alternative indicators. This situation could also occur if `asclogit` drops cases, or observations if you use the `altwise` option, because of missing values.
Stored results

asclogit stores the following in e():

Scalars

- `e(N)` number of observations
- `e(N_case)` number of cases
- `e(k)` number of parameters
- `e(k_alt)` number of alternatives
- `e(k_indvars)` number of alternative-specific variables
- `e(k_casevars)` number of case-specific variables
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(df_m)` model degrees of freedom
- `e(ll)` log likelihood
- `e(N_clust)` number of clusters
- `e(const)` constant indicator
- `e(i_base)` base alternative index
- `e(chi2)` chi-squared
- `e(F)` F statistic
- `e(p)` significance
- `e(alt_min)` minimum number of alternatives
- `e(alt_avg)` average number of alternatives
- `e(alt_max)` maximum number of alternatives
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

Macros

- `e(cmd)` asclogit
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(indvars)` alternative-specific independent variable
- `e(casevars)` case-specific variables
- `e(case)` variable defining cases
- `e(altvar)` variable defining alternatives
- `e(alteqs)` alternative equation names
- `e(alt#)` alternative labels
- `e(vtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(offset)` linear offset variable
- `e(chi2type)` Wald, type of model chi-squared test
- `e(vce)` vcetype specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` max or min; whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of ml method
- `e(user)` name of likelihood-evaluator program
- `e(technique)` maximization technique
- `e(datasignature)` the checksum
- `e(datasignaturevars)` variables used in calculation of checksum
- `e(properties)` b V
- `e(estat_cmd)` program used to implement estat
- `e(predict)` program used to implement predict
- `e(marginsnotok)` predictions disallowed by margins
Methods and formulas

In this model, we have a set of unordered alternatives indexed by 1, 2, ..., J. Let \( y_{ij} \), \( j = 1, \ldots, J \), be an indicator variable for the alternative actually chosen by the \( i \)th individual (case). That is, \( y_{ij} = 1 \) if individual \( i \) chose alternative \( j \) and \( y_{ij} = 0 \) otherwise. The independent variables come in two forms: alternative specific and case specific. Alternative-specific variables vary among the alternatives (as well as cases), and case-specific variables vary only among cases. Assume that we have \( p \) alternative-specific variables so that for case \( i \) we have a \( J \times p \) matrix, \( X_i \). Further, assume that we have \( q \) case-specific variables so that we have a \( 1 \times q \) vector \( z_i \) for case \( i \). The deterministic component of the random-utility model can then be expressed as

\[
\eta_i = X_i\beta + (z_iA)' = X_i\beta + (z_i \otimes I_J)\text{vec}(A') = (X_i, z_i \otimes I_J)\begin{pmatrix} \beta \\ \text{vec}(A') \end{pmatrix} = X_i^*\beta^*
\]

As before, \( \beta \) is a \( p \times 1 \) vector of alternative-specific regression coefficients, and \( A = (\alpha_1, \ldots, \alpha_J) \) is a \( q \times J \) matrix of case-specific regression coefficients; remember that we must fix one of the \( \alpha_j \) to the constant vector to normalize the location. Here \( I_J \) is the \( J \times J \) identity matrix, \( \text{vec()} \) is the vector function that creates a vector from a matrix by placing each column of the matrix on top of the other (see [M-5] vec()), and \( \otimes \) is the Kronecker product (see [M-2] op_kronecker).

We have rewritten the linear equation so that it is a form that can be used by clogit, namely, \( X_i^*\beta^* \), where

\[
X_i^* = (X_i, z_i \otimes I_J)
\]

\[
\beta^* = \begin{pmatrix} \beta \\ \text{vec}(A') \end{pmatrix}
\]

With this in mind, see Methods and formulas in [R] clogit for the computational details of the conditional logit model.

This command supports the clustered version of the Huber/White/sandwich estimator of the variance using vce(robust) and vce(cluster casevar). See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas. Specifying vce(robust) is equivalent to specifying vce(cluster casevar), where casevar is the variable that identifies the cases.

<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

Special-interest postestimation commands

`estat alternatives` displays summary statistics about the alternatives in the estimation sample.

`estat mfx` computes probability marginal effects.
Syntax for predict

\texttt{predict [type] newvar [if] [in] [, statistic options]}

\texttt{predict [type] \{stub\*|newvarlist\} [if] [in], scores}

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{pr}</td>
<td>probability that each alternative is chosen; the default</td>
</tr>
<tr>
<td>\texttt{xb}</td>
<td>linear prediction</td>
</tr>
<tr>
<td>\texttt{stdp}</td>
<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{*k(#</td>
<td>observed)}</td>
</tr>
<tr>
<td>\texttt{altwise}</td>
<td>use alternativewise deletion instead of casewise deletion when computing probabilities</td>
</tr>
<tr>
<td>\texttt{nooffset}</td>
<td>ignore the offset() variable specified in asclogit</td>
</tr>
</tbody>
</table>

\texttt{*k(#|observed)} may be used only with \texttt{pr}.

These statistics are available both in and out of sample; type \texttt{predict ... if e(sample) ...} if wanted only for the estimation sample.

Menu for predict

Statistics \> Postestimation \> Predictions, residuals, etc.

Options for predict

\texttt{pr} computes the probability of choosing each alternative conditioned on each case choosing \texttt{k()} alternatives. This is the default statistic with default \texttt{k(1)}; one alternative per case is chosen.

\texttt{xb} computes the linear prediction.

\texttt{stdp} computes the standard error of the linear prediction.

\texttt{k(#|observed)} conditions the probability on \# alternatives per case or on the observed number of alternatives. The default is \texttt{k(1)}. This option may be used only with the \texttt{pr} option.

\texttt{altwise} specifies that alternativewise deletion be used when marking out observations due to missing values in your variables. The default is to use casewise deletion. The \texttt{xb} and \texttt{stdp} options always use alternativewise deletion.

\texttt{nooffset} is relevant only if you specified \texttt{offset(varname)} for asclogit. It modifies the calculations made by predict so that they ignore the offset variable; the linear prediction is treated as \texttt{x}\textbf{β} rather than as \texttt{x}\textbf{β} + offset.

\texttt{scores} calculates the scores for each coefficient in \texttt{e(b)}. This option requires a new variable list of length equal to the number of columns in \texttt{e(b)}. Otherwise, use the \texttt{stub\*} option to have predict generate enumerated variables with prefix \texttt{stub}. 
## Syntax for estat

**Alternative summary statistics**

```
estat alternatives
```

**Marginal effects**

```
estat mfx [if] [in] [, options]
```

### options

</tr>
</tbody>
</table>

## Menu for estat

Statistics > Postestimation > Reports and statistics

## Options for estat mfx

- **Main**
  - `varlist(varlist)` specifies the variables for which to display marginal effects. The default is all variables.
  - `at(mean [atlist] | median [atlist])` specifies the values at which the marginal effects are to be calculated. `atlist` is
    ```
    [[ alternative:variable = # ] [ variable = # ] [ alternative:offset = # ] [...]]
    ```

  The default is to calculate the marginal effects at the means of the independent variables by using the estimation sample, `at(mean)`. If `offset()` is used during estimation, the means of the offsets (by alternative) are computed by default.

  After specifying the summary statistic, you can specify a series of specific values for variables. You can specify values for alternative-specific variables by alternative, or you can specify one value for all alternatives. You can specify only one value for case-specific variables. You specify values for the `offset()` variable (if present) the same way as for alternative-specific variables. For example, in the `choice` dataset (car choice), `income` is a case-specific variable, whereas `dealer` is an alternative-specific variable. The following would be a legal syntax for `estat mfx`:

  `. estat mfx, at(mean American:dealer=18 income=40)`
When `nodiscrete` is not specified, `at(mean [atlist])` or `at(median [atlist])` has no effect on computing marginal effects for indicator variables, which are calculated as the discrete change in the simulated probability as the indicator variable changes from 0 to 1.

The mean and median computations respect any `if` or `in` qualifiers, so you can restrict the data over which the statistic is computed. You can even restrict the values to a specific case, for example,

```
.estat mfx if case==21
```

`k(#)` computes the probabilities conditioned on # alternatives chosen. The default is one alternative chosen.

```
<table>
<thead>
<tr>
<th>Options</th>
</tr>
</thead>
<tbody>
<tr>
<td>level(#) sets the confidence level; default is <code>level(95)</code>.</td>
</tr>
<tr>
<td><code>nodiscrete</code> specifies that indicator variables be treated as continuous variables. An indicator variable is one that takes on the value 0 or 1 in the estimation sample. By default, the discrete change in the simulated probability is computed as the indicator variable changes from 0 to 1.</td>
</tr>
<tr>
<td><code>noesample</code> specifies that the whole dataset be considered instead of only those marked in the <code>e(sample)</code> defined by the <code>asclogit</code> command.</td>
</tr>
<tr>
<td><code>nowght</code> specifies that weights be ignored when calculating the medians.</td>
</tr>
</tbody>
</table>
```

## Remarks and examples

Remarks are presented under the following headings:

- **Predicted probabilities**
- **Obtaining estimation statistics**

### Predicted probabilities

After fitting a McFadden’s choice model with alternative-specific conditional logistic regression, you can use `predict` to obtain the estimated probability of alternative choices given case profiles.

#### Example 1

In example 1 of [R] `asclogit`, we fit a model of consumer choice of automobile. The alternatives are nationality of the automobile manufacturer: American, Japanese, or European. There is one alternative-specific variable in the model, `dealer`, which contains the number of dealerships of each nationality in the consumer’s city. The case-specific variables are `sex`, the consumer’s sex, and `income`, the consumer’s income in thousands of dollars.

```
use http://www.stata-press.com/data/r13/choice
.asclogit choice dealer, case(id) alternatives(car) casevars(sex income) 
(output omitted)
.predict p 
(option pr assumed; Pr(car))
.predict p2, k(2) 
(option pr assumed; Pr(car))
.format p p2 %6.4f
```

### Obtaining estimation statistics

Here we will demonstrate the specialized `estat` subcommands after `asclogit`. Use `estat alternatives` to obtain a table of alternative statistics. The table will contain the alternative values, labels (if any), the number of cases in which each alternative is present, the frequency that the alternative is selected, and the percent selected.

Use `estat mfx` to obtain marginal effects after `asclogit`.

#### Example 2

We will continue with the automobile choice example, where we first list the alternative statistics and then compute the marginal effects at the mean income in our sample, assuming that there are five automobile dealers for each nationality. We will evaluate the probabilities for females because `sex` is coded 0 for females, and we will be obtaining the discrete change from 0 to 1.

(*) dp/dx is for discrete change of indicator variable from 0 to 1

The marginal effect of income indicates that there is a lower chance for a consumer to buy American automobiles with an increase in income. There is an indication that men have a higher preference for European automobiles than women but a lower preference for Japanese automobiles. We did not include the marginal effects for dealer because we view these as nuisance parameters, so we adjusted the probabilities by fixing dealer to a constant, 0.

Stored results

`estat mfx` stores the following in `r()`:

Scalars

- `r(pr_alt)` scalars containing the computed probability of each alternative evaluated at the value that is labeled X in the table output. Here `alt` are the labels in the macro `e(alteqs)`.

Matrices

- `r(alt)` matrices containing the computed marginal effects and associated statistics. There is one matrix for each alternative, where `alt` are the labels in the macro `e(alteqs)`. Column 1 of each matrix contains the marginal effects; column 2, their standard errors; column 3, their z statistics; and columns 4 and 5, the confidence intervals. Column 6 contains the values of the independent variables used to compute the probabilities `r(pr_alt)`.

Methods and formulas

The deterministic component of the random-utility model can be expressed as

$$\eta = X\beta + (z\mathbf{A})'$$

$$= X\beta + (z \otimes I_J) \text{vec}(A')$$

$$= (X, \ z \otimes I_J) \begin{pmatrix} \beta \\ \text{vec}(A') \end{pmatrix}$$

$$= X^* \beta^*$$

where $X$ is the $J \times p$ matrix containing the alternative-specific covariates, $z$ is a $1 \times q$ vector of case-specific variables, $\beta$ is a $p \times 1$ vector of alternative-specific regression coefficients, and $\mathbf{A} = (\alpha_1, \ldots, \alpha_J)$ is a $q \times J$ matrix of case-specific regression coefficients (with one of the $\alpha_j$ fixed to the constant). Here $I_J$ is the $J \times J$ identity matrix, vec() is the vector function that creates a vector from a matrix by placing each column of the matrix on top of the other (see [M-5] vec()), and $\otimes$ is the Kronecker product (see [M-2] op_kronecker).
We have rewritten the linear equation so that it is a form that we all recognize, namely, \( \eta = X^* \beta^* \), where

\[
X^* = (X, \ z \otimes I_J)
\]

\[
\beta^* = \begin{pmatrix} \beta \\ vec(A') \end{pmatrix}
\]

To compute the marginal effects, we use the derivative of the log likelihood \( \partial \ell(y|\eta)/\partial \eta \), where \( \ell(y|\eta) = \log Pr(y|\eta) \) is the log of the probability of the choice indicator vector \( y \) given the linear predictor vector \( \eta \). Namely,

\[
\frac{\partial Pr(y|\eta)}{\partial vec(X^*)'} = Pr(y|\eta) \frac{\partial \ell(y|\eta)}{\partial \eta'} \frac{\partial \eta}{\partial vec(X^*)'} = Pr(y|\eta) \frac{\partial \ell(y|\eta)}{\partial \eta'} (\beta^* \otimes I_J)
\]

The standard errors of the marginal effects are computed using the delta method.

Syntax

```
asmprobit depvar [ indepvars ] [ if ] [ in ] [ weight ], case(varname)

alternatives(varname) [ options ]
```

Options

Model

* case(varname)
  use varname to identify cases

* alternatives(varname)
  use varname to identify the alternatives available for each case

  casevars(varlist)
  case-specific variables

  constraints(constraints)
  apply specified linear constraints

  collinear
  keep collinear variables

Model 2

  correlation(correlation)
  correlation structure of the latent-variable errors

  stddev(stddev)
  variance structure of the latent-variable errors

  structural
  use the structural covariance parameterization; default is the
differenced covariance parameterization

  factor(#)
  use the factor covariance structure with dimension #

  noconstant
  suppress the alternative-specific constant terms

  basealternative(# | lbl | str)
  alternative used for normalizing location

  scalealternative(# | lbl | str)
  alternative used for normalizing scale

  altwise
  use alternativewise deletion instead of casewise deletion

SE/Robust

  vce(vcetype)
  vcetype may be oim, robust, cluster clustvar, opg,
  bootstrap, or jackknife

Reporting

  level(#)
  set confidence level; default is level(95)

  notransform
  do not transform variance–covariance estimates to the standard
deviation and correlation metric

  noconsreport
  do not display constraints

  display_options
  control column formats and line width
Integration

intmethod(seqtype) type of quasi- or pseudouniform point set
intpoints(#) number of points in each sequence
intburn(#) starting index in the Hammersley or Halton sequence
intseed(code | #) pseudouniform random-number seed
antithetics use antithetic draws
nopivot do not use integration interval pivoting
initbhhh(#) use the BHHH optimization algorithm for the first # iterations
favor(speed | space) favor speed or space when generating integration points

Maximization

maximize_options control the maximization process
coeflegend display legend instead of statistics

correlation Description

unstructured one correlation parameter for each pair of alternatives; correlations with the basealternative() are zero; the default
exchangeable one correlation parameter common to all pairs of alternatives; correlations with the basealternative() are zero
independent constrain all correlation parameters to zero
pattern matname user-specified matrix identifying the correlation pattern
fixed matname user-specified matrix identifying the fixed and free correlation parameters

stddev Description

heteroskedastic estimate standard deviation for each alternative; standard deviations for basealternative() and scalealternative() set to one
homoskedastic all standard deviations are one
pattern matname user-specified matrix identifying the standard deviation pattern
fixed matname user-specified matrix identifying the fixed and free standard deviations

seqtype Description

hammersley Hammersley point set
halton Halton point set
random uniform pseudorandom point set

*case(varname) and alternatives(varname) are required.

bootstrap, by, jackknife, statsby, and xi are allowed; see [U] 11.1.10 Prefix commands.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.

coefflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
**asmprobit** fits multinomial probit (MNP) models by using maximum simulated likelihood (MSL) implemented by the Geweke–Hajivassiliou–Keane (GHK) algorithm. By estimating the variance–covariance parameters of the latent-variable errors, the model allows you to relax the independence of irrelevant alternatives (IIA) property that is characteristic of the multinomial logistic model.

**asmprobit** requires multiple observations for each case (decision), where each observation represents an alternative that may be chosen. The cases are identified by the variable specified in the `case()` option, whereas the alternatives are identified by the variable specified in the `alternative()` option. The outcome (chosen alternative) is identified by a value of 1 in `depvar`, with 0 indicating the alternatives that were not chosen; only one alternative may be chosen for each case.

**asmprobit** allows two types of independent variables: alternative-specific variables and case-specific variables. Alternative-specific variables vary across both cases and alternatives and are specified in `indepvars`. Case-specific variables vary only across cases and are specified in the `casevars()` option.

### Options

- **Model 1**
  - `case(varname)` specifies the variable that identifies each case. This variable identifies the individuals or entities making a choice. `case()` is required.
  - `alternatives(varname)` specifies the variable that identifies the alternatives for each case. The number of alternatives can vary with each case; the maximum number of alternatives is 20. `alternatives()` is required.
  - `casevars(varlist)` specifies the case-specific variables that are constant for each `case()`. If there are a maximum of $J$ alternatives, there will be $J - 1$ sets of coefficients associated with `casevars()`. `constraints(constraints)`, collinear; see [R] estimation options.

- **Model 2**
  - `correlation(correlation)` specifies the correlation structure of the latent-variable errors.
    - `correlation(unstructured)` is the most general and has $J(J - 3)/2 + 1$ unique correlation parameters. This is the default unless `stdev()` or `structural` are specified.
    - `correlation(exchangeable)` provides for one correlation coefficient common to all latent variables, except the latent variable associated with the `basealternative()` option.
    - `correlation(independent)` assumes that all correlations are zero.
    - `correlation(pattern matname)` and `correlation(fixed matname)` give you more flexibility in defining the correlation structure. See Variance structures later in this entry for more information.
  - `stdev(stdev)` specifies the variance structure of the latent-variable errors.
stddev(heteroskedastic) is the most general and has \( J - 2 \) estimable parameters. The standard deviations of the latent-variable errors for the alternatives specified in basealternative() and scalealternative() are fixed to one.

stddev(homoskedastic) constrains all the standard deviations to equal one.

stddev(pattern matname) and stddev(fixed matname) give you added flexibility in defining the standard deviation parameters. See Variance structures later in this entry for more information.

structural requests the \( J \times J \) structural covariance parameterization instead of the default \( J - 1 \times J - 1 \) differenced covariance parameterization (the covariance of the latent errors differenced with that of the base alternative). The differenced covariance parameterization will achieve the same MSL regardless of the choice of basealternative() and scalealternative(). On the other hand, the structural covariance parameterization imposes more normalizations that may bound the model away from its maximum likelihood and thus prevent convergence with some datasets or choices of basealternative() and scalealternative().

factor(#) requests that the factor covariance structure of dimension # be used. The factor() option can be used with the structural option but cannot be used with stddev() or correlation(). A \( \# \times J \) (or \( \# \times J - 1 \)) matrix, \( C \), is used to factor the covariance matrix as \( I + C' C \), where \( I \) is the identity matrix of dimension \( J \) (or \( J - 1 \)). The column dimension of \( C \) depends on whether the covariance is structural or differenced. The row dimension of \( C \), \( \# \), must be less than or equal to floor\(((J(J-1)/2-1)/(J-2)) \), because there are only \( J(J-1)/2 - 1 \) identifiable variance–covariance parameters. This covariance parameterization may be useful for reducing the number of covariance parameters that need to be estimated.

If the covariance is structural, the column of \( C \) corresponding to the base alternative contains zeros. The column corresponding to the scale alternative has a one in the first row and zeros elsewhere. If the covariance is differenced, the column corresponding to the scale alternative (differenced with the base) has a one in the first row and zeros elsewhere.

noconstant suppresses the \( J - 1 \) alternative-specific constant terms.

basealternative(# | lbl | str) specifies the alternative used to normalize the latent-variable location (also referred to as the level of utility). The base alternative may be specified as a number, label, or string. The standard deviation for the latent-variable error associated with the base alternative is fixed to one, and its correlations with all other latent-variable errors are set to zero. The default is the first alternative when sorted. If a fixed or pattern matrix is given in the stddev() and correlation() options, the basealternative() will be implied by the fixed standard deviations and correlations in the matrix specifications. basealternative() cannot be equal to scalealternative().

scalealternative(# | lbl | str) specifies the alternative used to normalize the latent-variable scale (also referred to as the scale of utility). The scale alternative may be specified as a number, label, or string. The default is to use the second alternative when sorted. If a fixed or pattern matrix is given in the stddev() option, the scalealternative() will be implied by the fixed standard deviations in the matrix specification. scalealternative() cannot be equal to basealternative().

If a fixed or pattern matrix is given for the stddev() option, the base alternative and scale alternative are implied by the standard deviations and correlations in the matrix specifications, and they need not be specified in the basealternative() and scalealternative() options.

altwise specifies that alternativewise deletion be used when marking out observations due to missing values in your variables. The default is to use casewise deletion; that is, the entire group of observations making up a case is deleted if any missing values are encountered. This option does not apply to observations that are marked out by the if or in qualifier or the by prefix.
vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

If specifying vce(bootstrap) or vce(jackknife), you must also specify basealternative() and scalealternative().

Reporting

level(#) ; see [R] estimation options.

notransform prevents retransforming the Cholesky-factored variance–covariance estimates to the correlation and standard deviation metric.

This option has no effect if structural is not specified because the default differenced variance–covariance estimates have no interesting interpretation as correlations and standard deviations. notransform also has no effect if the correlation() and stddev() options are specified with anything other than their default values. Here it is generally not possible to factor the variance–covariance matrix, so optimization is already performed using the standard deviation and correlation representations.

nocnsreport ; see [R] estimation options.

display_options: cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch ; see [R] estimation options.

Integration

intmethod(hammersley | halton | random) specifies the method of generating the point sets used in the quasi–Monte Carlo integration of the multivariate normal density. intmethod(hammersley), the default, uses the Hammersley sequence; intmethod(halton) uses the Halton sequence; and intmethod(random) uses a sequence of uniform random numbers.

intpoints(#) specifies the number of points to use in the quasi–Monte Carlo integration. If this option is not specified, the number of points is 50 × J if intmethod(hammersley) or intmethod(halton) is used and 100 × J if intmethod(random) is used. Larger values of intpoints() provide better approximations of the log likelihood, but at the cost of added computation time.

intburn(#) specifies where in the Hammersley or Halton sequence to start, which helps reduce the correlation between the sequences of each dimension. The default is 0. This option may not be specified with intmethod(random).

intseed(code | #) specifies the seed to use for generating the uniform pseudorandom sequence. This option may be specified only with intmethod(random). code refers to a string that records the state of the random-number generator runiform(); see [R] set seed. An integer value # may be used also. The default is to use the current seed value from Stata’s uniform random-number generator, which can be obtained from c(seed).

antithetics specifies that antithetic draws be used. The antithetic draw for the J − 1 vector uniform-random variables, x, is 1 − x.

nopivot turns off integration interval pivoting. By default, asmprobit will pivot the wider intervals of integration to the interior of the multivariate integration. This improves the accuracy of the quadrature estimate. However, discontinuities may result in the computation of numerical second-order derivatives using finite differencing (for the Newton–Raphson optimize technique, tech(nr))
when few simulation points are used, resulting in a non–positive-definite Hessian. \texttt{asmprobit}
uses the Broyden–Fletcher–Goldfarb–Shanno optimization algorithm, by default, which does not require computing the Hessian numerically using finite differencing.

\texttt{initbhhh(\#)} specifies that the Berndt–Hall–Hall–Hausman (BHHH) algorithm be used for the initial \# optimization steps. This option is the only way to use the BHHH algorithm along with other optimization techniques. The algorithm switching feature of \texttt{ml}'s \texttt{technique()} option cannot include bhhh.

\texttt{favor(speed|space)} instructs \texttt{asmprobit} to favor either speed or space when generating the integration points. \texttt{favor(speed)} is the default. When favoring speed, the integration points are generated once and stored in memory, thus increasing the speed of evaluating the likelihood. This speed increase can be seen when there are many cases or when the user specifies a large number of integration points, \texttt{intpoints(\#)}. When favoring space, the integration points are generated repeatedly with each likelihood evaluation.

For unbalanced data, where the number of alternatives varies with each case, the estimates computed using \texttt{intmethod(random)} will vary slightly between \texttt{favor(speed)} and \texttt{favor(space)}. This is because the uniform sequences will not be identical, even when initiating the sequences using the same uniform seed, \texttt{intseed(code|\#)}. For \texttt{favor(speed)}, \texttt{ncase} blocks of \texttt{intpoints(\#)} $\times J - 2$ uniform points are generated, where $J$ is the maximum number of alternatives. For \texttt{favor(space)}, the column dimension of the matrices of points varies with the number of alternatives that each case has.

The following options may be particularly useful in obtaining convergence with \texttt{asmprobit}:
\begin{verbatim}
difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize.
\end{verbatim}

The following options are available with \texttt{asmprobit} but is not shown in the dialog box:
\texttt{coeflegend}; see [R] estimation options.

### Remarks and examples

Remarks are presented under the following headings:

- Introduction
- Variance structures
Introduction

The MNP model is used with discrete dependent variables that take on more than two outcomes that do not have a natural ordering. The stochastic error terms are assumed to have a multivariate normal distribution that is heteroskedastic and correlated. Say that you have a set of $J$ unordered alternatives that are modeled by a regression of both case-specific and alternative-specific covariates. A “case” refers to the information on one decision maker. Underlying the model is the set of $J$ latent variables (utilities),

$$
\eta_{ij} = x_{ij}'\beta + z_i^j\alpha_j + \xi_{ij}
$$

(1)

where $i$ denotes cases and $j$ denotes alternatives. $x_{ij}$ is a $1 \times p$ vector of alternative-specific variables, $\beta$ is a $p \times 1$ vector of parameters, $z_i^j$ is a $1 \times q$ vector of case-specific variables, $\alpha_j$ is a $q \times 1$ vector of parameters for the $j$th alternative, and $\xi_i = (\xi_{i1}, \ldots, \xi_{iJ})$ is distributed multivariate normal with mean zero and covariance matrix $\Omega$. The decision maker selects the alternative whose latent variable is highest.

Because the MNP model allows for a general covariance structure in $\xi_{ij}$, it does not impose the IIA property inherent in multinomial logistic and conditional logistic models. That is, the MNP model permits the odds of choosing one alternative over another to depend on the remaining alternatives. For example, consider the choice of travel mode between two cities: air, train, bus, or car, as a function of the travel mode cost, travel time (alternative-specific variables), and an individual’s income (a case-specific variable). The odds of choosing air travel over a bus may not be independent of the train alternative because both bus and train travel are public ground transportation. That is, the probability of choosing air travel is

$$
Pr(\text{air} > \text{bus} | \text{air} > \text{train}, \text{air} > \text{car}) 
$$

and the two events $\text{air} > \text{bus}$ and $\text{air} > \text{train}$ may be correlated.

An alternative to MNP that will allow a nested correlation structure in $\xi_{ij}$ is the nested logit model (see [R] nlogit).

The added flexibility of the MNP model does impose a significant computation burden because of the need to evaluate probabilities from the multivariate normal distribution. These probabilities are evaluated using simulation techniques because a closed-form solution does not exist. See Methods and formulas for more information.

Not all the $J$ sets of regression coefficients $\alpha_j$ are identifiable, nor are all $J(J + 1)/2$ elements of the variance–covariance matrix $\Omega$. As described by Train (2009, sec. 2.5), the model requires normalization because both the location (level) and scale of the latent variable are irrelevant. Increasing the latent variables by a constant does not change which $\eta_{ij}$ is the maximum for decision maker $i$, nor does multiplying them by a constant. To normalize location, we choose an alternative, indexed by $k$, say, and take the difference between the latent variable $k$ and the $J - 1$ others,

$$
v_{ijk} = \eta_{ij} - \eta_{ik} 
= (x_{ij} - x_{ik})'\beta + z_i^j(\alpha_j - \alpha_k) + \xi_{ij} - \xi_{ik} 
= \delta_{ij}^j'\beta + z_i^j\gamma_j^j + \epsilon_{ij}^j 
= \lambda_{ij}^j + \epsilon_{ij}^j
$$

(2)

where $j' = j$ if $j < k$ and $j' = j - 1$ if $j > k$, so that $j' = 1, \ldots, J - 1$. One can now work with the $(J - 1) \times (J - 1)$ covariance matrix $\Sigma_{(k)}$ for $\epsilon_i' = (\epsilon_{i1}, \ldots, \epsilon_{iJ-1})$. The $k$th alternative here is the basealternative() in asmpobit. From (2), the probability that decision maker $i$ chooses alternative $k$, for example, is

$$
Pr(i \text{ chooses } k) = Pr(v_{i1k} \leq 0, \ldots, v_{i,J-1,k} \leq 0) 
= Pr(\epsilon_{i1} \leq -\lambda_{i1}, \ldots, \epsilon_{i,J-1} \leq -\lambda_{i,J-1})
$$
To normalize for scale, one of the diagonal elements of $\Sigma(k)$ must be fixed to a constant. In \texttt{asmprobit}, this is the error variance for the alternative specified by \texttt{scalealternative()}. Thus there are a total of, at most, $J(J-1)/2-1$ identifiable variance–covariance parameters. See \texttt{Variance structures} below for more on this issue.

In fact, the model is slightly more general in that not all cases need to have faced all $J$ alternatives. The model allows for situations in which some cases chose among all possible alternatives, whereas other cases were given a choice among a subset of them, and perhaps other cases were given a choice among a different subset. The number of observations for each case is equal to the number of alternatives faced.

The MNP model is often motivated using a random-utility consumer-choice framework. Equation (1) represents the utility that consumer $i$ receives from good $j$. The consumer purchases the good for which the utility is highest. Because utility is ordinal, all that matters is the ranking of the utilities from the alternatives. Thus one must normalize for location and scale.

\section*{Example 1}

Application of MNP models is common in the analysis of transportation data. Greene (2012, sec. 18.2.9) uses travel-mode choice data between Sydney and Melbourne to demonstrate estimating parameters of various discrete-choice models. The data contain information on 210 individuals’ choices of travel mode. The four alternatives are air, train, bus, and car, with indices 1, 2, 3, and 4, respectively. One alternative-specific variable is travelcost, a measure of generalized cost of travel that is equal to the sum of in-vehicle cost and a wagelike measure times the amount of time spent traveling. A second alternative-specific variable is the terminal time, termtime, which is zero for car transportation. Household income, income, is a case-specific variable.

\begin{verbatim}
use http://www.stata-press.com/data/r13/travel
list id mode choice travelcost termtime income in 1/12, sepby(id)

The model of travel choice is

$$\eta_{ij} = \beta_1 \text{travelcost}_{ij} + \beta_2 \text{termtime}_{ij} + \alpha_{1j} \text{income}_i + \alpha_{0j} + \xi_{ij}$$

The alternatives can be grouped as air and ground travel. With this in mind, we set the air alternative to be the \texttt{basealternative()} and choose train as the scaling alternative. Because these are the first and second alternatives in the \texttt{mode} variable, they are also the defaults.

(mode=air is the alternative normalizing location)
(mode=train is the alternative normalizing scale)
. estimates store full

By default, the differenced covariance parameterization is used, so the covariance matrix for this model is $3 \times 3$. There are two free variances to estimate and three correlations. To help ensure that the covariance matrix remains positive definite, asmprobit uses the square root transformation, where it optimizes on the Cholesky-factored variance–covariance. To ensure that the diagonal elements of the Cholesky estimates remain positive, we use the log transformation. The estimates labeled $/ln12_2$ and $/ln13_3$ in the coefficient table are the log-transformed diagonal elements of the Cholesky matrix. The estimates labeled $/12_1$, $/13_1$, and $/13_2$ are the off-diagonal entries for elements $(2, 1)$, $(3, 1)$, and $(3, 2)$ of the Cholesky matrix.

Although the transformed parameters of the differenced covariance parameterization are difficult to interpret, you can view them untransformed by using the estat command. Typing

We can reduce the number of covariance parameters in the model by using the factor model by Cameron and Trivedi (2005). For large models with many alternatives, the parameter reduction can be dramatic, but for our example we will use factor(1), a one-dimension factor model, to reduce by 3 the number of parameters associated with the covariance matrix.

Note: covariances are for alternatives differed with air

Variance structures

The matrix Ω has J(J + 1)/2 distinct elements because it is symmetric. Selecting a base alternative, normalizing its error variance to one, and constraining the correlations between its error and the other errors reduces the number of estimable parameters by J. Moreover, selecting a scale alternative and normalizing its error variance to one reduces the number by one, as well. Hence, there are at most m = J(J − 1)/2 − 1 estimable parameters in Ω.
In practice, estimating all $m$ parameters can be difficult, so one must often place more restrictions on the parameters. The `asmprobit` command provides the `correlation()` option to specify restrictions on the $J(J - 3)/2 + 1$ correlation parameters not already restricted as a result of choosing the base alternatives, and it provides `stddev()` to specify restrictions on the $J - 2$ standard deviations not already restricted as a result of choosing the base and scale alternatives.

When the `structural` option is used, `asmprobit` fits the model by assuming that all $m$ parameters can be estimated, which is equivalent to specifying `correlation(unstructured)` and `stddev(heteroskedastic)`. The unstructured correlation structure means that all $J(J - 3)/2 + 1$ of the remaining correlation parameters will be estimated, and the heteroskedastic specification means that all $J - 2$ standard deviations will be estimated. With these default settings, the log likelihood is maximized with respect to the Cholesky decomposition of $\Omega$, and then the parameters are transformed to the standard deviation and correlation form.

The `correlation(exchangeable)` option forces the $J(J - 3)/2 + 1$ correlation parameters to be equal, and `correlation(independent)` forces all the correlations to be zero. Using the `stddev(homoskedastic)` option forces all $J$ standard deviations to be one. These options may help in obtaining convergence for a model if the default options do not produce satisfactory results. In fact, when fitting a complex model, it may be advantageous to first fit a simple one and then proceed with removing the restrictions one at a time.

Advanced users may wish to specify alternative variance structures of their own choosing, and the next few paragraphs explain how to do so.

The `correlation(pattern matname)` allows you to give the name of a $J \times J$ matrix that identifies a correlation structure. Sequential positive integers starting at 1 are used to identify each correlation parameter: if there are three correlation parameters, they are identified by 1, 2, and 3. The integers can be repeated to indicate that correlations with the same number should be constrained to be equal. A zero or a missing value (.) indicates that the correlation is to be set to zero. `asmprobit` considers only the elements of the matrix below the main diagonal.

Suppose that you have a model with four alternatives, numbered 1–4, and alternative 1 is the base. The unstructured and exchangeable correlation structures identified in the $4 \times 4$ lower triangular matrices are

\[
\begin{bmatrix}
1 & 2 & 3 & 4 \\
\cdot & 0 & \cdot & \cdot \\
2 & 0 & 1 & \cdot \\
3 & 0 & 2 & 3 \\
4 & 0 & 2 & 1 & \cdot \\
\end{bmatrix}
\quad\quad \begin{bmatrix}
1 & 2 & 3 & 4 \\
\cdot & 0 & \cdot & \cdot \\
2 & 0 & 1 & \cdot \\
3 & 0 & 1 & \cdot \\
4 & 0 & 1 & \cdot \\
\end{bmatrix}
\]

`asmprobit` labels these correlation structures unstructured and exchangeable, even though the correlations corresponding to the base alternative are set to zero. More formally: these terms are appropriate when considering the $(J - 1) \times (J - 1)$ submatrix $\Sigma_{(k)}$ defined in the `Introduction` above.

You can also use the `correlation(fixed matname)` option to specify a matrix that specifies fixed and free parameters. Here the free parameters (those that are to be estimated) are identified by a missing value, and nonmissing values represent correlations that are to be taken as given. Below is a correlation structure that would set the correlations of alternative 1 to be 0.5:

\[
\begin{bmatrix}
1 & 2 & 3 & 4 \\
\cdot & \cdot & \cdot & \cdot \\
2 & 0.5 & \cdot & \cdot \\
3 & 0.5 & \cdot & \cdot \\
4 & 0.5 & \cdot & \cdot \\
\end{bmatrix}
\]
The order of the elements of the pattern or fixed matrices must be the same as the numeric order of the alternative levels.

To specify the structure of the standard deviations—the diagonal elements of $\Omega$—you can use the `stddev(pattern matname)` option, where `matname` is a $1 \times J$ matrix. Sequential positive integers starting at 1 are used to identify each standard deviation parameter. The integers can be repeated to indicate that standard deviations with the same number are to be constrained to be equal. A missing value indicates that the corresponding standard deviation is to be set to one. In the four-alternative example mentioned above, suppose that you wish to set the first and second standard deviations to one and that you wish to constrain the third and fourth standard deviations to be equal; the following pattern matrix will do that:

$$
\begin{pmatrix}
1 & 2 & 3 & 4 \\
1 & & & 1 \\
\end{pmatrix}
$$

Using the `stddev(fixed matname)` option allows you to identify the fixed and free standard deviations. Fixed standard deviations are entered as positive real numbers, and free parameters are identified with missing values. For example, to constrain the first and second standard deviations to equal one and to allow the third and fourth to be estimated, you would use this fixed matrix:

$$
\begin{pmatrix}
1 & 2 & 3 & 4 \\
1 & 1 & & \\
\end{pmatrix}
$$

When supplying either the pattern or the fixed matrices, you must ensure that the model is properly scaled. At least two standard deviations must be constant for the model to be scaled. A warning is issued if asmprobit detects that the model is not scaled.

The order of the elements of the pattern or fixed matrices must be the same as the numeric order of the alternative levels.

> Example 2

In example 1, we used the differenced covariance parameterization, the default. We now use the structural option to view the $J - 2$ standard deviation estimates and the $(J - 1)(J - 2)/2$ correlation estimates. Here we will fix the standard deviations for the air and train alternatives to 1 and the correlations between air and the rest of the alternatives to 0.

(mode=air is the alternative normalizing location)
(mode=train is the alternative normalizing scale)

When comparing this output to that of example 1, we see that we have achieved the same log likelihood. That is, the structural parameterization using air as the base alternative and train as the scale alternative applied no restrictions on the model. This will not always be the case. We leave it up to you to try different base and scale alternatives, and you will see that not all the different combinations will achieve the same log likelihood. This is not true for the differenced covariance parameterization: it will always achieve the same log likelihood (and the maximum possible likelihood) regardless of the base and scale alternatives. This is why it is the default parameterization.
For an exercise, we can compute the differenced covariance displayed in example 1 by using the following ado-code.

```
. estat covariance

The slight difference in the regression coefficients between the example 1 and example 2 coefficient tables reflects the accuracy of the \[M-5\] ghk() algorithm using 200 points from the Hammersley sequence.

We now fit the model using the exchangeable correlation matrix and compare the models with a likelihood-ratio test.

(mode=air is the alternative normalizing location)
(mode=train is the alternative normalizing scale)
.lrtest full.
Likelihood-ratio test  LR chi2(2) = 0.75
(Assumption: . nested in full)  Prob > chi2 = 0.6882

The likelihood-ratio test suggests that a common correlation is a plausible hypothesis, but this could be an artifact of the small sample size. The labeling of the standard deviation and correlation estimates has changed from /lnsigma and /atanhr, in the previous example, to /lnsigmaP and /atanhrP. The “P” identifies the parameter’s index in the pattern matrices used by asmprobit. The pattern matrices are stored in e(stdpattern) and e(corpattern).
Technical note

Another way to fit the model with the exchangeable correlation structure in example 2 is to use the `constraint` command to define the constraints on the \( \rho \) parameters manually and then apply those.

```
  constraint 1 [atanhr3_2]_cons = [atanhr4_2]_cons
  constraint 2 [atanhr3_2]_cons = [atanhr4_3]_cons
  asmprobit choice travelcost termtime, case(id) alternatives(mode)
  > casevars(income) constraints(1 2) structural
```

With this method, however, we must keep track of what parameterization of the \( \rho \)s is used in estimation, and that depends on the options specified.

Example 3

In the last example, we used the `correlation(exchangeable)` option, reducing the number of correlation parameters from three to one. We can explore a two–correlation parameter model by specifying a pattern matrix in the `correlation()` option. Suppose that we wish to have the correlation between train and bus be equal to the correlation between bus and car and to have the standard deviations for the bus and car equations be equal. We will use air as the base category and train as the scale category.

(mode=air is the alternative normalizing location)
(mode=train is the alternative normalizing scale)

In the call to asmprobit, we did not need to specify the basealternative() and scalealternative() options because they are implied by the specifications of the pattern matrices.
Technical note

If you experience convergence problems, try specifying `nopivot`, increasing `intpoints()`, specifying `antithetics`, specifying `technique(nr)` with `difficult`, or specifying a switching algorithm in the `technique()` option. As a last resort, you can use the `nrtolerance()` and `showtolerance` options. Changing the base and scale alternative in the model specification can also affect convergence if the `structural` option is used.

Because simulation methods are used to obtain multivariate normal probabilities, the estimates obtained have a limited degree of precision. Moreover, the solutions are particularly sensitive to the starting values used. Experimenting with different starting values may help in obtaining convergence, and doing so is a good way to verify previous results.

If you wish to use the BHHH algorithm along with another maximization algorithm, you must specify the `initbhhh(#)` option, where `#` is the number of BHHH iterations to use before switching to the algorithm specified in `technique()`. The BHHH algorithm uses an outer-product-of-gradients approximation for the Hessian, and `asmprobit` must perform the gradient calculations differently than for the other algorithms.

Technical note

If there are no alternative-specific variables in your model, the variance–covariance matrix parameters are not identifiable. For such a model to converge, you would therefore need to use `correlation(independent)` and `stddev(homoskedastic)`. A better alternative is to use `mprobit`, which is geared specifically toward models with only case-specific variables. See [R] `mprobit`. 
Stored results

asmprobit stores the following in \( \text{e()} \):

 Scalars
- \( \text{e(N)} \): number of observations
- \( \text{e(N_case)} \): number of cases
- \( \text{e(k)} \): number of parameters
- \( \text{e(k_alt)} \): number of alternatives
- \( \text{e(k_indvars)} \): number of alternative-specific variables
- \( \text{e(k_casevars)} \): number of case-specific variables
- \( \text{e(k_sigma)} \): number of variance estimates
- \( \text{e(k_rho)} \): number of correlation estimates
- \( \text{e(k_eq)} \): number of equations in \( \text{e(b)} \)
- \( \text{e(k_eq_model)} \): number of equations in overall model test
- \( \text{e(df_m)} \): model degrees of freedom
- \( \text{e(ll)} \): log simulated-likelihood
- \( \text{e(N_clust)} \): number of clusters
- \( \text{e(const)} \): constant indicator
- \( \text{e(i_base)} \): base alternative index
- \( \text{e(i_scale)} \): scale alternative index
- \( \text{e(mc_points)} \): number of Monte Carlo replications
- \( \text{e(mc_burn)} \): starting sequence index
- \( \text{e(mc_antithetics)} \): antithetics indicator
- \( \text{e(chi2)} \): \( \chi^2 \)
- \( \text{e(p)} \): significance
- \( \text{e(fullcov)} \): unstructured covariance indicator
- \( \text{e(structcov)} \): 1 if structured covariance; 0 otherwise
- \( \text{e(cholesky)} \): Cholesky-factored covariance indicator
- \( \text{e(alt_min)} \): minimum number of alternatives
- \( \text{e(alt_avg)} \): average number of alternatives
- \( \text{e(alt_max)} \): maximum number of alternatives
- \( \text{e(rank)} \): rank of \( \text{e(V)} \)
- \( \text{e(ic)} \): number of iterations
- \( \text{e(rc)} \): return code
- \( \text{e(converged)} \): 1 if converged, 0 otherwise

### Methods and formulas

The simulated maximum likelihood estimates for the MNP are obtained using `ml`; see `[R] ml`. The likelihood evaluator implements the GHK algorithm to approximate the multivariate distribution function (Geweke 1989; Hajivassiliou and McFadden 1998; Keane and Wolpin 1994). The technique is also described in detail by Genz (1992), but Genz describes a more general algorithm where both...
lower and upper bounds of integration are finite. We briefly describe the GHK simulator and refer you to Bolduc (1999) for the score computations.

As discussed earlier, the latent variables for a \( J \)-alternative model are \( \eta_{ij} = x_{ij}\beta + z_i\alpha_j + \xi_{ij} \), for \( j = 1, \ldots, J, \ i = 1, \ldots, n \), and \( \xi_i' = (\xi_{i,1}, \ldots, \xi_{i,J}) \sim \text{MVN}(0, \Omega) \). The experimenter observes alternative \( k \) for the \( i \)th observation if \( k = \text{arg max}(\eta_{ij}, j = 1, \ldots, J) \). Let

\[
v_{ij'} = \eta_{ij} - \eta_{ik} = (x_{ij} - x_{ik})\beta + z_i(\alpha_j - \alpha_k) + \xi_{ij} - \xi_{ik} = \delta_{ij'}\beta + z_i\gamma_j' + \epsilon_{ij'}
\]

where \( j' = j \) if \( j < k \) and \( j' = j - 1 \) if \( j > k \), so that \( j' = 1, \ldots, J - 1 \). Further, \( \epsilon_i = (\epsilon_{i1}, \ldots, \epsilon_{i,J-1}) \sim \text{MVN}(0, \Sigma(k)) \). \( \Sigma \) is indexed by \( k \) because it depends on the choice made. We denote the deterministic part of the model as \( \lambda_{ij'} = \delta_{ij'}\beta + z_j\gamma_j' \), and the probability of this event is

\[
\Pr(y_i = k) = \Pr(v_{i1} \leq 0, \ldots, v_{i,J-1} \leq 0) = \Pr(\epsilon_{i1} \leq -\lambda_{i1}, \ldots, \epsilon_{i,J-1} \leq -\lambda_{i,J-1}) = (2\pi)^{-(J-1)/2} |\Sigma(k)|^{-1/2} \int_{-\infty}^{-\lambda_{i1}} \cdots \int_{-\infty}^{-\lambda_{i,J-1}} \exp \left( -\frac{1}{2} \epsilon_i' \Sigma^{-1}(k) \epsilon_i \right) d\epsilon_i
\]

**Simulated likelihood**

For clarity in the discussion that follows, we drop the index denoting case so that for an arbitrary observation \( \upsilon' = (v_1, \ldots, v_{J-1}) \), \( \lambda' = (\lambda_1, \ldots, \lambda_{J-1}) \), and \( \epsilon' = (\epsilon_1, \ldots, \epsilon_{J-1}) \).

The Cholesky-factored variance–covariance, \( \Sigma = LL' \), is lower triangular,

\[
L = \begin{pmatrix}
l_{11} & 0 & \ldots & 0 \\
l_{21} & l_{22} & \ldots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
l_{J-1,1} & l_{J-1,2} & \ldots & l_{J-1,J-1}
\end{pmatrix}
\]

and the correlated latent-variable errors can be expressed as linear functions of uncorrelated normal variates, \( \epsilon = L\zeta' \), where \( \zeta' = (\zeta_1, \ldots, \zeta_{J-1}) \) and \( \zeta_j \sim \text{iid N}(0, 1) \). We now have \( \upsilon = \lambda + L\zeta' \), and by defining

\[
z_j = \begin{cases} 
-\frac{\lambda_1}{l_{11}} & \text{for } j = 1 \\
-\frac{\lambda_j + \sum_{i=1}^{j-1} l_{ji}\zeta_i}{l_{jj}} & \text{for } j = 2, \ldots, J - 1
\end{cases}
\]

we can express the probability statement (3) as the product of conditional probabilities

\[
\Pr(y_i = k) = \Pr(\zeta_1 \leq z_1) \Pr(\zeta_2 \leq z_2 \mid \zeta_1 \leq z_1) \cdots \Pr(\zeta_{J-1} \leq z_{J-1} \mid \zeta_1 \leq z_1, \ldots, \zeta_{J-2} \leq z_{J-2})
\]
because

\[ \Pr(v_1 \leq 0) = \Pr(\lambda_1 + l_{11}\xi_1 \leq 0) = \Pr\left(\xi_1 \leq -\frac{\lambda_1}{l_{11}}\right) \]

\[ \Pr(v_2 \leq 0) = \Pr(\lambda_2 + l_{21}\xi_1 + l_{22}\xi_2 \leq 0) = \Pr\left(\xi_2 \leq -\frac{\lambda_2 + l_{21}\xi_1}{l_{22}} | \xi_1 \leq -\frac{\lambda_1}{l_{11}}\right) \]

The Monte Carlo algorithm then must make draws from the truncated standard normal distribution. It does so by generating \( J - 1 \) uniform variates, \( \delta_j, j = 1, \ldots, J - 1 \), and computing

\[ \tilde{\zeta}_j = \begin{cases} \Phi^{-1}\left\{ \delta_1 \Phi\left(-\frac{\lambda_1}{l_{11}}\right) \right\} & \text{for } j = 1 \\ \Phi^{-1}\left\{ \delta_j \Phi\left(-\frac{\lambda_j - \sum_{i=1}^{j-1} l_{ji}\tilde{\zeta}_i}{l_{jj}}\right) \right\} & \text{for } j = 2, \ldots, J - 1 \end{cases} \]

Define \( \tilde{z}_j \) by replacing \( \tilde{\zeta}_i \) for \( \zeta_i \) in (4) so that the simulated probability for the \( l \)th draw is

\[ p_l = \prod_{j=1}^{J-1} \Phi(\tilde{z}_j) \]

To increase accuracy, the bounds of integration, \( \lambda_j \), are ordered so that the largest integration intervals are on the inside. The rows and columns of the variance–covariance matrix are pivoted accordingly (Genz 1992).

For a more detailed description of the GHK algorithm in Stata, see Gates (2006).

Repeated draws are made, say, \( N \), and the simulated likelihood for the \( i \)th case, denoted \( \hat{L}_i \), is computed as

\[ \hat{L}_i = \frac{1}{N} \sum_{l=1}^{N} p_l \]

The overall simulated log likelihood is \( \sum_i \log \hat{L}_i \).

If the true likelihood is \( L_i \), the error bound on the approximation can be expressed as

\[ |\hat{L}_i - L_i| \leq V(L_i)D_N\{\delta_i\} \]

where \( V(L_i) \) is the total variation of \( L_i \) and \( D_N \) is the discrepancy, or nonuniformity, of the set of abscissas. For the uniform pseudorandom sequence, \( \delta_i \), the discrepancy is of order \( O\{(\log \log N/N)^{1/2}\} \). The order of discrepancy can be improved by using quasirandom sequences.

Quasi–Monte Carlo integration is carried out by \texttt{asmprobit} by replacing the uniform deviates with either the Halton or the Hammersley sequences. These sequences spread the points more evenly than the uniform random sequence and have a smaller order of discrepancy, \( O\{((\log N)^{J-1})/N\} \) and \( O\{((\log N)^{J-2})/N\} \), respectively. The Halton sequence of dimension \( J - 1 \) is generated from the first \( J - 1 \) primes, \( p_k \), so that on draw \( l \) we have \( h_l = \{r_{p_1}(l), r_{p_2}(l), \ldots, r_{p_{J-1}}(l)\} \), where
\[ r_{pk}(l) = \sum_{j=0}^{q} b_{jk}(l)p_k^{-j-1} \in (0, 1) \]

is the radical inverse function of \( l \) with base \( p_k \) so that \( \sum_{j=0}^{q} b_{jk}(l)p_k^j = l \), where \( p_k^q \leq l < p_k^{q+1} \) (Fang and Wang 1994).

This function is demonstrated with base \( p_3 = 5 \) and \( l = 33 \), which generates \( r_5(33) \). Here \( q = 2 \), \( b_{0,3}(33) = 3 \), \( b_{1,5}(33) = 1 \), and \( b_{2,5}(33) = 1 \), so that \( r_5(33) = 3/5 + 1/25 + 1/625 \).

The Hammersley sequence uses an evenly spaced set of points with the first \( J - 2 \) components of the Halton sequence

\[ h_l = \left\{ \frac{2l - 1}{2N}, r_{p_1}(l), r_{p_2}(l), \ldots, r_{p_{J-2}}(l) \right\} \]

for \( l = 1, \ldots, N \).

For a more detailed description of the Halton and Hammersley sequences, see Drukker and Gates (2006).

Computations for the derivatives of the simulated likelihood are taken from Bolduc (1999). Bolduc gives the analytical first-order derivatives for the log of the simulated likelihood with respect to the regression coefficients and the parameters of the Cholesky-factored variance–covariance matrix. \texttt{asmprobit} uses these analytical first-order derivatives and numerical second-order derivatives.

This command supports the clustered version of the Huber/White/sandwich estimator of the variance using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}. See \texttt{[P] \_robust}, particularly Maximum likelihood estimators and Methods and formulas. Specifying \texttt{vce(robust)} is equivalent to specifying \texttt{vce(cluster casevar)}, where \texttt{casevar} is the variable that identifies the cases.

Title

asmprobit postestimation — Postestimation tools for asmprobit

Description

The following postestimation commands are of special interest after asmprobit:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>estat alternatives</td>
<td>alternative summary statistics</td>
</tr>
<tr>
<td>estat covariance</td>
<td>covariance matrix of the latent-variable errors for the alternatives</td>
</tr>
<tr>
<td>estat correlation</td>
<td>correlation matrix of the latent-variable errors for the alternatives</td>
</tr>
<tr>
<td>estat facweights</td>
<td>covariance factor weights matrix</td>
</tr>
<tr>
<td>estat mfx</td>
<td>marginal effects</td>
</tr>
</tbody>
</table>

The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>estat ic</td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td>estat summarize</td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td>estat vce</td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td>estimates</td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td>lincom</td>
<td>point estimates, standard errors, testing, and inference for linear</td>
</tr>
<tr>
<td></td>
<td>combinations of coefficients</td>
</tr>
<tr>
<td>lrtest</td>
<td>likelihood-ratio test</td>
</tr>
<tr>
<td>nlcom</td>
<td>point estimates, standard errors, testing, and inference for nonlinear</td>
</tr>
<tr>
<td></td>
<td>combinations of coefficients</td>
</tr>
<tr>
<td>predict</td>
<td>predicted probabilities, estimated linear predictor and its standard error</td>
</tr>
<tr>
<td>predictnl</td>
<td>point estimates, standard errors, testing, and inference for generalized</td>
</tr>
<tr>
<td></td>
<td>predictions</td>
</tr>
<tr>
<td>test</td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td>testnl</td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

Special-interest postestimation commands

estat alternatives displays summary statistics about the alternatives in the estimation sample and provides a mapping between the index numbers that label the covariance parameters of the model and their associated values and labels for the alternative variable.

estat covariance computes the estimated variance–covariance matrix of the latent-variable errors for the alternatives. The estimates are displayed, and the variance–covariance matrix is stored in r(cov).
estat correlation computes the estimated correlation matrix of the latent-variable errors for the alternatives. The estimates are displayed, and the correlation matrix is stored in `r(cor)`.

estat facweights displays the covariance factor weights matrix and stores it in `r(C)`.

estat mfx computes the simulated probability marginal effects.

**Syntax for predict**

```
predict [type] newvar [if] [in] [, statistic altwise]
predict [type] {stub*|newvarlist} [if] [in], scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>probability alternative is chosen; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample)` ... if wanted only for the estimation sample.

**Menu for predict**

Statistics > Postestimation > Predictions, residuals, etc.

**Options for predict**

- **Main**
  - `pr`, the default, calculates the probability that alternative \( j \) is chosen in case \( i \).
  - `xb` calculates the linear prediction \( x_{ij} \beta + z_i \alpha_j \) for alternative \( j \) and case \( i \).
  - `stdp` calculates the standard error of the linear predictor.

- **altwise** specifies that alternativewise deletion be used when marking out observations due to missing values in your variables. The default is to use casewise deletion. The `xb` and `stdp` options always use alternativewise deletion.

- **scores** calculates the scores for each coefficient in `e(b)`. This option requires a new variable list of length equal to the number of columns in `e(b)`. Otherwise, use the `stub*` option to have `predict` generate enumerated variables with prefix `stub`. 
Syntax for estat

Alternative summary statistics

estat alternatives

Covariance matrix of the latent-variable errors for the alternatives

estat covariance [, format(%) fmt] border(bspec) left(#)

Correlation matrix of the latent-variable errors for the alternatives

estat correlation [, format(%) fmt] border(bspec) left(#)

Covariance factor weights matrix

estat facweights [, format(%) fmt] border(bspec) left(#)

Marginal effects

estat mfx [if] [in] [, estat_mfx_options]

estat_mfx_options Description

Main
varlist(varlist) display marginal effects for varlist
at(mean [atlist] | median [atlist]) calculate marginal effects at these values

Options
level(#) set confidence interval level; default is level(95)
nodiscrete treat indicator variables as continuous
nosecond do not restrict calculation of means and medians to the estimation sample
noweight ignore weights when calculating means and medians

Menu for estat

Statistics > Postestimation > Reports and statistics

Options for estat

Options for estat are presented under the following headings:

Options for estat covariance, estat correlation, and estat facweights
Options for estat mfx
Options for estat covariance, estat correlation, and estat facweights

format(%, fmt) sets the matrix display format. The default for estat covariance and estat facweights is format(%, 9.0g); the default for estat correlation is format(%, 9.4f).

border(bspec) sets the matrix display border style. The default is border(all). See [P] matlist.

left(#) sets the matrix display left indent. The default is left(2). See [P] matlist.

Options for estat mfx

varlist(varlist) specifies the variables for which to display marginal effects. The default is all variables.

at(mean [atlist] | median [atlist]) specifies the values at which the marginal effects are to be calculated. atlist is:

[[alternative:variable = #] [variable = #] [....]]

The default is to calculate the marginal effects at the means of the independent variables at the estimation sample, at(mean).

After specifying the summary statistic, you can specify a series of specific values for variables. You can specify values for alternative-specific variables by alternative, or you can specify one value for all alternatives. You can specify only one value for case-specific variables. For example, in travel.dta, income is a case-specific variable, whereas termtime and travelcost are alternative-specific variables. The following would be a legal syntax for estat mfx:

. estat mfx, at(mean air:termtime=50 travelcost=100 income=60)

When nodiscrete is not specified, at(mean [atlist]) or at(median [atlist]) has no effect on computing marginal effects for indicator variables, which are calculated as the discrete change in the simulated probability as the indicator variable changes from 0 to 1.

The mean and median computations respect any if and in qualifiers, so you can restrict the data over which the means or medians are computed. You can even restrict the values to a specific case; for example,

. estat mfx if case==21

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

nodiscrete specifies that indicator variables be treated as continuous variables. An indicator variable is one that takes on the value 0 or 1 in the estimation sample. By default, the discrete change in the simulated probability is computed as the indicator variable changes from 0 to 1.

noesample specifies that the whole dataset be considered instead of only those marked in the e(sample) defined by the asmprobit command.

nowght specifies that weights be ignored when calculating the means or medians.

Remarks and examples

Remarks are presented under the following headings:

Predicted probabilities
Obtaining estimation statistics
Obtaining marginal effects
Predicted probabilities

After fitting an alternative-specific multinomial probit model, you can use predict to obtain the simulated probabilities that an individual will choose each of the alternatives. When evaluating the multivariate normal probabilities via Monte Carlo simulation, predict uses the same method to generate the random sequence of numbers as the previous call to asmprobit. For example, if you specified intmethod(Halton) when fitting the model, predict also uses the Halton sequence.

Example 1

In example 1 of [R] asmprobit, we fit a model of individuals’ travel-mode choices. We can obtain the simulated probabilities that an individual chooses each alternative by using predict:

```
. use http://www.stata-press.com/data/r13/travel
. asmprobit choice travelcost termtime, case(id) alternatives(mode)
> casevars(income)
(output omitted)
. predict prob
(option pr assumed; Pr(mode))
. list id mode prob choice in 1/12, sepby(id)
```

<table>
<thead>
<tr>
<th>id</th>
<th>mode</th>
<th>prob</th>
<th>choice</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>air</td>
<td>0.1494137</td>
<td>0</td>
</tr>
<tr>
<td>2</td>
<td>train</td>
<td>0.329167</td>
<td>0</td>
</tr>
<tr>
<td>3</td>
<td>bus</td>
<td>0.1320298</td>
<td>0</td>
</tr>
<tr>
<td>4</td>
<td>car</td>
<td>0.3898562</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>air</td>
<td>0.2565875</td>
<td>0</td>
</tr>
<tr>
<td>6</td>
<td>train</td>
<td>0.2761054</td>
<td>0</td>
</tr>
<tr>
<td>7</td>
<td>bus</td>
<td>0.0116135</td>
<td>0</td>
</tr>
<tr>
<td>8</td>
<td>car</td>
<td>0.4556921</td>
<td>1</td>
</tr>
<tr>
<td>9</td>
<td>air</td>
<td>0.2098406</td>
<td>0</td>
</tr>
<tr>
<td>10</td>
<td>train</td>
<td>0.1081824</td>
<td>0</td>
</tr>
<tr>
<td>11</td>
<td>bus</td>
<td>0.1671841</td>
<td>0</td>
</tr>
<tr>
<td>12</td>
<td>car</td>
<td>0.5147822</td>
<td>1</td>
</tr>
</tbody>
</table>

Obtaining estimation statistics

Once you have fit a multinomial probit model, you can obtain the estimated variance or correlation matrices for the model alternatives by using the estat command.

Example 2

To display the correlations of the errors in the latent-variable equations, we type

```
. estat correlation
```

<table>
<thead>
<tr>
<th></th>
<th>train</th>
<th>bus</th>
<th>car</th>
</tr>
</thead>
<tbody>
<tr>
<td>train</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>bus</td>
<td>0.8909</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td>car</td>
<td>0.7895</td>
<td>0.8951</td>
<td>1.0000</td>
</tr>
</tbody>
</table>

Note: correlations are for alternatives differenced with air
The covariance matrix can be displayed by typing

```
. estat covariance
```

<table>
<thead>
<tr>
<th></th>
<th>train</th>
<th>bus</th>
<th>car</th>
</tr>
</thead>
<tbody>
<tr>
<td>train</td>
<td>2</td>
<td></td>
<td></td>
</tr>
<tr>
<td>bus</td>
<td>1.600208</td>
<td>1.613068</td>
<td></td>
</tr>
<tr>
<td>car</td>
<td>1.37471</td>
<td>1.399703</td>
<td>1.515884</td>
</tr>
</tbody>
</table>

Note: covariances are for alternatives differenced with air

### Obtaining marginal effects

The marginal effects are computed as the derivative of the simulated probability for an alternative with respect to an independent variable. A table of marginal effects is displayed for each alternative, with the table containing the marginal effect for each case-specific variable and the alternative for each alternative-specific variable.

By default, the marginal effects are computed at the means of each continuous independent variable over the estimation sample. For indicator variables, the difference in the simulated probability evaluated at 0 and 1 is computed by default. Indicator variables will be treated as continuous variables if the `nodiscrete` option is used.

#### Example 3

Continuing with our model from example 1, we obtain the marginal effects for alternatives `air`, `train`, `bus`, and `car` evaluated at the mean values of each independent variable. Recall that the `travelcost` and `termtime` variables are alternative specific, taking on different values for each alternative, so they have a separate marginal effect for each alternative.
. estat mfx

| air      | .005441| .002161   | 2.52  | 0.012 | .001205     | .009677| 61.01  |
| train    | .007346| .002228   | 3.30  | 0.001 | .00298      | .011713| 35.69  |
| bus      | .005879| .002256   | 2.61  | 0.009 | .001456     | .010301| 41.657 |
| car      | -.018666| .003938  | -4.74 | 0.000 | -.026385    | -.010948| 0      |
| casevars |        |           |       |       |             |       |
| income   | .005246| .002166   | 2.42  | 0.015 | .001002     | .00949 | 34.548 |

First, we note that there is a separate marginal effects table for each alternative and that table begins by reporting the overall probability of choosing the alternative, for example, 0.2944 for air travel. We see in the first table that a unit increase in terminal time for air travel from 61.01 minutes will result in a decrease in probability of choosing air travel (when the probability is evaluated at the mean of all variables) by approximately 0.01, with a 95% confidence interval of about −0.016 to −0.005. Travel cost has a less negative effect of choosing air travel (at the average cost of 102.65). Alternatively, an increase in terminal time and travel cost for train, bus, or car from these mean values will increase the chance for air travel to be chosen. Also, with an increase in income from 34.5, it would appear that an individual would be more likely to choose air or automobile travel over bus or train. (While the marginal effect for bus travel is positive, it is not significant.)

Example 4

Plotting the simulated probability marginal effect evaluated over a range of values for an independent variable may be more revealing than a table of values. Below are the commands for generating the simulated probability marginal effect of air travel for increasing air travel terminal time. We fix all other independent variables at their medians.

```
. qui gen meff = .
. qui gen tt = .
. qui gen lb = .
. qui gen ub = .
. forvalues i=0/19 {
  2. local termtime = 5+5*i
  3. qui replace tt = `termtime' if _n == `i'+1
  4. qui estat mfx, at(median air:termtime=`termtime') var(termtime)
  5. mat air = r(air)
  6. qui replace meff = air[1,1] if _n == `i'+1
  7. qui replace lb = air[1,5] if _n == `i'+1
  8. qui replace ub = air[1,6] if _n == `i'+1
  9. qui replace prob = r(pr_air) if _n == `i'+1
 10. }
. label variable tt "terminal time"
```
From the graphs, we see that the simulated probability of choosing air travel decreases in a sigmoid fashion. The marginal effects display the rate of change in the simulated probability as a function of the air travel terminal time. The rate of change in the probability of choosing air travel decreases until the air travel terminal time reaches about 45; thereafter, it increases.

**Stored results**

*estat mfx* stores the following in *r()*:

**Scalars**

Scalar

$r(pr_{alt})$

scalars containing the computed probability of each alternative evaluated at the value that is labeled X in the table output. Here *alt* are the labels in the macro *e(alteqs)*.

**Matrices**

Matrix

$r(alt)$

matrices containing the computed marginal effects and associated statistics. There is one matrix for each alternative, where *alt* are the labels in the macro *e(alteqs)*. Column 1 of each matrix contains the marginal effects; column 2, their standard errors; columns 3 and 4, their *z* statistics and the *p*-values for the *z* statistics; and columns 5 and 6, the confidence intervals. Column 7 contains the values of the independent variables used to compute the probabilities $r(pr_{alt})$. 

\[ \text{probability of choosing air travel} \]

\[ \text{marginal effect of air travel} \text{ terminal time and 95% confidence interval} \]

\[ \text{probability of choosing} \text{ air travel} \]

\[ \text{marginal effect of air travel} \text{ terminal time and 95% confidence interval} \]
Methods and formulas

Marginal effects

The marginal effects are computed as the derivative of the simulated probability with respect to each independent variable. A set of marginal effects is computed for each alternative; thus, for \( J \) alternatives, there will be \( J \) tables. Moreover, the alternative-specific variables will have \( J \) entries, one for each alternative in each table. The details of computing the effects are different for alternative-specific variables and case-specific variables, as well as for continuous and indicator variables.

We use the latent-variable notation of \textit{asmprobit} (see \texttt{[R] \textit{asmprobit}}) for a \( J \)-alternative model and, for notational convenience, we will drop any subscripts involving observations. We then have the following linear functions \( \eta_j = x_j \beta + z \alpha_j \), for \( j = 1, \ldots, J \). Let \( k \) index the alternative of interest, and then

\[
v_{j'} = \eta_j - \eta_k = (x_j - x_k) \beta + z(\alpha_j - \alpha_k) + \epsilon_{j'}
\]

where \( j' = j \) if \( j < k \) and \( j' = j - 1 \) if \( j > k \), so that \( j' = 1, \ldots, J - 1 \) and \( \epsilon_{j'} \sim \text{MVN}(0, \Sigma) \). Denote \( p_k = \Pr(v_1 \leq 0, \ldots, v_{J-1} \leq 0) \) as the simulated probability of choosing alternative \( k \) given profile \( x_k \) and \( z \). The marginal effects are then \( \partial p_k / \partial x_k \), \( \partial p_k / \partial x_j \), and \( \partial p_k / \partial z \), where \( k = 1, \ldots, J \), \( j \neq k \). \textit{asmprobit} analytically computes the first-order derivatives of the simulated probability with respect to the \( v \)'s, and the marginal effects for \( x \)'s and \( z \) are obtained via the chain rule. The standard errors for the marginal effects are computed using the delta method.

Syntax

asroprobit depvar [indepvars] [if] [in] [weight], case(varname)

alternatives(varname) [options]

options

Model
* case(varname)  
use varname to identify cases

* alternatives(varname)  
use varname to identify the alternatives available for each case

casevars(varlist)  

case-specific variables

constraints(constraints)  
apply specified linear constraints

collinear  
keep collinear variables

Model 2

correlation(correlation)  
correlation structure of the latent-variable errors

stddev(stddev)  

variation structure of the latent-variable errors

structural  

use the structural covariance parameterization; default is the
differenced covariance parameterization

factor(#)  

use the factor covariance structure with dimension #

noconstant  
suppress the alternative-specific constant terms

basealternative(# | lbl | str)  
alternative used for normalizing location

scalealternative(# | lbl | str)  
alternative used for normalizing scale

altwise  
use alternativewise deletion instead of casewise deletion

reverse  
interpret the lowest rank in depvar as the best; the default is the
highest rank is the best

SE/Robust
vce(vcetype)  
vcetype may be oim, robust, cluster clustvar, opg,

bootstrap, or jackknife

Reporting
level(#)  
set confidence level; default is level(95)

notransform  
do not transform variance–covariance estimates to the standard
deviation and correlation metric

nocnsreport  
do not display constraints

display_options  
control column formats and line width
Integration

\texttt{intmethod(seqtype)} \quad \text{type of quasi- or pseudouniform sequence}
\texttt{intpoints(#)} \quad \text{number of points in each sequence}
\texttt{intburn(#)} \quad \text{starting index in the Hammersley or Halton sequence}
\texttt{intseed(code | #)} \quad \text{pseudouniform random-number seed}
\texttt{antithetics} \quad \text{use antithetic draws}
\texttt{nopivot} \quad \text{do not use integration interval pivoting}

asprobit — Alternative-specific rank-ordered probit regression

Menu

Statistics > Ordinal outcomes > Rank-ordered probit regression

Description

asprobit fits rank-ordered probit (ROP) models by using maximum simulated likelihood (MSL). The model allows you to relax the independence of irrelevant alternatives (IIA) property that is characteristic of the rank-ordered logistic model by estimating the variance–covariance parameters of the latent-variable errors. Each unique identifier in the case() variable has multiple alternatives identified in the alternatives() variable, and depvar contains the ranked alternatives made by each case. Only the order in the ranks, not the magnitude of their differences, is assumed to be relevant. By default, the largest rank indicates the more desirable alternative. Use the reverse option if the lowest rank should be interpreted as the more desirable alternative. Tied ranks are allowed, but they increase the computation time because all permutations of the tied ranks are used in computing the likelihood for each case. asprobit allows two types of independent variables: alternative-specific variables, in which the values of each variable vary with each alternative, and case-specific variables, which vary with each case.

The estimation technique of asprobit is nearly identical to that of asmprobit, and the two routines share many of the same options; see [R] asmprobit.

Options

**Model**

- **case(varname)** specifies the variable that identifies each case. This variable identifies the individuals or entities making a choice. case() is required.
- **alternatives(varname)** specifies the variable that identifies the alternatives available for each case. The number of alternatives can vary with each case; the maximum number of alternatives is 20. alternatives() is required.
- **casevars(varlist)** specifies the case-specific variables that are constant for each case(). If there are a maximum of J alternatives, there will be J – 1 sets of coefficients associated with casevars().
- **constraints(constraints)**, collinear: see [R] estimation options.

**Model 2**

- **correlation(correlation)** specifies the correlation structure of the latent-variable errors. correlation(unstructured) is the most general and has \( J(J - 3)/2 + 1 \) unique correlation parameters. This is the default unless stddev() or structural are specified.
- correlation(exchangeable) provides for one correlation coefficient common to all latent variables, except the latent variable associated with the basealternative().
- correlation(independent) assumes that all correlations are zero.
- correlation(pattern matname) and correlation(fixed matname) give you more flexibility in defining the correlation structure. See Variance structures in [R] asmprobit for more information.
- **stddev(stddev)** specifies the variance structure of the latent-variable errors. stddev(heteroskedastic) is the most general and has \( J - 2 \) estimable parameters. The standard deviations of the latent-variable errors for the alternatives specified in basealternative() and scalealternative() are fixed to one.
stddev(homoskedastic) constrains all the standard deviations to equal one.

stddev(pattern matname) and stddev(fixed matname) give you added flexibility in defining the standard deviation parameters. See Variance structures in [R] asmprob for more information.

structural requests the $J \times J$ structural covariance parameterization instead of the default $J-1 \times J-1$ differenced covariance parameterization (the covariance of the latent errors differenced with that of the base alternative). The differenced covariance parameterization will achieve the same maximum simulated likelihood regardless of the choice of basealternative() and scalealternative(). On the other hand, the structural covariance parameterization imposes more normalizations that may bound the model away from its maximum likelihood and thus prevent convergence with some datasets or choices of basealternative() and scalealternative().

factor(#) requests that the factor covariance structure of dimension # be used. The factor() option can be used with the structural option but cannot be used with stddev() or correlation(). A #$ \times J$ (or #$ \times J-1$) matrix, C, is used to factor the covariance matrix as $I + C'C$, where $I$ is the identity matrix of dimension $J$ (or $J-1$). The column dimension of C depends on whether the covariance is structural or differenced. The row dimension of C, #, must be less than or equal to floor($((J-1)/2-1)/(J-2)$), because there are only $J(J-1)/2-1$ identifiable variance–covariance parameters. This covariance parameterization may be useful for reducing the number of covariance parameters that need to be estimated.

If the covariance is structural, the column of C corresponding to the base alternative contains zeros. The column corresponding to the scale alternative has a one in the first row and zeros elsewhere. If the covariance is differenced, the column corresponding to the scale alternative (differenced with the base) has a one in the first row and zeros elsewhere.

noconstant suppresses the $J-1$ alternative-specific constant terms.

basealternative(# | lbl | str) specifies the alternative used to normalize the latent-variable location (also referred to as the level of utility). The base alternative may be specified as a number, label, or string. The standard deviation for the latent-variable error associated with the base alternative is fixed to one, and its correlations with all other latent-variable errors are set to zero. The default is the first alternative when sorted. If a fixed or pattern matrix is given in the stddev() and correlation() options, the basealternative() will be implied by the fixed standard deviations and correlations in the matrix specifications. basealternative() cannot be equal to scalealternative().

scalealternative(# | lbl | str) specifies the alternative used to normalize the latent-variable scale (also referred to as the scale of utility). The scale alternative may be specified as a number, label, or string. The default is to use the second alternative when sorted. If a fixed or pattern matrix is given in the stddev() option, the scalealternative() will be implied by the fixed standard deviations in the matrix specification. scalealternative() cannot be equal to basealternative().

If a fixed or pattern matrix is given for the stddev() option, the base alternative and scale alternative are implied by the standard deviations and correlations in the matrix specifications, and they need not be specified in the basealternative() and scalealternative() options.

altwise specifies that alternativewise deletion be used when marking out observations due to missing values in your variables. The default is to use casewise deletion; that is, the entire group of observations making up a case is deleted if any missing values are encountered. This option does not apply to observations that are marked out by the if or in qualifier or the by prefix.

reverse directs asprobit to interpret the rank in depvar that is smallest in value as the preferred alternative. By default, the rank that is largest in value is the favored alternative.
vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

If specifying vce(bootstrap) or vce(jackknife), you must also specify basealternative() and scalealternative().

level(#) ; see [R] estimation options.

notransform prevents retransforming the Cholesky-factored variance–covariance estimates to the correlation and standard deviation metric.

This option has no effect if structural is not specified because the default differenced variance–covariance estimates have no interesting interpretation as correlations and standard deviations. notransform also has no effect if the correlation() and stddev() options are specified with anything other than their default values. Here it is generally not possible to factor the variance–covariance matrix, so optimization is already performed using the standard deviation and correlation representations.

correlation(); see [R] estimation options.

display_options: cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

intmethod(hammersley | halton | random) specifies the method of generating the point sets used in the quasi–Monte Carlo integration of the multivariate normal density. intmethod(hammersley), the default, uses the Hammersley sequence; intmethod(halton) uses the Halton sequence; and intmethod(random) uses a sequence of uniform random numbers.

intpoints(#) specifies the number of points to use in the quasi–Monte Carlo integration. If this option is not specified, the number of points is $50 \times J$ if intmethod(hammersley) or intmethod(halton) is used and $100 \times J$ if intmethod(random) is used. Larger values of intpoints() provide better approximations of the log likelihood, but at the cost of added computation time.

intburn(#) specifies where in the Hammersley or Halton sequence to start, which helps reduce the correlation between the sequences of each dimension. The default is 0. This option may not be specified with intmethod(random).

intseed(code | #) specifies the seed to use for generating the uniform pseudorandom sequence. This option may be specified only with intmethod(random). code refers to a string that records the state of the random-number generator runiform(); see [R] set seed. An integer value # may be used also. The default is to use the current seed value from Stata’s uniform random-number generator, which can be obtained from c(seed).

antithetics specifies that antithetic draws be used. The antithetic draw for the $J - 1$ vector uniform-random variables, $x$, is $1 - x$.

nopivot turns off integration interval pivoting. By default, asprobit will pivot the wider intervals of integration to the interior of the multivariate integration. This improves the accuracy of the quadrature estimate. However, discontinuities may result in the computation of numerical second-order derivatives using finite differencing (for the Newton–Raphson optimize technique, tech(nr))
when few simulation points are used, resulting in a non–positive-definite Hessian. `asroprobit` uses the Broyden–Fletcher–Goldfarb–Shanno optimization algorithm, by default, which does not require computing the Hessian numerically using finite differencing.

`initbhhh(#{})` specifies that the Berndt–Hall–Hall–Hausman (BHHH) algorithm be used for the initial # optimization steps. This option is the only way to use the BHHH algorithm along with other optimization techniques. The algorithm switching feature of `ml’s technique(#{})` option cannot include bhhh.

`favor(speed|space)` instructs `asroprobit` to favor either speed or space when generating the integration points. `favor(speed)` is the default. When favoring speed, the integration points are generated once and stored in memory, thus increasing the speed of evaluating the likelihood. This speed increase can be seen when there are many cases or when the user specifies a large number of integration points, `intpoints(#{})`. When favoring space, the integration points are generated repeatedly with each likelihood evaluation.

For unbalanced data, where the number of alternatives varies with each case, the estimates computed using `intmethod(random)` will vary slightly between `favor(speed)` and `favor(space)`. This is because the uniform sequences will not be identical, even when initiating the sequences using the same uniform seed, `intseed(code | #{})`. For `favor(speed)`, `ncase` blocks of `intpoints(#{}) × J − 2` uniform points are generated, where $J$ is the maximum number of alternatives. For `favor(space)`, the column dimension of the matrices of points varies with the number of alternatives that each case has.

```
Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#{}), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#{}), ltolerance(#{}), nrtolerance(#{}), nonrtolerance, and from(init_specs); see [R] maximize.
```

The following options may be particularly useful in obtaining convergence with `asroprobit`: `difficult`, `technique(algorithm_spec)`, `nrtolerance(#{})`, `nonrtolerance`, and `from(init_specs)`.

If `technique(#{})` contains more than one algorithm specification, `bhhh` cannot be one of them. To use the BHHH algorithm with another algorithm, use the `initbhhh(#{})` option and specify the other algorithm in `technique(#{})`.

Setting the optimization type to `technique(bhhh)` resets the default `vcetype` to `vce(opg)`.

When specifying `from(matname [, copy])`, the values in `matname` associated with the latent-variable error variances must be for the log-transformed standard deviations and inverse-hyperbolic tangent-transformed correlations. This option makes using the coefficient vector from a previously fitted `asroprobit` model convenient as a starting point.

The following option is available with `asroprobit` but is not shown in the dialog box: `coeflegend`; see [R] estimation options.

### Remarks and examples

The mathematical description and numerical computations of the rank-ordered probit model are similar to that of the multinomial probit model. The only difference is that the dependent variable of the rank-ordered probit model is ordinal, showing preferences among alternatives, as opposed to the binary dependent variable of the multinomial probit model, indicating a chosen alternative. We will describe how the likelihood of a ranking is computed using the latent-variable framework here,
but for details of the latent-variable parameterization of these models and the method of maximum simulated likelihood, see [R] asmprobit.

Consider the latent-variable parameterization of a $J$ alternative rank-ordered probit model. Using the notation from asmprobit, we have variables $\eta_{ij}$, $j = 1, \ldots, J$, such that

$$\eta_{ij} = x_{ij}\beta + z_i\alpha_j + \xi_{ij}$$

Here the $x_{ij}$ are the alternative-specific independent variables, the $z_i$ are the case-specific variables, and the $\xi_{ij}$ are multivariate normal with mean zero and covariance $\Omega$. Without loss of generality, assume that individual $i$ ranks the alternatives in order of the alternative indices $j = 1, 2, \ldots, J$, so the alternative $J$ is the preferred alternative and alternative 1 is the least preferred alternative. The probability of this ranking given $\beta$ and $\alpha_j$ is the probability that $\eta_{ij, J-1} - \eta_{ij, J} \leq 0$ and $\eta_{ij, J-2} - \eta_{ij, J-1} \leq 0$, ..., and $\eta_{ij, 1} - \eta_{ij, 2} \leq 0$.

Example 1

Long and Freese (2014, 477) provide an example of a rank-ordered logit model with alternative-specific variables. We use this dataset to demonstrate asroprobit. The data come from the Wisconsin Longitudinal Study. This is a study of 1957 Wisconsin high school graduates that were asked to rate their relative preference of four job characteristics: esteem, a job other people regard highly; variety, a job that is not repetitive and allows you to do a variety of things; autonomy, a job where your supervisor does not check on you frequently; and security, a job with a low risk of being laid off. The case-specific covariates are gender, female, an indicator variable for females, and score, a score on a general mental ability test measured in standard deviations. The alternative-specific variables are high and low, which indicate whether the respondent’s current job is high or low in esteem, variety, autonomy, or security. This approach provides three states for a respondent’s current job status for each alternative, $(1, 0)$, $(0, 1)$, and $(0, 0)$, using the notation (high, low). The score $(1, 1)$ is omitted because the respondent’s current job cannot be considered both high and low in one of the job characteristics. The $(0, 0)$ score would indicate that the respondent’s current job does not rank high or low (is neutral) in a job characteristic. The alternatives are ranked such that 1 is the preferred alternative and 4 is the least preferred.

</table>
The three cases listed have tied ranks. \texttt{asroprobit} will allow ties, but at the cost of increased computation time. To evaluate the likelihood of the first observation, \texttt{asroprobit} must compute

\[
\Pr(\text{esteem} = 3, \text{variety} = 1, \text{autonomy} = 4, \text{security} = 2) + \\
\Pr(\text{esteem} = 3, \text{variety} = 2, \text{autonomy} = 4, \text{security} = 1)
\]

and both of these probabilities are estimated using simulation. In fact, the full dataset contains 7,237 tied ranks and \texttt{asroprobit} takes a great deal of time to estimate the parameters. For exposition, we estimate the rank-ordered probit model by using the cases without ties. These cases are marked in the variable \texttt{noties}.

The model of job preference is

\[
\eta_{ij} = \beta_1 \text{high}_{ij} + \beta_2 \text{low}_{ij} + \alpha_{1j} \text{female}_i + \alpha_{2j} \text{score}_i + \alpha_{0j} + \xi_{ij}
\]

for \( j = 1, 2, 3, 4 \). The base alternative will be \texttt{esteem}, so \( \alpha_{01} = \alpha_{11} = \alpha_{21} = 0 \).
. asprobit rank high low if noti, case(id) alternatives(jobchar)

Note: covariances are for alternatives differenced with esteem
gives the (co)variances. [R] mprobit explains that if the latent-variable errors are independent, then the correlations in the differenced parameterization should be \( \sim 0.5 \) and the variances should be \( \sim 2.0 \), which seems to be the case here.

The coefficient estimates for the probit models can be difficult to interpret because of the normalization for location and scale. The regression estimates for the case-specific variables will be relative to the base alternative and the regression estimates for both the case-specific and alternative-specific variables are affected by the scale normalization. The more pronounced the heteroskedasticity and correlations, the more pronounced the resulting estimate differences when choosing alternatives to normalize for location and scale. However, when using the differenced covariance structure, you will obtain the same model likelihood regardless of which alternatives you choose as the base and scale alternatives. For model interpretation, you can examine the estimated probabilities and marginal effects by using postestimation routines predict and estat mfx. See [R] asprobit postestimation.
Stored results

asprobit stores the following in e():

Scalars
  e(N)                number of observations
  e(N_case)           number of cases
  e(N_ties)           number of ties
  e(k)                number of parameters
  e(k_alt)            number of alternatives
  e(k_indvars)        number of alternative-specific variables
  e(k_casevars)       number of case-specific variables
  e(k_sigma)          number of variance estimates
  e(k_rho)            number of correlation estimates
  e(k_eq)             number of equations in e(b)
  e(k_eq_model)       number of equations in overall model test
  e(df_m)             model degrees of freedom
  e(ll)               log simulated-likelihood
  e(N_clust)          number of clusters
  e(const)            constant indicator
  e(i_base)           base alternative index

  e(rc)               return code
  e(converged)        1 if converged, 0 otherwise
Methods and formulas

From a computational perspective, asroprobit is similar to asmprobit and the two programs share many numerical tools. Therefore, we will use the notation from Methods and formulas in \[R\] asmprobit to discuss the rank-ordered probit probability model.

The latent variables for a \( J \)-alternative model are \( \eta_{ij} = x_{ij}\beta + z_i\alpha_j + \xi_{ij} \), for \( j = 1, \ldots, J \), \( i = 1, \ldots, n \), and \( \xi_i = (\xi_{i,1}, \ldots, \xi_{i,J}) \sim \text{MVN}(0, \Omega) \). Without loss of generality, assume for
the \( i \)th observation that an individual ranks the alternatives in the order of their numeric indices, \( y_i = (J, J - 1, \ldots, 1) \), so the first alternative is the most preferred and the last alternative is the least preferred. We can then difference the latent variables such that

\[
\begin{align*}
v_{ik} &= \eta_{i,k+1} - \eta_{i,k} \\
&= (x_{i,k+1} - x_{i,k})\beta + z_i(\alpha_{k+1} - \alpha_k) + \xi_{i,k+1} - \xi_{ik} \\
&= \delta_{ik}\beta + z_i\gamma_k + \epsilon_{ik}
\end{align*}
\]

for \( k = 1, \ldots, J - 1 \) and where \( \epsilon_i = (\epsilon_{i1}, \ldots, \epsilon_{i,J-1}) \sim \text{MVN}(0, \Sigma_{(i)}) \). \( \Sigma \) is indexed by \( i \) because it is specific to the ranking of individual \( i \). We denote the deterministic part of the model as \( \lambda_{ik} = \delta_{ik}\beta + z_i\gamma_k \), and the probability of this event is

\[
\Pr(y_i) = \Pr(v_{i1} \leq 0, \ldots, v_{i,J-1} \leq 0) \\
= \Pr(\epsilon_{i1} \leq -\lambda_{i1}, \ldots, \epsilon_{i,J-1} \leq -\lambda_{i,J-1}) \\
= (2\pi)^{-\frac{(J-1)}{2}} |\Sigma_{(i)}|^{-1/2} \int_{-\infty}^{-\lambda_{i1}} \cdots \int_{-\infty}^{-\lambda_{i,J-1}} \exp\left(-\frac{1}{2}z'\Sigma_{(i)}^{-1}z\right) dz
\]

The integral has the same form as (3) of Methods and formulas in [R] asmprobit. See [R] asmprobit for details on evaluating this integral numerically by using simulation.

asroprobit handles tied ranks by enumeration. For \( k \) tied ranks, it will generate \( k! \) rankings, where ! is the factorial operator \( k! = k(k-1)(k-2) \cdots (2)(1) \). For two sets of tied ranks of size \( k_1 \) and \( k_2 \), asroprobit will generate \( k_1!k_2! \) rankings. The total probability is the sum of the probability of each ranking. For example, if there are two tied ranks such that \( y_i = (J, J, J - 2, \ldots, 1) \), then asroprobit will evaluate \( \Pr(y_i) = \Pr(y_{i(1)}^1) + \Pr(y_{i(2)}^2) \), where \( y_{i(1)}^1 = (J, J - 1, J - 2, \ldots, 1) \) and \( y_{i(2)}^2 = (J - 1, J, J - 2, \ldots, 1) \).

This command supports the clustered version of the Huber/White/sandwich estimator of the variance using vce(robust) and vce(cluster clustvar). See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas. Specifying vce(robust) is equivalent to specifying vce(cluster casevar), where casevar is the variable that identifies the cases.

Description

The following postestimation commands are of special interest after asprobit:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>estat alternatives</td>
<td>alternative summary statistics</td>
</tr>
<tr>
<td>estat covariance</td>
<td>covariance matrix of the latent-variable errors for the alternatives</td>
</tr>
<tr>
<td>estat correlation</td>
<td>correlation matrix of the latent-variable errors for the alternatives</td>
</tr>
<tr>
<td>estat facweights</td>
<td>covariance factor weights matrix</td>
</tr>
<tr>
<td>estat mfx</td>
<td>marginal effects</td>
</tr>
</tbody>
</table>

The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>estat ic</td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>

<tr>
<td>testnl</td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

Special-interest postestimation commands

estat alternatives displays summary statistics about the alternatives in the estimation sample. The command also provides a mapping between the index numbers that label the covariance parameters of the model and their associated values and labels for the alternative variable.

estat covariance computes the estimated variance–covariance matrix of the latent-variable errors for the alternatives. The estimates are displayed, and the variance–covariance matrix is stored in r(cov).
estat correlation computes the estimated correlation matrix of the latent-variable errors for the alternatives. The estimates are displayed, and the correlation matrix is stored in \( r(corr) \).

estat facweights displays the covariance factor weights matrix and stores it in \( r(C) \).

estat mfx computes marginal effects of a simulated probability of a set of ranked alternatives. The probability is stored in \( r(pr) \), the matrix of rankings is stored in \( r(ranks) \), and the matrix of marginal-effect statistics is stored in \( r(mfx) \).

### Syntax for predict

```
predict [type] newvar [if] [in] [, statistic altwise]

predict [type] { stub* | newvarlist } [if] [in], scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>pr</strong></td>
<td>probability of each ranking, by case; the default</td>
</tr>
<tr>
<td><strong>pr1</strong></td>
<td>probability that each alternative is preferred</td>
</tr>
<tr>
<td><strong>xb</strong></td>
<td>linear prediction</td>
</tr>
<tr>
<td><strong>stdp</strong></td>
<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ... if wanted` only for the estimation sample.

### Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

### Options for predict

- **Main**
  - `pr`, the default, calculates the probability of each ranking. For each case, one probability is computed for the ranks in `e(depvar)`.
  - `pr1` calculates the probability that each alternative is preferred.
  - `xb` calculates the linear prediction \( x_{ij}\beta + z_i\alpha_j \) for alternative \( j \) and case \( i \).
  - `stdp` calculates the standard error of the linear predictor.
  - `altwise` specifies that alternativewise deletion be used when marking out observations due to missing values in your variables. The default is to use casewise deletion. The `xb` and `stdp` options always use alternativewise deletion.
  - `scores` calculates the scores for each coefficient in `e(b)`. This option requires a new variable list of length equal to the number of columns in `e(b)`. Otherwise, use the `stub*` option to have `predict` generate enumerated variables with prefix `stub`.

Options for estat

Options for estat are presented under the following headings:

Options for estat covariance, estat correlation, and estat facweights
Options for estat mfx
Options for estat covariance, estat correlation, and estat facweights

format(%) sets the matrix display format. The default for estat covariance and estat facweights is format(%.0g). The default for estat correlation is format(%.4f).

border() sets the matrix display border style. The default is border(all). See [P] matlist.

left(#) sets the matrix display left indent. The default is left(2). See [P] matlist.

Options for estat mfx

Main

varlist(varlist) specifies the variables for which to display marginal effects. The default is all variables.

at(median [atlist]) specifies the values at which the marginal effects are to be calculated. atlist is

[ alternative:variable = # variable = # [ ... ] ]

The marginal effects are calculated at the medians of the independent variables.

After specifying the summary statistic, you can specify specific values for variables. You can specify values for alternative-specific variables by alternative, or you can specify one value for all alternatives. You can specify only one value for case-specific variables. For example, in the wlsrank dataset, female and score are case-specific variables, whereas high and low are alternative-specific variables. The following would be a legal syntax for estat mfx:

. estat mfx, at(median high=0 esteem:high=1 low=0 security:low=1 female=1)

When nodiscrete is not specified, at(median [atlist]) has no effect on computing marginal effects for indicator variables, which are calculated as the discrete change in the simulated probability as the indicator variable changes from 0 to 1.

The median computations respect any if or in qualifiers, so you can restrict the data over which the medians are computed. You can even restrict the values to a specific case, for example,

. estat mfx if case==13

rank(ranklist) specifies the ranks for the alternatives. ranklist is

alternative = # alternative = # [ ... ]

The default is to rank the calculated latent variables. Alternatives excluded from rank() are omitted from the analysis. You must therefore specify at least two alternatives in rank(). You may have tied ranks in the rank specification. Only the order in the ranks is relevant.

Options

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

nodiscrete specifies that indicator variables be treated as continuous variables. An indicator variable is one that takes on the value 0 or 1 in the estimation sample. By default, the discrete change in the simulated probability is computed as the indicator variable changes from 0 to 1.

noesample specifies that the whole dataset be considered instead of only those marked in the e(sample) defined by the asprobit command.

nowght specifies that weights be ignored when calculating the medians.
Remarks and examples

Remarks are presented under the following headings:

Predicted probabilities
Obtaining estimation statistics

Predicted probabilities

After fitting an alternative-specific rank-ordered probit model, you can use `predict` to obtain the probabilities of alternative rankings or the probabilities of each alternative being preferred. When evaluating the multivariate normal probabilities via (quasi) Monte Carlo, `predict` uses the same method to generate the (quasi) random sequence of numbers as the previous call to `asroprobit`. For example, if you specified `intmethod(halton)` when fitting the model, `predict` also uses Halton sequences.

Example 1

In example 1 of [R] `asroprobit`, we fit a model of job characteristic preferences. This is a study of 1957 Wisconsin high school graduates that were asked to rate their relative preference of four job characteristics: esteem, a job other people regard highly; variety, a job that is not repetitive and allows you to do a variety of things; autonomy, a job where your supervisor does not check on you frequently; and security, a job with a low risk of being laid off. The case-specific covariates are gender, `female`, an indicator variable for females, and `score`, a score on a general mental ability test measured in standard deviations. The alternative-specific variables are `high` and `low`, which indicate whether the respondent’s current job is high or low in esteem, variety, autonomy, or security. This approach provides three states for a respondent’s current job status for each alternative, (1, 0), (0, 1), and (0, 0), using the notation (high, low). The score (1, 1) is omitted because the respondent’s current job cannot be considered both high and low in one of the job characteristics. The (0, 0) score would indicate that the respondent’s current job does not rank high or low (is neutral) in a job characteristic. The alternatives are ranked such that 1 is the preferred alternative and 4 is the least preferred.

We can obtain the probabilities of the observed alternative rankings, the `pr` option, and the probability of each alternative being preferred, the `pr1` option, by using `predict`: 
. use http://www.stata-press.com/data/r13/wlsrank
(1992 Wisconsin Longitudinal Study data on job values)
. asprobit rank high low if noties, case(id) alternatives(jobchar)
> casevars(female score) reverse
(output omitted)
. keep if e(sample)
(11244 observations deleted)
. predict prob, pr
. predict prob1, pr1
. list id jobchar prob prob1 rank female score high low in 1/12

</table>

The prob variable is constant for each case because it contains the probability of the ranking in the rank variable. On the other hand, the prob1 variable contains the estimated probability of each alternative being preferred. For each case, the sum of the values in prob1 will be approximately 1.0. They do not add up to exactly 1.0 because of approximations due to the GHK algorithm.

### Obtaining estimation statistics

For examples of the specialized estat subcommands covariance and correlation, see [R] asmprobit postestimation. The entry also has a good example of computing marginal effects after asmprobit that is applicable to asprobit. Below we will elaborate further on marginal effects after asprobit where we manipulate the rank() option.

#### Example 2

We will continue with the preferred job characteristics example where we first compute the marginal effects for case id = 13.
. estat mfx if id==13, rank(security=3 autonomy=1 variety=2 esteem=4)

\[ \Pr(\text{esteem}=4 \ \text{variety}=2 \ \text{autonomy}=1 \ \text{security}=3) = .04218068 \]

| variable          | dp/dx   | Std. Err. | z     | P>|z| | 95% C.I. | X     |
|-------------------|---------|-----------|-------|-------|---------|-------|
| high*             |         |           |       |       |         |       |
| esteem            | -.008713| .001964   | -4.44| 0.000 | -.012562| -.004864| 0     |
| variety           | -.009102| .003127   | -2.91| 0.004 | -.015231| -.002973| 1     |
| autonomy          | .025535 | .007029   | 3.63 | 0.000 | .011758 | .039313| 0     |
| security          | -.003745| .001394   | -2.69| 0.007 | -.006477| -.001013| 0     |
| low*              |         |           |       |       |         |       |
| esteem            | .001614 | .002646   | 0.61 | 0.542 | -.003572| .00698  | 1     |
| variety           | .001809 | .003012   | 0.60 | 0.548 | -.004094| .007712| 0     |
| autonomy          | -.003849| .006104   | -0.63| 0.528 | -.015813| .008115| 0     |
| security          | .000582 | .000985   | 0.59 | 0.554 | -.001348| .002813| 1     |
| casevars          |         |           |       |       |         |       |
| female*           | .009767 | .009064   | 1.08 | 0.281 | -.007998| .027533| 0     |
| score             | .008587 | .004488   | 1.91 | 0.056 | -.00021 | .017384| .32465|

(*) dp/dx is for discrete change of indicator variable from 0 to 1

Next we compute the marginal effects for the probability that autonomy is preferred given the profile of case id = 13.

. estat mfx if id==13, rank(security=2 autonomy=1 variety=2 esteem=2)

\[ \Pr(\text{esteem}=3 \ \text{variety}=4 \ \text{autonomy}=1 \ \text{security}=2) + \]
\[ \Pr(\text{esteem}=4 \ \text{variety}=3 \ \text{autonomy}=1 \ \text{security}=2) + \]
\[ \Pr(\text{esteem}=2 \ \text{variety}=4 \ \text{autonomy}=1 \ \text{security}=3) + \]
\[ \Pr(\text{esteem}=4 \ \text{variety}=2 \ \text{autonomy}=1 \ \text{security}=3) + \]
\[ \Pr(\text{esteem}=2 \ \text{variety}=3 \ \text{autonomy}=1 \ \text{security}=4) + \]
\[ \Pr(\text{esteem}=3 \ \text{variety}=2 \ \text{autonomy}=1 \ \text{security}=4) = .10276103 \]

| variable          | dp/dx   | Std. Err. | z     | P>|z| | 95% C.I. | X     |

(*) dp/dx is for discrete change of indicator variable from 0 to 1

The probability computed by estat mfx matches the probability computed by predict, pr1 only within three digits. This outcome is because of how the computation is carried out and the numeric inaccuracy of the GHK simulator using a Hammersley point set of length 200. The computation carried out by estat mfx literally computes all six probabilities listed in the header of the MFX table and sums them. The computation by predict, pr1 is the same as predict after asmprobit (multinomial probit): it computes the probability that autonomy is chosen, thus requiring only one
call to the GHK simulator. Hence, there is a difference in the reported values even though the two probability statements are equivalent.

Stored results

`estat mfx` stores the following in `r()`:  

Scalars
- `r(pr)` scalar containing the computed probability of the ranked alternatives.

Matrices
- `r(ranks)` column vector containing the alternative ranks. The rownames identify the alternatives.
- `r(mfx)` matrix containing the computed marginal effects and associated statistics. Column 1 of the matrix contains the marginal effects; column 2, their standard errors; column 3, their $z$ statistics; and columns 4 and 5, the confidence intervals. Column 6 contains the values of the independent variables used to compute the probabilities $r(pr)$.

[U] 20 Estimation and postestimation commands
Description

This entry discusses a statistical issue that arises when using the Bayesian information criterion (BIC) to compare models.

Stata calculates BIC, assuming $N = e(N)$—we will explain—but sometimes it would be better if a different $N$ were used. Commands that calculate BIC have an n() option, allowing you to specify the $N$ to be used.

In summary,

1. If you are comparing results estimated by the same estimation command, using the default BIC calculation is probably fine. There is an issue, but most researchers would ignore it.
2. If you are comparing results estimated by different estimation commands, you need to be on your guard.
   a. If the different estimation commands share the same definitions of observations, independence, and the like, you are back in case 1.
   b. If they differ in these regards, you need to think about the value of $N$ that should be used. For example, logit and xtlogit differ in that the former assumes independent observations and the latter, independent panels.
   c. If estimation commands differ in the events being used over which the likelihood function is calculated, the information criteria may not be comparable at all. We say information criteria because this would apply equally to the Akaike information criterion (AIC), as well as to BIC. For instance, streg and stcox produce such incomparable results. The events used by streg are the actual survival times, whereas the events used by stcox are failures within risk pools, conditional on the times at which failures occurred.

Remarks and examples

Remarks are presented under the following headings:

- Background
- The problem of determining $N$
- The problem of conformable likelihoods
- The first problem does not arise with AIC; the second problem does
- Calculating BIC correctly
Background

The AIC and the BIC are two popular measures for comparing maximum likelihood models. AIC and BIC are defined as

\[ \text{AIC} = -2 \times \ln(\text{likelihood}) + 2 \times k \]
\[ \text{BIC} = -2 \times \ln(\text{likelihood}) + \ln(N) \times k \]

where

\[ k = \text{number of parameters estimated} \]
\[ N = \text{number of observations} \]

We are going to discuss AIC along with BIC because AIC has some of the problems that BIC has, but not all.

AIC and BIC can be viewed as measures that combine fit and complexity. Fit is measured negatively by \(-2 \times \ln(\text{likelihood})\); the larger the value, the worse the fit. Complexity is measured positively, either by \(2 \times k\) (AIC) or \(\ln(N) \times k\) (BIC).

Given two models fit on the same data, the model with the smaller value of the information criterion is considered to be better.

There is substantial literature on these measures: see Akaike (1974); Raftery (1995); Sakamoto, Ishiguro, and Kitagawa (1986); and Schwarz (1978).

When Stata calculates the above measures, it uses the rank of e(V) for \(k\) and it uses e(N) for \(N\). e(V) and e(N) are Stata notation for results stored by the estimation command. e(V) is the variance–covariance matrix of the estimated parameters, and e(N) is the number of observations in the dataset used in calculating the result.

The problem of determining N

The difference between AIC and BIC is that AIC uses the constant 2 to weight \(k\), whereas BIC uses \(\ln(N)\).

Determining what value of \(N\) should be used is problematic. Despite appearances, the definition “\(N\) is the number of observations” is not easy to make operational. \(N\) does not appear in the likelihood function itself, \(N\) is not the output of a standard statistical formula, and what is an observation is often subjective.

Example 1

Often what is meant by \(N\) is obvious. Consider a simple logit model. What is meant by \(N\) is the number of observations that are statistically independent and that corresponds to \(M\), the number of observations in the dataset used in the calculation. We will write \(N = M\).

But now assume that the same dataset has a grouping variable and the data are thought to be clustered within group. To keep the problem simple, let’s pretend that there are \(G\) groups and \(m\) observations within group, so that \(M = G \times m\). Because you are worried about intragroup correlation, you fit your model with xtlogit, grouping on the grouping variable. Now you wish to calculate BIC. What is the \(N\) that should be used? \(N = M\) or \(N = G\)?
That is a deep question. If the observations really are independent, then you should use $N = M$. If the observations within group are not just correlated but are duplicates of one another, and they had to be so, then you should use $M = G$. Between those two extremes, you should probably use a number between $N$ and $G$, but determining what that number should be from measured correlations is difficult. Using $N = M$ is conservative in that, if anything, it overweights complexity. Conservativeness, however, is subjective, too: using $N = G$ could be considered more conservative in that fewer constraints are being placed on the data.

When the estimated correlation is high, our reaction would be that using $N = G$ is probably more reasonable. Our first reaction, however, would be that using BIC to compare models is probably a misuse of the measure.

Stata uses $N = M$. An informal survey of web-based literature suggests that $N = M$ is the popular choice.

There is another reason, not so good, to choose $N = M$. It makes across-model comparisons more likely to be valid when performed without thinking about the issue. Say that you wish to compare the logit and xtlogit results. Thus you need to calculate

$$ BIC_p = -2 \times \ln(\text{likelihood}_p) + \ln(N_p) \times k $$

$$ BIC_x = -2 \times \ln(\text{likelihood}_x) + \ln(N_x) \times k $$

Whatever $N$ you use, you must use the same $N$ in both formulas. Stata’s choice of $N = M$ at least meets that test.

### Example 2

In the above example, using $N = M$ is reasonable. Now let’s look at when using $N = M$ is wrong, even if popular.

Consider a model fit by stcox. Using $N = M$ is certainly wrong if for no other reason than $M$ is not even a well-defined number. The same data can be represented by different datasets with different numbers of observations. For example, in one dataset, there might be 1 observation per subject. In another, the same subjects could have two records each, the first recording the first half of the time at risk and the second recording the remaining part. All statistics calculated by Stata on either dataset would be the same, but $M$ would be different.

Deciding on the right definition, however, is difficult. Viewed one way, $N$ in the Cox regression case should be the number of risk pools, $R$, because the Cox regression calculation is made on the basis of the independent risk pools. Viewed another way, $N$ should be the number of subjects, $N_{\text{subj}}$, because, even though the likelihood function is based on risk pools, the parameters estimated are at the subject level.

You can decide which argument you prefer.

For parametric survival models, in single-record data, $N = M$ is unambiguously correct. For multirecord data, there is an argument for $N = M$ and for $N = N_{\text{subj}}$. 
The problem of conformable likelihoods

The problem of conformable likelihoods does not concern \( N \). Researchers sometimes use information criteria such as BIC and AIC to make comparisons across models. For that to be valid, the likelihoods must be conformable; that is, the likelihoods must all measure the same thing.

It is common to think of the likelihood function as the \( \text{Pr}(\text{data} | \text{parameters}) \), but in fact, the likelihood is

\[
\text{Pr}(\text{particular events in the data} | \text{parameters})
\]

You must ensure that the events are the same.

For instance, they are not the same in the semiparametric Cox regression and the various parametric survival models. In Cox regression, the events are, at each failure time, that the subjects observed to fail in fact failed, given that failures occurred at those times. In the parametric models, the events are that each subject failed exactly when the subject was observed to fail.

The formula for AIC and BIC is

\[
\text{measure} = -2 \times \ln(\text{likelihood}) + \text{complexity}
\]

When you are comparing models, if the likelihoods are measuring different events, even if the models obtain estimates of the same parameters, differences in the information measures are irrelevant.

The first problem does not arise with AIC; the second problem does

Regardless of model, the problem of defining \( N \) never arises with AIC because \( N \) is not used in the AIC calculation. AIC uses a constant 2 to weight complexity as measured by \( k \), rather than \( \ln(N) \).

For both AIC and BIC, however, the likelihood functions must be conformable; that is, they must be measuring the same event.

Calculating BIC correctly

When using BIC to compare results, and especially when using BIC to compare results from different models, you should think carefully about how \( N \) should be defined. Then specify that number by using the \( n() \) option:

```
. estimates stats full sub, n(74)
```

Akaike’s information criterion and Bayesian information criterion

<table>
<thead>
<tr>
<th>Model</th>
<th>Obs</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>full</td>
<td>74</td>
<td>-45.03321</td>
<td>-20.59083</td>
<td>4</td>
<td>49.18167</td>
<td>58.39793</td>
</tr>
<tr>
<td>sub</td>
<td>74</td>
<td>-45.03321</td>
<td>-27.17516</td>
<td>3</td>
<td>60.35031</td>
<td>67.26251</td>
</tr>
</tbody>
</table>

Note: \( N=74 \) used in calculating BIC

Both estimates stats and estat ic allow the \( n() \) option; see [R] estimates stats and [R] estat ic.
Methods and formulas

AIC and BIC are defined as

\[
\text{AIC} = -2 \times \ln(\text{likelihood}) + 2 \times k
\]

\[
\text{BIC} = -2 \times \ln(\text{likelihood}) + \ln(N) \times k
\]

where \( k \) is the model degrees of freedom calculated as the rank of variance–covariance matrix of the parameters \( e(V) \) and \( N \) is the number of observations used in estimation or, more precisely, the number of independent terms in the likelihood. Operationally, \( N \) is defined as \( e(N) \) unless the \( n() \) option is specified.

### Description

**Model**

- `noconstant` suppress constant term
- `or` use logit link and report odds ratios
- `rr` use log link and report risk ratios
- `hr` use log-complement link and report health ratios
- `rd` use identity link and report risk differences
- `n(# | varname)` use `#` or `varname` for number of trials
- `exposure(varname)` include \( \ln(varname) \) in model with coefficient constrained to 1
- `offset(varname)` include `varname` in model with coefficient constrained to 1
- `constraints(constraints)` apply specified linear constraints
- `collinear` keep collinear variables
- `mu(varname)` use `varname` as the initial estimate for the mean of `depvar`
- `init(varname)` synonym for `mu(varname)`

**SE/Robust**

- `vce(vcetype)` `vcetype` may be `eim`, `robust`, `cluster clustvar`, `oim`, `opg`, `bootstrap`, `jackknife`, `hac kernel`, `jackknife1`, or `unbiased`
- `t(varname)` variable name corresponding to time
- `vfactor(#)` multiply variance matrix by scalar `#`
- `disp(#)` quasi-likelihood multiplier
- `scale(x2 | dev | #)` set the scale parameter; default is `scale(1)`

**Reporting**

- `level(#)` set confidence level; default is `level(95)`
- `coefficients` report nonexponentiated coefficients
- `nocnsreport` do not display constraints
- `display_options` control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Maximization

\texttt{irls} use iterated, reweighted least-squares optimization; the default
\texttt{ml} use maximum likelihood optimization

\texttt{maximize\_options} control the maximization process; seldom used
\texttt{fisher(#)} Fisher scoring steps
\texttt{search} search for good starting values
\texttt{coeflegend} display legend instead of statistics

\texttt{indepvars} may contain factor variables; see [U] 11.4.3 \texttt{Factor variables}.
\texttt{depvar} and \texttt{indepvars} may contain time-series operators; see [U] 11.4.4 \texttt{Time-series varlists}.
\texttt{bootstrap}, \texttt{by}, \texttt{fp}, \texttt{jackknife}, \texttt{mi estimate}, \texttt{rolling}, and \texttt{statsby} are allowed; see [U] 11.1.10 \texttt{Prefix commands}.
\texttt{vce} is not allowed with the \texttt{mi estimate} prefix; see [MI] \texttt{mi estimate}.
Weights are not allowed with the \texttt{bootstrap} prefix; see [R] \texttt{bootstrap}.
\texttt{aweights} are not allowed with the \texttt{jackknife} prefix; see [R] \texttt{jackknife}.
\texttt{fweights}, \texttt{aweights}, \texttt{iweights}, and \texttt{pweights} are allowed; see [U] 11.1.6 \texttt{weight}.
\texttt{coeflegend} does not appear in the dialog box.

See [U] 20 \texttt{Estimation and postestimation commands} for more capabilities of estimation commands.

Menu

Statistics > Generalized linear models > GLM for the binomial family

Description

\texttt{binreg} fits generalized linear models for the binomial family. It estimates odds ratios, risk ratios, health ratios, and risk differences. The available links are

<table>
<thead>
<tr>
<th>Option</th>
<th>Implied link</th>
<th>Parameter</th>
</tr>
</thead>
<tbody>
<tr>
<td>or \texttt{or}</td>
<td>\texttt{logit}</td>
<td>odds ratios = \text{exp}(\beta)</td>
</tr>
<tr>
<td>rr \texttt{rr}</td>
<td>\texttt{log}</td>
<td>risk ratios = \text{exp}(\beta)</td>
</tr>
<tr>
<td>hr \texttt{hr}</td>
<td>log complement</td>
<td>health ratios = \text{exp}(\beta)</td>
</tr>
<tr>
<td>rd \texttt{rd}</td>
<td>\texttt{identity}</td>
<td>risk differences = \beta</td>
</tr>
</tbody>
</table>

Estimates of odds, risk, and health ratios are obtained by exponentiating the appropriate coefficients. The \texttt{or} option produces the same results as Stata’s \texttt{logistic} command, and \texttt{or coefficients} yields the same results as the \texttt{logit} command. When no link is specified, \texttt{or} is assumed.

Options

\texttt{noconstant}; see [R] \texttt{estimation options}.

\texttt{or} requests the logit link and results in odds ratios if \texttt{coefficients} is not specified.
\texttt{rr} requests the log link and results in risk ratios if \texttt{coefficients} is not specified.
\texttt{hr} requests the log-complement link and results in health ratios if \texttt{coefficients} is not specified.
\texttt{rd} requests the identity link and results in risk differences.
n(# | varname) specifies either a constant integer to use as the denominator for the binomial family or a variable that holds the denominator for each observation.

exposure(varname), offset(varname), constraints(constraints), collinear; see [R] estimation options. constraints(constraints) and collinear are not allowed with irls.

mu(varname) specifies varname containing an initial estimate for the mean of depvar. This option can be useful if you encounter convergence difficulties. init(varname) is a synonym.

vce(vcetype) specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), that are derived from asymptotic theory (oim, opg), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce option.

vce(eim), the default, uses the expected information matrix (EIM) for the variance estimator. binreg also allows the following:

vce(hac kernel [ # ] ) specifies that a heteroskedasticity- and autocorrelation-consistent (HAC) variance estimate be used. HAC refers to the general form for combining weighted matrices to form the variance estimate. There are three kernels built into binreg. kernel is a user-written program or one of

   nwest | gallant | anderson

   If # is not specified, \( N - 2 \) is assumed.

vce(jackknife1) specifies that the one-step jackknife estimate of variance be used.

vce(unbiased) specifies that the unbiased sandwich estimate of variance be used.

t(varname) specifies the variable name corresponding to time; see [TS] tsset. binreg does not always need to know t(), though it does if vce(hac ...) is specified. Then you can either specify the time variable with t(), or you can tsset your data before calling binreg. When the time variable is required, binreg assumes that the observations are spaced equally over time.

vfactor(#) specifies a scalar by which to multiply the resulting variance matrix. This option allows users to match output with other packages, which may apply degrees of freedom or other small-sample corrections to estimates of variance.

disp(#) multiplies the variance of depvar by # and divides the deviance by #. The resulting distributions are members of the quasilikelihood family.

scale(x2 | dev | #) overrides the default scale parameter. This option is allowed only with Hessian (information matrix) variance estimates.

By default, scale(1) is assumed for the discrete distributions (binomial, Poisson, and negative binomial), and scale(x2) is assumed for the continuous distributions (Gaussian, gamma, and inverse Gaussian).

scale(x2) specifies that the scale parameter be set to the Pearson chi-squared (or generalized chi-squared) statistic divided by the residual degrees of freedom, which was recommended by McCullagh and Nelder (1989) as a good general choice for continuous distributions.

scale(dev) sets the scale parameter to the deviance divided by the residual degrees of freedom. This option provides an alternative to scale(x2) for continuous distributions and overdispersed or underdispersed discrete distributions.

scale(#) sets the scale parameter to #.
Reporting

level(\#), noconstant; see [R] estimation options.

coefficients displays the nonexponentiated coefficients and corresponding standard errors and confidence intervals. This option has no effect when the rd option is specified, because it always presents the nonexponentiated coefficients.

nocnsreport; see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(\#, \#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see [R] estimation options.

Maximization

irls requests iterated, reweighted least-squares (IRLS) optimization of the deviance instead of Newton–Raphson optimization of the log likelihood. This option is the default.

ml requests that optimization be carried out by using Stata’s ml command; see [R] ml.

maximize_options: technique(algorithm_spec), [no] log, trace, gradient, showstep, hessian, showtolerance, difficult, iterate(\#), tolerance(\#), ltolerance(\#), nrtolerance(\#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

Setting the optimization method to ml, with technique() set to something other than BHHH, changes the vcetype to vce(oim). Specifying technique(bhhh) changes vcetype to vce(opg).

fisher(\#) specifies the number of Newton–Raphson steps that should use the Fisher scoring Hessian or EIM before switching to the observed information matrix (OIM). This option is available only if ml is specified and is useful only for Newton–Raphson optimization.

search specifies that the command search for good starting values. This option is available only if ml is specified and is useful only for Newton–Raphson optimization.

The following option is available with binreg but is not shown in the dialog box:

coeflegend; see [R] estimation options.

Remarks and examples

Wacholder (1986) suggests methods for estimating risk ratios and risk differences from prospective binomial data. These estimates are obtained by selecting the proper link functions in the generalized linear-model framework. (See Methods and formulas for details; also see [R] glm.)

Example 1

Wacholder (1986) presents an example, using data from Wright et al. (1983), of an investigation of the relationship between alcohol consumption and the risk of a low-birthweight baby. Covariates examined included whether the mother smoked (yes or no), mother’s social class (three levels), and drinking frequency (light, moderate, or heavy). The data for the 18 possible categories determined by the covariates are illustrated below.

Let’s first describe the data and list a few observations.
. use http://www.stata-press.com/data/r13/binreg

By default, Stata reports the risk ratios (the exponentiated regression coefficients) estimated by the model. We can see that the risk ratio comparing heavy drinkers with light drinkers, after adjusting for smoking and social class, is 1.974078. That is, mothers who drink heavily during their pregnancy have approximately twice the risk of delivering low-birthweight babies as mothers who are light drinkers.
The nonexponentiated coefficients can be obtained with the `coefficients` option:

```
.binreg n_lbw_babies i.soc i.alc i.smo, n(n_women) rr coefficients
```

The risk difference between heavy drinkers and light drinkers is 0.0801291. Because the risk differences are obtained directly from the coefficients estimated by using the identity link, the coefficients option has no effect here.
Health ratios are obtained with the `hr` option. The health ratios (exponentiated coefficients for the log-complement link) are reported directly.

Stored results

`binreg`, irls stores the following in `e()`:

Scalars

- `e(N)` number of observations
- `e(k)` number of parameters
- `e(k_eq_model)` number of equations in overall model test
- `e(df_m)` model degrees of freedom
- `e(df)` residual degrees of freedom
- `e(phi)` model scale parameter
- `e(disp)` dispersion parameter
- `e(bic)` model BIC
- `e(N_clust)` number of clusters
- `e(deviance)` deviance
- `e(deviance_s)` scaled deviance
- `e(deviance_p)` Pearson deviance
- `e(deviance_ps)` scaled Pearson deviance
- `e(dispers)` dispersion
- `e(dispers_s)` scaled dispersion
- `e(dispers_p)` Pearson dispersion
- `e(dispers_ps)` scaled Pearson dispersion
- `e(vf)` factor set by `vfactor()`, 1 if not set
- `e(rank)` rank of `e(V)`
- `e(rc)` return code

Macros

- `e(cmd)` `binreg`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(eform)` `eform()` option implied by `or`, `rr`, `hr`, or `rd`
- `e(varfunc)` program to calculate variance function
- `e(varfuncf)` variance function
- `e(link)` program to calculate link function
- `e(linkt)` link title
- `e(linkf)` link function
- `e(m)` number of binomial trials
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title_f1)` family–link title
- `e(clustvar)` name of cluster variable
- `e(offset)` linear offset variable
- `e(cons)` `noconstant` or not set
- `e(hac_kernel)` HAC kernel
- `e(hac_lag)` HAC lag
- `e(vce)` `vcetype` specified in `vce()`
- `e(vctype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(opt1)` optimization title, line 1
- `e(opt2)` optimization title, line 2
- `e(properties)` `b V`
- `e(predict)` program used to implement `predict`
- `e(marginsok)` predictions allowed by `margins`
- `e(marginsnotok)` predictions disallowed by `margins`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`
Matrices

- \( e(b) \): coefficient vector
- \( e(Cns) \): constraints matrix
- \( e(V) \): variance–covariance matrix of the estimators
- \( e(V_{modelbased}) \): model-based variance

Functions

- \( e(sample) \): marks estimation sample

\textbf{binreg, ml} stores the following in \( e() \):

Scalars

- \( e(N) \): number of observations
- \( e(k) \): number of parameters
- \( e(k_{eq}) \): number of equations in \( e(b) \)
- \( e(k_{eq_model}) \): number of equations in overall model test
- \( e(k_{dv}) \): number of dependent variables
- \( e(df_m) \): model degrees of freedom
- \( e(df) \): residual degrees of freedom
- \( e(phi) \): model scale parameter
- \( e(aic) \) or \( e(bic) \): model AIC, if \texttt{ml}
- \( e(ll) \): log likelihood, if \texttt{ml}
- \( e(N_{clust}) \): number of clusters
- \( e(chi2) \): \( \chi^2 \) significance of model test
- \( e(deviance) \): deviance
- \( e(deviance_s) \): scaled deviance
- \( e(deviance_p) \): Pearson deviance
- \( e(deviance_ps) \): scaled Pearson deviance
- \( e(dispers) \): dispersion
- \( e(dispers_s) \): scaled dispersion
- \( e(dispers_p) \): Pearson dispersion
- \( e(dispers_ps) \): scaled Pearson dispersion
- \( e(vf) \): factor set by \texttt{vfactor()}, 1 if not set
- \( e(rank) \): rank of \( e(V) \)
- \( e(ic) \): number of iterations
- \( e(rc) \): return code
- \( e(converged) \): 1 if converged, 0 otherwise

Macros

- \( e(cmd) \): \texttt{binreg}
- \( e(cmdline) \): command as typed
- \( e(depvar) \): name of dependent variable
- \( e(eform) \): \texttt{eform()} option implied by \texttt{or, rr, hr, or rd}
- \( e(varfunc) \): program to calculate variance function
- \( e(varfuncf) \): variance title
- \( e(link) \): program to calculate link function
- \( e(linkt) \): link title
- \( e(linkf) \): link function
- \( e(m) \): number of binomial trials
- \( e(wt) \): weight type
- \( e(wexp) \): weight expression
- \( e(title) \): title in estimation output
- \( e(title_fl) \): family–link title
- \( e(clustvar) \): name of cluster variable
- \( e(offset) \): linear offset variable
- \( e(cons) \): noconstant or not set
- \( e(hac_kernel) \): HAC kernel
- \( e(hac_lag) \): HAC lag
- \( e(chi2type) \): Wald; type of model \( \chi^2 \) test
- \( e(vce) \): \texttt{vcetype} specified in \texttt{vce()}
Methods and formulas

Let $\pi_i$ be the probability of success for the $i$th observation, $i = 1, \ldots, N$, and let $X\beta$ be the linear predictor. The link function relates the covariates of each observation to its respective probability through the linear predictor.

In logistic regression, the logit link is used:

$$\ln\left(\frac{\pi}{1 - \pi}\right) = X\beta$$

The regression coefficient $\beta_k$ represents the change in the logarithm of the odds associated with a one-unit change in the value of the $X_k$ covariate; thus $\exp(\beta_k)$ is the ratio of the odds associated with a change of one unit in $X_k$.

For risk differences, the identity link $\pi = X\beta$ is used. The regression coefficient $\beta_k$ represents the risk difference associated with a change of one unit in $X_k$. When using the identity link, you can obtain fitted probabilities outside the interval $(0, 1)$. As suggested by Wacholder, at each iteration, fitted probabilities are checked for range conditions (and put back in range if necessary). For example, if the identity link results in a fitted probability that is smaller than $1e^{-4}$, the probability is replaced with $1e^{-4}$ before the link function is calculated.

A similar adjustment is made for the logarithmic link, which is used for estimating the risk ratio, $\ln(\pi) = X\beta$, where $\exp(\beta_k)$ is the risk ratio associated with a change of one unit in $X_k$, and for the log-complement link used to estimate the probability of no disease or health, where $\exp(\beta_k)$ represents the “health ratio” associated with a change of one unit in $X_k$.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using vce(robust) and vce(cluster clustvar), respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

- **Main**
  - mu, the default, specifies that `predict` calculate the expected value of \( y \), equal to \( g^{-1}(\mathbf{x} \hat{\beta}) \) [\( g^{-1}(\mathbf{x} \hat{\beta}) \)] for the binomial family.
  - xb calculates the linear prediction \( \eta = \mathbf{x} \hat{\beta} \).
  - eta is a synonym for xb.
  - stdp calculates the standard error of the linear prediction.
anscombe calculates the Anscombe (1953) residuals to produce residuals that closely follow a normal distribution.

cooksd calculates Cook’s distance, which measures the aggregate change in the estimated coefficients when each observation is left out of the estimation.

deviance calculates the deviance residuals, which are recommended by McCullagh and Nelder (1989) and others as having the best properties for examining goodness of fit of a GLM. They are approximately normally distributed if the model is correct and may be plotted against the fitted values or against a covariate to inspect the model’s fit. Also see the pearson option below.

hat calculates the diagonals of the “hat” matrix, analogous to linear regression.

likelihood calculates a weighted average of the standardized deviance and standardized Pearson (described below) residuals.

pearson calculates the Pearson residuals, which often have markedly skewed distributions for nonnormal family distributions. Also see the deviance option above.

response calculates the differences between the observed and fitted outcomes.

score calculates the equation-level score, $\partial \ln L / \partial (x_j \beta)$.

working calculates the working residuals, which are response residuals weighted according to the derivative of the link function.

Options

nooffset is relevant only if you specified offset(varname) for binreg. It modifies the calculations made by predict so that they ignore the offset variable; the linear prediction is treated as $x_j b$ rather than as $x_j b + offset_j$.

adjusted adjusts the deviance residual to make the convergence to the limiting normal distribution faster. The adjustment deals with adding to the deviance residual a higher-order term depending on the variance function family. This option is allowed only when deviance is specified.

standardized requests that the residual be multiplied by the factor $(1 - h)^{-1/2}$, where $h$ is the diagonal of the hat matrix. This step is done to take into account the correlation between depvar and its predicted value.

studentized requests that the residual be multiplied by one over the square root of the estimated scale parameter.

modified requests that the denominator of the residual be modified to be a reasonable estimate of the variance of depvar. The base residual is multiplied by the factor $(k/w)^{-1/2}$, where $k$ is either one or the user-specified dispersion parameter and $w$ is the specified weight (or one if left unspecified).

biprobit — Bivariate probit regression

Syntax

Bivariate probit regression

\[ \text{biprobit } \text{depvar}_1 \text{ depvar}_2 \ [\text{indepvars} ] \ [\text{if } \text{in}] \ [\text{weight}] , \text{options} \]

Seemingly unrelated bivariate probit regression

\[ \text{biprobit } \text{equation}_1 \text{ equation}_2 \ [\text{if }] \ [\text{in}] \ [\text{weight}] , \text{su_options} \]

where equation1 and equation2 are specified as

\[ ( [\text{eqname}:] \text{depvar} [=] \text{indepvars} ] , \text{noconstant offset(varname)} ] \]

options Description

Model

noconstant suppress constant term
partial fit partial observability model
offset1(varname) offset variable for first equation
offset2(varname) offset variable for second equation
constraints(constraints) apply specified linear constraints
collinear keep collinear variables

SE/Robust

vce(vcetype) vcetype may be oim, robust, cluster clustvar, opg, bootstrap, or jackknife

Reporting

level(#) set confidence level; default is level(95)
noskip perform likelihood-ratio test
noconsreport do not display constraints
display_options control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

Maximization

maximize_options control the maximization process; seldom used
coefflegend display legend instead of statistics
su_options  Description

Model

- **partial**  fit partial observability model
- **constraints (constraints)**  apply specified linear constraints
- **collinear**  keep collinear variables

SE/Robust

- **vce(vcetype)**  vcetype may be oim, robust, cluster clustvar, opg, bootstrap, or jackknife

Reporting

- **_level(#)***  set confidence level; default is _level(95)_
- **nose**  perform likelihood-ratio test
- **nocnsreport**  do not display constraints
- **display_options**  control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

Maximization

- **maximize_options**  control the maximization process; seldom used
- **coeflegend**  display legend instead of statistics

*depvars* may contain factor variables; see [U] 11.4.3 Factor variables.

*depvar1, depvar2, indepvars,* and *depvar* may contain time-series operators; see [U] 11.4.4 Time-series varlists.

*bootstrap, by, fp, jackknife, rolling, statsby,* and *svy* are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the *bootstrap* prefix; see [R] bootstrap.

_vce(), noskip,* and weights are not allowed with the *svy* prefix; see [SVY] svy.

*pweights, fweights,* and *iweights* are allowed; see [U] 11.1.6 weight.

_coeflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Menu**

**biprobit**

Statistics > Binary outcomes > Bivariate probit regression

**seemingly unrelated biprobit**

Statistics > Binary outcomes > Seemingly unrelated bivariate probit regression

**Description**

_biprobit_ fits maximum-likelihood two-equation probit models—either a bivariate probit or a seemingly unrelated probit (limited to two equations).
Options

Model

noconstant; see [R] estimation options.

partial specifies that the partial observability model be fit. This particular model commonly has poor convergence properties, so we recommend that you use the difficult option if you want to fit the Poirier partial observability model; see [R] maximize.

This model computes the product of the two dependent variables so that you do not have to replace each with the product.

offset1(varname), offset2(varname), constraints(constraints), collinear; see [R] estimation options.

SE/Robust

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting

level(#); see [R] estimation options.

noskip specifies that a full maximum-likelihood model with only a constant for the regression equation be fit. This model is not displayed but is used as the base model to compute a likelihood-ratio test for the model test statistic displayed in the estimation header. By default, the overall model test statistic is an asymptotically equivalent Wald test of all the parameters in the regression equation being zero (except the constant). For many models, this option can substantially increase estimation time.

nocnsreport; see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following option is available with biprobit but is not shown in the dialog box:

coefflegend; see [R] estimation options.

Remarks and examples

Example 1

We use the data from Pindyck and Rubinfeld (1998, 332). In this dataset, the variables are whether children attend private school (private), number of years the family has been at the present residence (years), log of property tax (logptax), log of income (loginc), and whether the head of the household voted for an increase in property taxes (vote).

We wish to model the bivariate outcomes of whether children attend private school and whether the head of the household voted for an increase in property tax based on the other covariates.

```
. use http://www.stata-press.com/data/r13/school

Likelihood-ratio test of rho=0: chi2(1) = 1.38444 Prob > chi2 = 0.2393
```

The output shows several iteration logs. The first iteration log corresponds to running the univariate probit model for the first equation, and the second log corresponds to running the univariate probit for the second model. If $\rho = 0$, the sum of the log likelihoods from these two models will equal the log likelihood of the bivariate probit model; this sum is printed in the iteration log as the comparison log likelihood.
The final iteration log is for fitting the full bivariate probit model. A likelihood-ratio test of the log likelihood for this model and the comparison log likelihood is presented at the end of the output. If we had specified the vce(robust) option, this test would be presented as a Wald test instead of as a likelihood-ratio test.

We could have fit the same model by using the seemingly unrelated syntax as

```
.biprobit (private=years logptax loginc) (vote=years logptax loginc)
```

**Stored results**

*biprobit* stores the following in *e() :

Scalars

- **e(N)**: number of observations
- **e(k)**: number of parameters
- **e(k_eq)**: number of equations in *e(b)*
- **e(k_aux)**: number of auxiliary parameters
- **e(k_eq_model)**: number of equations in overall model test
- **e(k dv)**: number of dependent variables
- **e(df_m)**: model degrees of freedom
- **e(ll)**: log likelihood
- **e(ll_0)**: log likelihood, constant-only model (*noskip* only)
- **e(ll_c)**: log likelihood, comparison model
- **e(N_clust)**: number of clusters
- **e(chi2)**: \( \chi^2 \)

Methods and formulas

The log likelihood, \( \ln L \), is given by

\[
\ln L = \sum_{j=1}^{n} w_j \ln \Phi_2 \left( q_{1j} \xi_j^\beta, q_{2j} \xi_j^\gamma, \rho_j^* \right)
\]

where \( \Phi_2() \) is the cumulative bivariate normal distribution function (with mean \( [0 \ 0]' \)) and \( w_j \) is an optional weight for observation \( j \). This derivation assumes that

\[
y_{i1j} = x_j \beta + \epsilon_{1j} + \text{offset}_j^\beta
\]
\[
y_{i2j} = z_j \gamma + \epsilon_{2j} + \text{offset}_j^\gamma
\]

\[
E(\epsilon_1) = E(\epsilon_2) = 0
\]
\[
\text{Var}(\epsilon_1) = \text{Var}(\epsilon_2) = 1
\]
\[
\text{Cov}(\epsilon_1, \epsilon_2) = \rho
\]

where \( y_{i1j}^* \) and \( y_{i2j}^* \) are the unobserved latent variables; instead, we observe only \( y_{ij} = 1 \) if \( y_{ij}^* > 0 \) and \( y_{ij} = 0 \) otherwise (for \( i = 1, 2 \)).

In the maximum likelihood estimation, \( \rho \) is not directly estimated, but \( \text{atanh} \rho \) is

\[
\text{atanh} \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)
\]

From the form of the likelihood, if \( \rho = 0 \), then the log likelihood for the bivariate probit models is equal to the sum of the log likelihoods of the two univariate probit models. A likelihood-ratio test may therefore be performed by comparing the likelihood of the full bivariate model with the sum of the log likelihoods for the univariate probit models.
This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

biprobit also supports estimation with survey data. For details on VCEs with survey data, see [SVY] variance estimation.

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

- **Main**
  - p11, the default, calculates the bivariate predicted probability $Pr(y_{1j} = 1, y_{2j} = 1)$.
  - p10 calculates the bivariate predicted probability $Pr(y_{1j} = 1, y_{2j} = 0)$.
  - p01 calculates the bivariate predicted probability $Pr(y_{1j} = 0, y_{2j} = 1)$.
  - p00 calculates the bivariate predicted probability $Pr(y_{1j} = 0, y_{2j} = 0)$.
  - pmarg1 calculates the univariate (marginal) predicted probability of success $Pr(y_{1j} = 1)$.
  - pmarg2 calculates the univariate (marginal) predicted probability of success $Pr(y_{2j} = 1)$.
  - pcond1 calculates the conditional (on success in equation 2) predicted probability of success $Pr(y_{1j} = 1, y_{2j} = 1)/Pr(y_{2j} = 1)$.
  - pcond2 calculates the conditional (on success in equation 1) predicted probability of success $Pr(y_{1j} = 1, y_{2j} = 1)/Pr(y_{1j} = 1)$. 
xb1 calculates the probit linear prediction $x_j \beta$.

xb2 calculates the probit linear prediction $z_j \gamma$.

stdp1 calculates the standard error of the linear prediction for equation 1.

stdp2 calculates the standard error of the linear prediction for equation 2.

nooffset is relevant only if you specified `offset1(varname)` or `offset2(varname)` for `biprobit`.
It modifies the calculations made by `predict` so that they ignore the offset variables; the linear predictions are treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_1$ and $z_j \gamma$ rather than as $z_j \gamma + \text{offset}_2$.

scores calculates equation-level score variables.
The first new variable will contain $\partial \ln L / \partial (x_j \beta)$.
The second new variable will contain $\partial \ln L / \partial (z_j \gamma)$.
The third new variable will contain $\partial \ln L / \partial (\text{atanh} \rho)$.

[U] 20 Estimation and postestimation commands
Title

bitest — Binomial probability test

Syntax

Binomial probability test

```
bitest varname== #p [ if ] [ in ] [ weight ] [, detail]
```

Immediate form of binomial probability test

```
bitesti #N #succ #p [, detail]
```

by is allowed with bitest; see [D] by.

fweights are allowed with bitest; see [U] 11.1.6 weight.

Menu

bitest
Statistics > Summaries, tables, and tests > Classical tests of hypotheses > Binomial probability test

bitesti
Statistics > Summaries, tables, and tests > Classical tests of hypotheses > Binomial probability test calculator

Description

bitest performs exact hypothesis tests for binomial random variables. The null hypothesis is that the probability of a success on a trial is #p. The total number of trials is the number of nonmissing values of varname (in bitest) or #N (in bitesti). The number of observed successes is the number of 1s in varname (in bitest) or #succ (in bitesti). varname must contain only 0s, 1s, and missing.

bitesti is the immediate form of bitest; see [U] 19 Immediate commands for a general introduction to immediate commands.

Option

```
Advanced  detail 
```

detail shows the probability of the observed number of successes, kobs; the probability of the number of successes on the opposite tail of the distribution that is used to compute the two-sided p-value, kopp; and the probability of the point next to kopp. This information can be safely ignored. See the technical note below for details.
Remarks and examples

Remarks are presented under the following headings:

*bitest*

*bitesti*

bitest

Example 1

We test 15 university students for high levels of one measure of visual quickness which, from other evidence, we believe is present in 30% of the nonuniversity population. Included in our data is quick, taking on the values 1 ("success") or 0 ("failure") depending on the outcome of the test.

```
. use http://www.stata-press.com/data/r13/quick
. bitest quick == 0.3
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>N</th>
<th>Observed k</th>
<th>Expected k</th>
<th>Assumed p</th>
<th>Observed p</th>
</tr>
</thead>
<tbody>
<tr>
<td>quick</td>
<td>15</td>
<td>7</td>
<td>4.5</td>
<td>0.30000</td>
<td>0.46667</td>
</tr>
</tbody>
</table>

Pr(k >= 7) = 0.131143 (one-sided test)
Pr(k <= 7) = 0.949987 (one-sided test)
Pr(k <= 1 or k >= 7) = 0.166410 (two-sided test)

The first part of the output reveals that, assuming a true probability of success of 0.3, the expected number of successes is 4.5 and that we observed seven. Said differently, the assumed frequency under the null hypothesis $H_0$ is 0.3, and the observed frequency is 0.47.

The first line under the table is a one-sided test; it is the probability of observing seven or more successes conditional on $p = 0.3$. It is a test of $H_0: p = 0.3$ versus the alternative hypothesis $H_A: p > 0.3$. Said in English, the alternative hypothesis is that more than 30% of university students score at high levels on this test of visual quickness. The $p$-value for this hypothesis test is 0.13.

The second line under the table is a one-sided test of $H_0$ versus the opposite alternative hypothesis $H_A: p < 0.3$.

The third line is the two-sided test. It is a test of $H_0$ versus the alternative hypothesis $H_A: p \neq 0.3$.

Technical note

The $p$-value of a hypothesis test is the probability (calculated assuming $H_0$ is true) of observing any outcome as extreme or more extreme than the observed outcome, with extreme meaning in the direction of the alternative hypothesis. In example 1, the outcomes $k = 8, 9, \ldots, 15$ are clearly “more extreme” than the observed outcome $k_{\text{obs}} = 7$ when considering the alternative hypothesis $H_A: p \neq 0.3$. However, outcomes with only a few successes are also in the direction of this alternative hypothesis. For two-sided hypotheses, outcomes with $k$ successes are considered “as extreme or more extreme” than the observed outcome $k_{\text{obs}}$ if $\Pr(k) \leq \Pr(k_{\text{obs}})$. Here $\Pr(k = 0)$ and $\Pr(k = 1)$ are both less than $\Pr(k = 7)$, so they are included in the two-sided $p$-value.

The `detail` option allows you to see the probability (assuming that $H_0$ is true) of the observed successes ($k = 7$) and the probability of the boundary point ($k = 1$) of the opposite tail used for the two-sided $p$-value.
. bitest quick == 0.3, detail

<table>
<thead>
<tr>
<th>Variable</th>
<th>N</th>
<th>Observed k</th>
<th>Expected k</th>
<th>Assumed p</th>
<th>Observed p</th>
</tr>
</thead>
<tbody>
<tr>
<td>quick</td>
<td>15</td>
<td>7</td>
<td>4.5</td>
<td>0.30000</td>
<td>0.46667</td>
</tr>
</tbody>
</table>

Pr(k >= 7) = 0.131143 (one-sided test)
Pr(k <= 7) = 0.949987 (one-sided test)
Pr(k <= 1 or k >= 7) = 0.166410 (two-sided test)
Pr(k == 7) = 0.081130 (observed)
Pr(k == 2) = 0.091560
Pr(k == 1) = 0.030520 (opposite extreme)

Also shown is the probability of the point next to the boundary point. This probability, namely, Pr(k = 2) = 0.092, is certainly close to the probability of the observed outcome Pr(k = 7) = 0.081, so some people might argue that k = 2 should be included in the two-sided p-value. Statisticians (at least some we know) would reply that the p-value is a precisely defined concept and that this is an arbitrary “fuzzification” of its definition. When you compute exact p-values according to the precise definition of a p-value, your type I error is never more than what you say it is—so no one can criticize you for being anticonservative. Including the point k = 2 is being overly conservative because it makes the p-value larger yet. But it is your choice; being overly conservative, at least in statistics, is always safe. Know that bitest and bitesti always keep to the precise definition of a p-value, so if you wish to include this extra point, you must do so by hand or by using the r() stored results; see Stored results below.

bitesti

Example 2

The binomial test is a function of two statistics and one parameter: N, the number of observations; k_{obs}, the number of observed successes; and p, the assumed probability of a success on a trial. For instance, in a city of N = 2,500,000, we observe k_{obs} = 36 cases of a particular disease when the population rate for the disease is p = 0.00001.

. bitesti 2500000 36 .00001

<table>
<thead>
<tr>
<th>N</th>
<th>Observed k</th>
<th>Expected k</th>
<th>Assumed p</th>
<th>Observed p</th>
</tr>
</thead>
<tbody>
<tr>
<td>2500000</td>
<td>36</td>
<td>25</td>
<td>0.00001</td>
<td>0.00001</td>
</tr>
</tbody>
</table>

Pr(k >= 36) = 0.022458 (one-sided test)
Pr(k <= 36) = 0.985448 (one-sided test)
Pr(k <= 14 or k >= 36) = 0.034859 (two-sided test)

Example 3

Boice and Monson (1977) present data on breast cancer cases and person-years of observations for women with tuberculosis who were repeatedly exposed to multiple x-ray fluoroscopies and for women with tuberculosis who were not. The data are

<table>
<thead>
<tr>
<th></th>
<th>Exposed</th>
<th>Not exposed</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Breast cancer</td>
<td>41</td>
<td>15</td>
<td>56</td>
</tr>
<tr>
<td>Person-years</td>
<td>28,010</td>
<td>19,017</td>
<td>47,027</td>
</tr>
</tbody>
</table>
We can thus test whether x-ray fluoroscopic examinations are associated with breast cancer; the assumed rate of exposure is \( p = 28010/47027 \).

<table>
<thead>
<tr>
<th>N</th>
<th>Observed k</th>
<th>Expected k</th>
<th>Assumed p</th>
<th>Observed p</th>
</tr>
</thead>
<tbody>
<tr>
<td>56</td>
<td>41</td>
<td>33.35446</td>
<td>0.59562</td>
<td>0.73214</td>
</tr>
</tbody>
</table>

\[
\text{Pr}(k \geq 41) = 0.023830 \quad \text{(one-sided test)}
\]

\[
\text{Pr}(k \leq 41) = 0.988373 \quad \text{(one-sided test)}
\]

\[
\text{Pr}(k \leq 25 \text{ or } k \geq 41) = 0.040852 \quad \text{(two-sided test)}
\]

**Stored results**

`bitest` and `bitesti` store the following in `r()`:

- Scalars:
  - `r(N)` number of trials
  - `r(p)` assumed probability of success
  - `r(k)` observed number of successes
  - `r(k_opp)` opposite extreme k
  - `r(P_k)` probability of observed k (detail only)
  - `r(P_opp)` probability of opposite extreme k (detail only)
  - `r(p_l)` lower one-sided p-value
  - `r(p_u)` upper one-sided p-value
  - `r(p)` two-sided p-value
  - `r(k_opp)` k next to opposite extreme (detail only)
  - `r(P_opp)` probability of k next to opposite extreme (detail only)

**Methods and formulas**

Let \( N \), \( k_{\text{obs}} \), and \( p \) be, respectively, the number of observations, the observed number of successes, and the assumed probability of success on a trial. The expected number of successes is \( Np \), and the observed probability of success on a trial is \( k_{\text{obs}}/N \).

`bitest` and `bitesti` compute exact p-values based on the binomial distribution. The upper one-sided p-value is

\[
\text{Pr}(k \geq k_{\text{obs}}) = \sum_{m=k_{\text{obs}}}^{N} \binom{N}{m} p^m (1-p)^{N-m}
\]

The lower one-sided p-value is

\[
\text{Pr}(k \leq k_{\text{obs}}) = \sum_{m=0}^{k_{\text{obs}}} \binom{N}{m} p^m (1-p)^{N-m}
\]

If \( k_{\text{obs}} \geq Np \), the two-sided p-value is

\[
\text{Pr}(k \leq k_{\text{opp}} \text{ or } k \geq k_{\text{obs}})
\]

where \( k_{\text{opp}} \) is the largest number \( \leq Np \) such that \( \text{Pr}(k = k_{\text{opp}}) \leq \text{Pr}(k = k_{\text{obs}}) \). If \( k_{\text{obs}} < Np \), the two-sided p-value is

\[
\text{Pr}(k \leq k_{\text{obs}} \text{ or } k \geq k_{\text{opp}})
\]

where \( k_{\text{opp}} \) is the smallest number \( \geq Np \) such that \( \text{Pr}(k = k_{\text{opp}}) \leq \text{Pr}(k = k_{\text{obs}}) \).

Statistics > Resampling > Bootstrap estimation

Description

bootstrap performs bootstrap estimation. Typing

   . bootstrap exp_list, reps(#) : command

executes command multiple times, bootstrapping the statistics in exp_list by resampling observations (with replacement) from the data in memory # times. This method is commonly referred to as the nonparametric bootstrap.

command defines the statistical command to be executed. Most Stata commands and user-written programs can be used with bootstrap, as long as they follow standard Stata syntax; see [U] 11 Language syntax. If the bca option is supplied, command must also work with jackknife; see [R] jackknife. The by prefix may not be part of command.

exp_list specifies the statistics to be collected from the execution of command. If command changes the contents in e(b), exp_list is optional and defaults to _b.
Because bootstrapping is a random process, if you want to be able to reproduce results, set the random-number seed by specifying the seed(#) option or by typing

```
. set seed #
```

where # is a seed of your choosing, before running bootstrap; see [R] set seed.

Many estimation commands allow the vce(bootstrap) option. For those commands, we recommend using vce(bootstrap) over bootstrap because the estimation command already handles clustering and other model-specific details for you. The bootstrap prefix command is intended for use with nonestimation commands, such as summarize, user-written commands, or functions of coefficients.

bs and bstrap are synonyms for bootstrap.

---

**Options**

`reps(#)` specifies the number of bootstrap replications to be performed. The default is 50. A total of 50–200 replications are generally adequate for estimates of standard error and thus are adequate for normal-approximation confidence intervals; see Mooney and Duval (1993, 11). Estimates of confidence intervals using the percentile or bias-corrected methods typically require 1,000 or more replications.

`strata(varlist)` specifies the variables that identify strata. If this option is specified, bootstrap samples are taken independently within each stratum.

`size(#)` specifies the size of the samples to be drawn. The default is _N, meaning to draw samples of the same size as the data. If specified, # must be less than or equal to the number of observations within strata().

If cluster() is specified, the default size is the number of clusters in the original dataset. For unbalanced clusters, resulting sample sizes will differ from replication to replication. For cluster sampling, # must be less than or equal to the number of clusters within strata().

`cluster(varlist)` specifies the variables that identify resampling clusters. If this option is specified, the sample drawn during each replication is a bootstrap sample of clusters.

`idcluster(newvar)` creates a new variable containing a unique identifier for each resampled cluster. This option requires that cluster() also be specified.

`saving(filename[, suboptions])` creates a Stata data file (.dta file) consisting of (for each statistic in exp_list) a variable containing the replicates.

`double` specifies that the results for each replication be saved as doubles, meaning 8-byte reals. By default, they are saved as floats, meaning 4-byte reals. This option may be used without the saving() option to compute the variance estimates by using double precision.

`every(#)` specifies that results be written to disk every #th replication. every() should be specified only in conjunction with saving() when command takes a long time for each replication. This option will allow recovery of partial results should some other software crash your computer. See [P] postfile.

`replace` specifies that filename be overwritten if it exists. This option does not appear in the dialog box.
bootstrap specifies that bootstrap estimate the acceleration of each statistic in exp_list. This estimate is used to construct BC$_alpha$ confidence intervals. Type estat bootstrap, bca to display the BC$_alpha$ confidence interval generated by the bootstrap command.

ties specifies that bootstrap adjust for ties in the replicate values when computing the median bias used to construct BC and BC$_a$ confidence intervals.

mse specifies that bootstrap compute the variance by using deviations of the replicates from the observed value of the statistics based on the entire dataset. By default, bootstrap computes the variance by using deviations from the average of the replicates.

Reporting

level(#); see [R] estimation options.

notable suppresses the display of the table of results.

noheader suppresses the display of the table header. This option implies nolegend. This option may also be specified when replaying estimation results.

nolegend suppresses the display of the table legend. This option may also be specified when replaying estimation results.

verbose specifies that the full table legend be displayed. By default, coefficients and standard errors are not displayed. This option may also be specified when replaying estimation results.

nodots suppresses display of the replication dots. By default, one dot character is displayed for each successful replication. A red ‘x’ is displayed if command returns an error or if one of the values in exp_list is missing.

noisily specifies that any output from command be displayed. This option implies the nodots option.

trace causes a trace of the execution of command to be displayed. This option implies the noisily option.

title(text) specifies a title to be displayed above the table of bootstrap results. The default title is the title stored in e(title) by an estimation command, or if e(title) is not filled in, Bootstrap results is used. title() may also be specified when replaying estimation results.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

eform_option causes the coefficient table to be displayed in exponentiated form; see [R] eform_option.

command determines which of the following are allowed (eform(string) and eform are always allowed):

<table>
<thead>
<tr>
<th>eform_option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>eform(string)</td>
<td>use string for the column title</td>
</tr>
<tr>
<td>eform</td>
<td>exponentiated coefficient, string is exp(b)</td>
</tr>
<tr>
<td>hr</td>
<td>hazard ratio, string is Haz. Ratio</td>
</tr>
<tr>
<td>shr</td>
<td>subhazard ratio, string is SHR</td>
</tr>
<tr>
<td>irr</td>
<td>incidence-rate ratio, string is IRR</td>
</tr>
<tr>
<td>or</td>
<td>odds ratio, string is Odds Ratio</td>
</tr>
<tr>
<td>rrr</td>
<td>relative-risk ratio, string is RRR</td>
</tr>
</tbody>
</table>
nodrop prevents observations outside e(sample) and the if and in qualifiers from being dropped before the data are resampled.

nowarn suppresses the display of a warning message when command does not set e(sample).

force suppresses the restriction that command not specify weights or be a svy command. This is a rarely used option. Use it only if you know what you are doing.

reject(exp) identifies an expression that indicates when results should be rejected. When exp is true, the resulting values are reset to missing values.

seed(#) sets the random-number seed. Specifying this option is equivalent to typing the following command prior to calling bootstrap:

```
  . set seed #
```

The following options are available with bootstrap but are not shown in the dialog box:

- **group(varname)** re-creates varname containing a unique identifier for each group across the resampled clusters. This option requires that idcluster() also be specified.

  This option is useful for maintaining unique group identifiers when sampling clusters with replacement. Suppose that cluster 1 contains 3 groups. If the idcluster(newclid) option is specified and cluster 1 is sampled multiple times, newclid uniquely identifies each copy of cluster 1. If group(newgroupid) is also specified, newgroupid uniquely identifies each copy of each group.

- **jackknifeopts(jkopts)** identifies options that are to be passed to jackknife when it computes the acceleration values for the BCα confidence intervals; see [R] jackknife. This option requires the bca option and is mostly used for passing the eclass, rclass, or n(#) option to jackknife.

**Introduction**

With few assumptions, bootstrapping provides a way of estimating standard errors and other measures of statistical precision (Efron 1979; Efron and Stein 1981; Efron 1982; Efron and Tibshirani 1986; Efron and Tibshirani 1993; also see Davison and Hinkley [1997]; Guan [2003]; Mooney and Duval [1993]; Poi [2004]; and Stine [1990]). It provides a way to obtain such measures when no formula is otherwise available or when available formulas make inappropriate assumptions. Cameron and Trivedi (2010, chap. 13) discuss many bootstrapping topics and demonstrate how to do them in Stata.
To illustrate bootstrapping, suppose that you have a dataset containing $N$ observations and an estimator that, when applied to the data, produces certain statistics. You draw, with replacement, $N$ observations from the $N$-observation dataset. In this random drawing, some of the original observations will appear once, some more than once, and some not at all. Using the resampled dataset, you apply the estimator and collect the statistics. This process is repeated many times; each time, a new random sample is drawn and the statistics are recalculated.

This process builds a dataset of replicated statistics. From these data, you can calculate the standard error by using the standard formula for the sample standard deviation

$$\hat{se} = \left( \frac{1}{k-1} \sum (\hat{\theta}_i - \bar{\theta})^2 \right)^{1/2}$$

where $\hat{\theta}_i$ is the statistic calculated using the $i$th bootstrap sample and $k$ is the number of replications. This formula gives an estimate of the standard error of the statistic, according to Hall and Wilson (1991). Although the average, $\bar{\theta}$, of the bootstrapped estimates is used in calculating the standard deviation, it is not used as the estimated value of the statistic itself. Instead, the original observed value of the statistic, $\hat{\theta}$, is used, meaning the value of the statistic computed using the original $N$ observations.

You might think that $\bar{\theta}$ is a better estimate of the parameter than $\hat{\theta}$, but it is not. If the statistic is biased, bootstrapping exaggerates the bias. In fact, the bias can be estimated as $\bar{\theta} - \hat{\theta}$ (Efron 1982, 33). Knowing this, you might be tempted to subtract this estimate of bias from $\hat{\theta}$ to produce an unbiased statistic. The bootstrap bias estimate has an indeterminate amount of random error, so this unbiased estimator may have greater mean squared error than the biased estimator (Mooney and Duval 1993; Hinkley 1978). Thus $\hat{\theta}$ is the best point estimate of the statistic.

The logic behind the bootstrap is that all measures of precision come from a statistic’s sampling distribution. When the statistic is estimated on a sample of size $N$ from some population, the sampling distribution tells you the relative frequencies of the values of the statistic. The sampling distribution, in turn, is determined by the distribution of the population and the formula used to estimate the statistic.

Sometimes the sampling distribution can be derived analytically. For instance, if the underlying population is distributed normally and you calculate means, the sampling distribution for the mean is also normal but has a smaller variance than that of the population. In other cases, deriving the sampling distribution is difficult, as when means are calculated from nonnormal populations. Sometimes, as in the case of means, it is not too difficult to derive the sampling distribution as the sample size goes to infinity ($N \to \infty$). However, such asymptotic distributions may not perform well when applied to finite samples.

If you knew the population distribution, you could obtain the sampling distribution by simulation: you could draw random samples of size $N$, calculate the statistic, and make a tally. Bootstrapping does precisely this, but it uses the observed distribution of the sample in place of the true population distribution. Thus the bootstrap procedure hinges on the assumption that the observed distribution is a good estimate of the underlying population distribution. In return, the bootstrap produces an estimate, called the bootstrap distribution, of the sampling distribution. From this, you can estimate the standard error of the statistic, produce confidence intervals, etc.

The accuracy with which the bootstrap distribution estimates the sampling distribution depends on the number of observations in the original sample and the number of replications in the bootstrap. A crudely estimated sampling distribution is adequate if you are only going to extract, say, a standard error. A better estimate is needed if you want to use the 2.5th and 97.5th percentiles of the distribution to produce a 95% confidence interval. To extract many features simultaneously about the distribution,
an even better estimate is needed. Generally, replications on the order of 1,000 produce very good estimates, but only 50–200 replications are needed for estimates of standard errors. See Poi (2004) for a method to choose the number of bootstrap replications.

Regression coefficients

Example 1

Let’s say that we wish to compute bootstrap estimates for the standard errors of the coefficients from the following regression:

```
use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
.regress mpg weight gear foreign
```

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>1629.67805</td>
<td>3</td>
<td>543.226016</td>
<td>F(3, 70) = 46.73</td>
</tr>
<tr>
<td>Residual</td>
<td>813.781411</td>
<td>70</td>
<td>11.6254487</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Total</td>
<td>2443.45946</td>
<td>73</td>
<td>33.4720474</td>
<td>R-squared = 0.6670</td>
</tr>
</tbody>
</table>

| mpg     | Coef.    | Std. Err. | t      | P>|t|  | [95% Conf. Interval] |
|---------|----------|-----------|--------|------|----------------------|
| weight  | -.006139 | .0007949  | -7.72  | 0.000| -.0077245 -.0045536  |
| gear_ratio | 1.457113 | 1.541286  | 0.95   | 0.348| -1.616884 4.53111   |
| foreign | -2.221682| 1.234961  | -1.80  | 0.076| -4.684735 .2413715  |
| _cons   | 36.10135 | 6.285984  | 5.74   | 0.000| 23.56435 48.63835   |

To run the bootstrap, we simply prefix the above regression command with the `bootstrap` command (specifying its options before the colon separator). We must set the random-number seed before calling bootstrap.

```
.bootstrap, reps(100) seed(1): regress mpg weight gear foreign
```

The displayed confidence interval is based on the assumption that the sampling (and hence bootstrap) distribution is approximately normal (see Methods and formulas below). Because this confidence interval is based on the standard error, it is a reasonable estimate if normality is approximately true, even for a few replications. Other types of confidence intervals are available after bootstrap; see [R] bootstrap postestimation.

We could instead supply names to our expressions when we run bootstrap. For example,

$. bootstrap diff=(_b[weight]-_b[gear]): regress mpg weight gear foreign

would bootstrap a statistic, named diff, equal to the difference between the coefficients on weight and gear_ratio.

Expressions

Example 2

When we use bootstrap, the list of statistics can contain complex expressions, as long as each expression is enclosed in parentheses. For example, to bootstrap the range of a variable x, we could type

$. bootstrap range=(r(max)-r(min)), reps(1000): summarize x

Of course, we could also bootstrap the minimum and maximum and later compute the range.

$. bootstrap max=r(max) min=r(min), reps(1000) saving(mybs): summarize x
$. use mybs, clear
(bootstrap: summarize)
$. generate range = max - min
$. bstat range, stat(19.5637501)

The difference between the maximum and minimum of x in the sample is 19.5637501.

The stat() option to bstat specifies the observed value of the statistic (range) to be summarized. This option is useful when, as shown above, the statistic of ultimate interest is not specified directly to bootstrap but instead is calculated by other means.

Here the observed values of r(max) and r(min) are stored as characteristics of the dataset created by bootstrap and are thus available for retrieval by bstat; see [R] bstat. The observed range, however, is unknown to bstat, so it must be specified.

Combining bootstrap datasets

You can combine two datasets from separate runs of bootstrap by using append (see [D] append) and then get the bootstrap statistics for the combined datasets by running bstat. The runs must have been performed independently (having different starting random-number seeds), and the original dataset, command, and bootstrap statistics must have been all the same.
A note about macros

In example 2, we executed the command

```
. bootstrap max=r(max) min=r(min), reps(1000) saving(mybs): summarize x
```

We did not enclose \texttt{r(max)} and \texttt{r(min)} in single quotes, as we would in most other contexts, because it would not produce what was intended:

```
. bootstrap 'r(max)' 'r(min)', reps(1000) saving(mybs): summarize x
```

To understand why, note that \texttt{'r(max)'} , like any reference to a local macro, will evaluate to a literal string containing the contents of \texttt{r(max)} before \texttt{bootstrap} is even executed. Typing the command above would appear to Stata as if we had typed

```
. bootstrap 14.5441234 33.4393293, reps(1000) saving(mybs): summarize x
```

Even worse, the current contents of \texttt{r(min)} and \texttt{r(max)} could be empty, producing an even more confusing result. To avoid this outcome, refer to statistics by name (for example, \texttt{r(max)}) and not by value (for example, \texttt{'r(max)'}).

Achieved significance level

\textbf{Example 3}

Suppose that we wish to estimate the \textit{achieved significance level} (ASL) of a test statistic by using the bootstrap. ASL is another name for \textit{p}-value. An example is

\[ \text{ASL} = \Pr \left( \hat{\theta}^* \geq \hat{\theta} \mid H_0 \right) \]

for an upper-tailed, alternative hypothesis, where \( H_0 \) denotes the null hypothesis, \( \hat{\theta} \) is the observed value of the test statistic, and \( \hat{\theta}^* \) is the random variable corresponding to the test statistic, assuming that \( H_0 \) is true.

Here we will compare the mean miles per gallon (mpg) between foreign and domestic cars by using the two-sample \( t \) test with unequal variances. The following results indicate the \textit{p}-value to be \( 0.0034 \) for the two-sided test using Satterthwaite’s approximation. Thus assuming that mean mpg is the same for foreign and domestic cars, we would expect to observe a \( t \) statistic more extreme (in absolute value) than 3.1797 in about 0.3\% of all possible samples of the type that we observed. Thus we have evidence to reject the null hypothesis that the means are equal.
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. ttest mpg, by(foreign) unequal

Two-sample t test with unequal variances

<table>

</tbody>
</table>

\[ \text{diff} = \text{mean(Domestic)} - \text{mean(Foreign)} \]
\[ t = -3.1797 \]

Ho: diff = 0  Satterthwaite’s degrees of freedom = 30.5463
Ha: diff < 0  Ha: diff != 0  Ha: diff > 0
Pr(T < t) = 0.0017  Pr(|T| > |t|) = 0.0034  Pr(T > t) = 0.9983

We also place the value of the test statistic in a scalar for later use.

. scalar tobs = r(t)

Efron and Tibshirani (1993, 224) describe an alternative to Satterthwaite’s approximation that estimates the ASL by bootstrapping the statistic from the test of equal means. Their idea is to recenter the two samples to the combined sample mean so that the data now conform to the null hypothesis but that the variances within the samples remain unchanged.

. summarize mpg, meanonly
. scalar omean = r(mean)
. summarize mpg if foreign==0, meanonly
. replace mpg = mpg - r(mean) + scalar(omean) if foreign==0
  mpg was int now float
  (52 real changes made)
. summarize mpg if foreign==1, meanonly
. replace mpg = mpg - r(mean) + scalar(omean) if foreign==1
  (22 real changes made)
. sort foreign
. by foreign: summarize mpg

<td>37.52457</td>
</tr>
</tbody>
</table>

Each sample (foreign and domestic) is a stratum, so the bootstrapped samples must have the same number of foreign and domestic cars as the original dataset. This requirement is facilitated by the `strata()` option to bootstrap. By typing the following, we bootstrap the test statistic using the modified dataset and save the values in `bsauto2.dta`: 
. keep mpg foreign
. set seed 1
. bootstrap t=r(t), rep(1000) strata(foreign) saving(bsauto2) nodots: ttest mpg, > by(foreign) unequal

Warning: Because ttest is not an estimation command or does not set
e(sample), bootstrap has no way to determine which observations are
used in calculating the statistics and so assumes that all
observations are used. This means that no observations will be
excluded from the resampling because of missing values or other
reasons.

If the assumption is not true, press Break, save the data, and drop
the observations that are to be excluded. Be sure that the dataset
in memory contains only the relevant data.

We can use the data in bsauto2.dta to estimate ASL via the fraction of bootstrap test statistics
that are more extreme than 3.1797.

. use bsauto2, clear
(bootstrap: ttest)
. generate indicator = abs(t) >= abs(scalar(tobs))
. summarize indicator, meanonly
. display "ASLboot = " r(mean)
ASLboot = .005

The result is ASLboot = 0.005. Assuming that the mean mpg is the same between foreign and
domestic cars, we would expect to observe a t statistic more extreme (in absolute value) than 3.1797
in about 0.5% of all possible samples of the type we observed. This finding is still strong evidence
to reject the hypothesis that the means are equal.

> Bootstrapping a ratio

> Example 4

Suppose that we wish to produce a bootstrap estimate of the ratio of two means. Because summarize
stores results for only one variable, we must call summarize twice to compute the means. Actually,
we could use collapse to compute the means in one call, but calling summarize twice is much
faster. Thus we will have to write a small program that will return the results we want.
We write the program below and save it to a file called `ratio.ado` (see [U] 17 Ado-files). Our program takes two variable names as input and saves them in the local macros `y` (first variable) and `x` (second variable). It then computes one statistic: the mean of ‘y’ divided by the mean of ‘x’. This value is returned as a scalar in `r(ratio)`. `ratio` also returns the ratio of the number of observations used to the mean for each variable.

```stata
program myratio, rclass
    version 13
    args y x
    confirm var `y'
    confirm var `x'
    tempname ymean yn
    summarize `y', meanonly
    scalar `ymean' = r(mean)
    return scalar n_`y' = r(N)
    summarize `x', meanonly
    return scalar n_`x' = r(N)
    return scalar ratio = `ymean'/r(mean)
end
```

Remember to test any newly written commands before using them with bootstrap.

```stata
. use http://www.stata-press.com/data/r13/auto, clear
   (1978 Automobile Data)
. summarize price
    
    Variable |       Obs       Mean    Std. Dev.     Min     Max
    ---------|-------------|-------------|-------------|--------|--------
    price    |        74  6165.257     2949.496   3291    15906
. scalar mean1=r(mean)
. summarize weight
    
    Variable |       Obs       Mean    Std. Dev.     Min     Max
    ---------|-------------|-------------|-------------|--------|--------
    weight   |        74  3019.459     777.1936   1760    4840
. scalar mean2=r(mean)
. di scalar(mean1)/scalar(mean2)
2.0418412
. myratio price weight
. return list
    scalars:
    r(ratio) = 2.041841210168278
    r(n_weight) = 74
    r(n_price) = 74
```
The results of running bootstrap on our program are

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. set seed 1
. bootstrap ratio=r(ratio), reps(1000) nowarn nodots: myratio price weight
```

As mentioned previously, we should specify the `saving()` option if we wish to save the bootstrap dataset.

---

**Warning messages and e(sample)**

`bootstrap` is not meant to be used with weighted calculations. `bootstrap` determines the presence of weights by parsing the prefixed command with standard syntax. However, commands like `stcox` and `streg` require that weights be specified in `stset`, and some user commands may allow weights to be specified by using an option instead of the standard syntax. Both cases pose a problem for `bootstrap` because it cannot determine the presence of weights under these circumstances. In these cases, we can only assume that you know what you are doing.

`bootstrap` does not know which variables of the dataset in memory matter to the calculation at hand. You can speed their execution by dropping unnecessary variables because, otherwise, they are included in each bootstrap sample.

You should thus drop observations with missing values. Leaving in missing values causes no problem in one sense because all Stata commands deal with missing values gracefully. It does, however, cause a statistical problem. Bootstrap sampling is defined as drawing, with replacement, samples of size $N$ from a set of $N$ observations. `bootstrap` determines $N$ by counting the number of observations in memory, not counting the number of nonmissing values on the relevant variables. The result is that too many observations are resampled; the resulting bootstrap samples, because they are drawn from a population with missing values, are of unequal sizes.

If the number of missing values relative to the sample size is small, this will make little difference. If you have many missing values, however, you should first drop the observations that contain them.

---

**Example 5**

To illustrate, we use the previous example but replace some of the values of `price` with missing values. The number of values of `price` used to compute the mean for each bootstrap is not constant. This is the purpose of the `Warning` message.
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. replace price = . if inlist(_n,1,3,5,7)
(4 real changes made, 4 to missing)
. set seed 1
. bootstrap ratio=r(ratio) np=r(n_price) nw=r(n_weight), reps(100) nodots:
   > myratio price weight

Warning: Because myratio is not an estimation command or does not set
e(sample), bootstrap has no way to determine which observations are
used in calculating the statistics and so assumes that all
observations are used. This means that no observations will be
excluded from the resampling because of missing values or other
reasons.

If the assumption is not true, press Break, save the data, and drop
the observations that are to be excluded. Be sure that the dataset
in memory contains only the relevant data.

Bootstrapping statistics from data with a complex structure

Here we describe how to bootstrap statistics from data with a complex structure, for example,
longitudinal or panel data, or matched data. bootstrap, however, is not designed to work with
complex survey data. It is important to include all necessary information about the structure of the
data in the bootstrap syntax to obtain correct bootstrap estimates for standard errors and confidence
intervals.

bootstrap offers several options identifying the specifics of the data. These options are strata(),
cluster(), idcluster(), and group(). The usage of strata() was described in example 3 above.
Below we demonstrate several examples that require specifying the other three options.

Example 6

Suppose that the auto data in example 1 above are clustered by rep78. We want to obtain
bootstrap estimates for the standard errors of the difference between the coefficients on weight and
gear_ratio, taking into account clustering.

We supply the cluster(rep78) option to bootstrap to request resampling from clusters rather
than from observations in the dataset.
bootstrap — Bootstrap sampling and estimation

```
. use http://www.stata-press.com/data/r13/auto, clear
   (1978 Automobile Data)
. keep if rep78<.
   (5 observations deleted)
. bootstrap diff=(_b[weight]-_b[gear]), seed(1) cluster(rep78): regress mpg
   > weight gear foreign
   (running regress on estimation sample)
Bootstrap replications (50)
     1  2  3  4  5
............................................. 50
Linear regression
      Number of obs   =    69
      Replications    =    50
      command:        regress mpg weight gear foreign
      diff:           _b[weight]-_b[gear]
      (Replications based on 5 clusters in rep78)

<table>
<thead>
<tr>
<th></th>
<th>Observed</th>
<th>Bootstrap</th>
<th></th>
<th></th>
<th>Normal-based</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Coef.</td>
<td>Std. Err.</td>

<td>z</td>
</tr>
<tr>
<td>diff</td>
<td>-1.910396</td>
<td>1.876778</td>
<td>-1.02</td>
<td>0.309</td>
<td>-5.588812</td>
</tr>
</tbody>
</table>
```

We drop missing values in rep78 before issuing the command because bootstrap does not allow missing values in cluster(). See the section above about using bootstrap when variables contain missing values.

We can also obtain these same results by using the following syntax:
```
. bootstrap diff=(_b[weight]-_b[gear]), seed(1): regress mpg weight gear foreign,
   > vce(cluster rep78)
```

When only clustered information is provided to the command, bootstrap can pick up the vce(cluster clustvar) option from the main command and use it to resample from clusters.

Example 7

Suppose now that we have matched data and want to use bootstrap to obtain estimates of the standard errors of the exponentiated difference between two coefficients (or, equivalently, the ratio of two odds ratios) estimated by clogit. Consider the example of matched case–control data on birthweight of infants described in example 2 of [R] clogit.

The infants are paired by being matched on mother's age. All groups, defined by the pairid variable, have 1:1 matching. clogit requires that the matching information, pairid, be supplied to the group() (or, equivalently, strata()) option to be used in computing the parameter estimates. Because the data are matched, we need to resample from groups rather than from the whole dataset. However, simply supplying the grouping variable pairid in cluster() is not enough with bootstrap, as it is with clustered data.
. use http://www.stata-press.com/data/r13/lowbirth2, clear
(Applied Logistic Regression, Hosmer & Lemeshow)
. bootstrap ratio=exp(_b[smoke]-_b[ptd]), seed(1) cluster(pairid): clogit low > lwt smoke ptd ht ui i.race, group(pairid)
(running clogit on estimation sample)
Bootstrap replications (50)
1  2  3  4  5
.................................................. 50
Bootstrap results
Number of obs = 112
Replications = 50
command: clogit low lwt smoke ptd ht ui i.race, group(pairid)
ratio: exp(_b[smoke]-_b[ptd])
(Replications based on 56 clusters in pairid)

<table>
<thead>
<tr>
<th></th>
<th>Observed</th>
<th>Bootstrap</th>
<th></th>
<th></th>
<th>Normal-based</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Coef.</td>
<td>Std. Err.</td>

<td>P&gt;</td>
<td>z</td>
</tr>
<tr>
<td>ratio</td>
<td>.6654095</td>
<td>17.71791</td>
<td>0.04</td>
<td>.970</td>
<td>-34.06106</td>
</tr>
</tbody>
</table>

For the syntax above, imagine that the first pair was sampled twice during a replication. Then the bootstrap sample has four subjects with pairid equal to one, which clearly violates the original 1:1 matching design. As a result, the estimates of the coefficients obtained from this bootstrap sample will be incorrect.

Therefore, in addition to resampling from groups, we need to ensure that resampled groups are uniquely identified in each of the bootstrap samples. The idcluster(newcluster) option is designed for this. It requests that at each replication bootstrap create the new variable, newcluster, containing unique identifiers for all resampled groups. Thus, to make sure that the correct matching is preserved during each replication, we need to specify the grouping variable in cluster(), supply a variable name to idcluster(), and use this variable as the grouping variable with clogit, as we demonstrate below.

. bootstrap ratio=exp(_b[smoke]-_b[ptd]), seed(1) cluster(pairid)
> idcluster(newpairid): clogit low lwt smoke ptd ht ui i.race, group(newpairid)
(running clogit on estimation sample)
Bootstrap replications (50)
1  2  3  4  5
.................................................. 50
Bootstrap results
Number of obs = 112
Replications = 50
command: clogit low lwt smoke ptd ht ui i.race, group(newpairid)
ratio: exp(_b[smoke]-_b[ptd])
(Replications based on 56 clusters in pairid)

<table>

</tr>
</tbody>
</table>

Note the difference between the estimates of the bootstrap standard error for the two specifications of the bootstrap syntax.
Technical note

Similarly, when you have panel (longitudinal) data, all resampled panels must be unique in each of the bootstrap samples to obtain correct bootstrap estimates of statistics. Therefore, both `cluster(panelvar)` and `idcluster(newpanelvar)` must be specified with `bootstrap`, and `i(newpanelvar)` must be used with the main command. Moreover, you must clear the current `xtset` settings by typing `xtset, clear` before calling `bootstrap`.

Example 8

Continuing with our birthweight data, suppose that we have more information about doctors supervising women’s pregnancies. We believe that the data on the pairs of infants from the same doctor may be correlated and want to adjust standard errors for possible correlation among the pairs. `clogit` offers the `vce(cluster clustvar)` option to do this.

Let’s add a cluster variable to our dataset. One thing to keep in mind is that to use `vce(cluster clustvar)`, groups in `group()` must be nested within clusters.

\[
\begin{align*}
\text{. use http://www.stata-press.com/data/r13/lowbirth2, clear} \\
\text{(Applied Logistic Regression, Hosmer & Lemeshow)} \\
\text{. set seed 12345} \\
\text{. by pairid, sort: egen byte doctor = total(int(2*runiform()+1)*(_n == 1))} \\
\text{. clogit low lwt smoke ptd ht ui i.race, group(pairid) vce(cluster doctor)}
\end{align*}
\]

```
Iteration 0: log pseudolikelihood = -26.768693
Iteration 1: log pseudolikelihood = -25.810476

</table>
```

To obtain correct bootstrap standard errors of the exponentiated difference between the two coefficients in this example, we need to make sure that both resampled clusters and groups within resampled clusters are unique in each of the bootstrap samples. To achieve this, `bootstrap` needs the information about clusters in `cluster()`, the variable name of the new identifier for clusters in `idcluster()`, and the information about groups in `group()`. We demonstrate the corresponding syntax of `bootstrap` below.
. bootstrap ratio=exp(_b[smoke]-_b[ptd]), seed(1) cluster(doctor) 
> idcluster(uidoctor) group(pairid): clogit low lwt smoke ptd ht ui i.race, 
>    group(pairid) 
(running clogit on estimation sample) 
Bootstrap replications (50) 
.................................................. 50 
Bootstrap results 
Number of obs = 112 
Replications = 50 
command: clogit low lwt smoke ptd ht ui i.race, group(pairid) 
ratio: exp(_b[smoke]-_b[ptd]) 

(Replications based on 2 clusters in doctor) 

<table>
<thead>
<tr>
<th></th>
<th>Observed</th>
<th>Bootstrap</th>
<th>Normal-based</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Coef.</td>
<td>Std. Err.</td>
<td>z</td>
</tr>
<tr>
<td>ratio</td>
<td>.6654095</td>
<td>.3156251</td>
<td>2.11</td>
</tr>
</tbody>
</table>

In the above syntax, although we specify `group(pairid)` with `clogit`, it is not the group identifiers of the original `pairid` variable that are used to compute parameter estimates from bootstrap samples. The way `bootstrap` works is that, at each replication, the clusters defined by `doctor` are resampled and the new variable, `uidoctor`, uniquely identifying resampled clusters is created. After that, another new variable uniquely identifying the `(uidoctor, group)` combination is created and renamed to have the same name as the grouping variable, `pairid`. This newly defined grouping variable is then used by `clogit` to obtain the parameter estimates from this bootstrap sample of clusters. After all replications are performed, the original values of the grouping variable are restored.

Technical note

The same logic must be used when running `bootstrap` with commands designed for panel (longitudinal) data that allow specifying the `cluster(clustervar)` option. To ensure that the combination of `(clustervar, panelvar)` values are unique in each of the bootstrap samples, `cluster(clustervar)`, `id-cluster(newclustervar)`, and `group(panelvar)` must be specified with `bootstrap`, and `i(panelvar)` must be used with the main command.

---

Bradley Efron was born in 1938 in Minnesota and studied mathematics and statistics at Caltech and Stanford; he has lived in northern California since 1960. He has worked on empirical Bayes, survival analysis, exponential families, bootstrap and jackknife methods, and confidence intervals, in conjunction with applied work in biostatistics, astronomy, and physics.

Efron is a member of the U.S. National Academy of Sciences and was awarded the U.S. National Medal of Science in 2005. He is by any standards one of the world’s leading statisticians: his work ranges from deep and elegant contributions in theoretical statistics to pathbreaking involvement in a variety of practical applications.
bootstrap stores the following in e():

Scalars
- \( e(N) \): sample size
- \( e(N\_reps) \): number of complete replications
- \( e(N\_misreps) \): number of incomplete replications
- \( e(N\_strata) \): number of strata
- \( e(N\_clust) \): number of clusters
- \( e(k\_eq) \): number of equations in \( e(b) \)
- \( e(k\_exp) \): number of standard expressions
- \( e(k\_eexp) \): number of extended expressions (i.e., \( _b \))
- \( e(k\_extra) \): number of extra equations beyond the original ones from \( e(b) \)
- \( e(level) \): confidence level for bootstrap CIs
- \( e(bs\_version) \): version for bootstrap results
- \( e(rank) \): rank of \( e(V) \)

Macros
- \( e(cmdname) \): command name from command
- \( e(cmd) \): same as \( e(cmdname) \) or bootstrap
- \( e(command) \): command as typed
- \( e(cmdline) \): command as typed
- \( e(prefix) \): bootstrap
- \( e(title) \): title in estimation output
- \( e(strata) \): strata variables
- \( e(cluster) \): cluster variables
- \( e(seed) \): initial random-number seed
- \( e(size) \): from the size(#) option
- \( e(exp#) \): expression for the \#th statistic
- \( e(ties) \): ties, if specified
- \( e(mse) \): mse, if specified
- \( e(vce) \): bootstrap
- \( e(vcetype) \): title used to label Std. Err.
- \( e(properties) \): \( b \ V \)

Matrices
- \( e(b) \): observed statistics
- \( e(b\_bs) \): bootstrap estimates
- \( e(reps) \): number of nonmissing results
- \( e(bias) \): estimated biases
- \( e(se) \): estimated standard errors
- \( e(z0) \): median biases
- \( e(accel) \): estimated accelerations
- \( e(ci\_normal) \): normal-approximation CIs
- \( e(ci\_percentile) \): percentile CIs
- \( e(ci\_bc) \): bias-corrected CIs
- \( e(ci\_bca) \): bias-corrected and accelerated CIs
- \( e(V) \): bootstrap variance–covariance matrix
- \( e(V\_modelbased) \): model-based variance

When \( exp\_list \) is \( _b \), bootstrap will also carry forward most of the results already in \( e() \) from command.

Methods and formulas

Let \( \hat{\theta} \) be the observed value of the statistic, that is, the value of the statistic calculated with the original dataset. Let \( i = 1, 2, \ldots, k \) denote the bootstrap samples, and let \( \hat{\theta}_i \) be the value of the statistic from the \( i \)th bootstrap sample.
When the `mse` option is specified, the standard error is estimated as

\[ \hat{se}_{\text{MSE}} = \left\{ \frac{1}{k} \sum_{i=1}^{k} (\hat{\theta}_i - \hat{\theta})^2 \right\}^{1/2} \]

Otherwise, the standard error is estimated as

\[ \hat{se} = \left\{ \frac{1}{k-1} \sum_{i=1}^{k} (\hat{\theta}_i - \bar{\theta})^2 \right\}^{1/2} \]

where

\[ \bar{\theta} = \frac{1}{k} \sum_{i=1}^{k} \hat{\theta}_i \]

The variance–covariance matrix is similarly computed. The bias is estimated as

\[ \hat{\text{bias}} = \theta - \hat{\theta} \]

Confidence intervals with nominal coverage rates \(1 - \alpha\) are calculated according to the following formulas. The normal-approximation method yields the confidence intervals

\[ [\hat{\theta} - z_{1-\alpha/2} \hat{se}, \hat{\theta} + z_{1-\alpha/2} \hat{se}] \]

where \(z_{1-\alpha/2}\) is the \((1 - \alpha/2)\)th quantile of the standard normal distribution. If the `mse` option is specified, `bootstrap` will report the normal confidence interval using \(\hat{se}_{\text{MSE}}\) instead of \(\hat{se}\). `estat bootstrap` only uses \(\hat{se}\) in the normal confidence interval.

The percentile method yields the confidence intervals

\[ [\theta^{*}_{\alpha/2}, \theta^{*}_{1-\alpha/2}] \]

where \(\theta^{*}_p\) is the \(p\)th quantile (the 100\(p\)th percentile) of the bootstrap distribution \((\hat{\theta}_1, \ldots, \hat{\theta}_k)\).

Let

\[ z_0 = \Phi^{-1}\{\#(\hat{\theta}_i \leq \hat{\theta})/k\} \]

where \#(\(\hat{\theta}_i \leq \hat{\theta}\)) is the number of elements of the bootstrap distribution that are less than or equal to the observed statistic and \(\Phi\) is the standard cumulative normal. \(z_0\) is known as the median bias of \(\hat{\theta}\). When the `ties` option is specified, \(z_0\) is estimated as \(#(\hat{\theta}_i < \hat{\theta}) + #(\hat{\theta}_i = \hat{\theta})/2\), which is the number of elements of the bootstrap distribution that are less than the observed statistic plus half the number of elements that are equal to the observed statistic.

Let

\[ a = \frac{\sum_{i=1}^{n}(\bar{\theta}(\cdot) - \hat{\theta}(i))^3}{6\{\sum_{i=1}^{n}(\bar{\theta}(\cdot) - \hat{\theta}(i))^2\}^{3/2}} \]

where \(\hat{\theta}(i)\) are the leave-one-out (jackknife) estimates of \(\hat{\theta}\) and \(\bar{\theta}(\cdot)\) is their mean. This expression is known as the jackknife estimate of acceleration for \(\hat{\theta}\). Let

\[ p_1 = \Phi\left\{z_0 + \frac{z_0 - z_{1-\alpha/2}}{1 - a(z_0 - z_{1-\alpha/2})}\right\} \]

\[ p_2 = \Phi\left\{z_0 + \frac{z_0 + z_{1-\alpha/2}}{1 - a(z_0 + z_{1-\alpha/2})}\right\} \]
where $z_{1-\alpha/2}$ is the $(1-\alpha/2)$th quantile of the normal distribution. The bias-corrected and accelerated (BC$_{a}$) method yields confidence intervals

$$\left[ \theta^*_{p_1}, \theta^*_{p_2} \right]$$

where $\theta^*_p$ is the $p$th quantile of the bootstrap distribution as defined previously. The bias-corrected (but not accelerated) method is a special case of BC$_{a}$ with $a = 0$.

*This postestimation command is allowed if it may be used after *command.*
Special-interest postestimation command

`estat bootstrap` displays a table of confidence intervals for each statistic from a bootstrap analysis.

Syntax for predict

The syntax of `predict` (and even if `predict` is allowed) following `bootstrap` depends upon the `command` used with `bootstrap`. If `predict` is not allowed, neither is `predictnl`.

Syntax for `estat bootstrap`

```
estat bootstrap [ , options ]
```

<table>

`bc`, `bca`, `normal`, and `percentile` may be used together.

Menu for `estat`

Statistics > Postestimation > Reports and statistics

Options for `estat bootstrap`

- `bc` is the default and displays bias-corrected confidence intervals.
- `bca` displays bias-corrected and accelerated confidence intervals. This option assumes that you also specified the `bca` option on the `bootstrap` prefix command.
- `normal` displays normal approximation confidence intervals.
- `percentile` displays percentile confidence intervals.
- `all` displays all available confidence intervals.
- `noheader` suppresses display of the table header. This option implies `nolegend`.
- `nolegend` suppresses display of the table legend, which identifies the rows of the table with the expressions they represent.
- `verbose` requests that the full table legend be displayed.
Remarks and examples

Example 1

The `estat bootstrap` postestimation command produces a table containing the observed value of the statistic, an estimate of its bias, the bootstrap standard error, and up to four different confidence intervals.

If we were interested merely in getting bootstrap standard errors for the model coefficients, we could use the `bootstrap` prefix with our estimation command. If we were interested in performing a thorough bootstrap analysis of the model coefficients, we could use the `estat bootstrap` postestimation command after fitting the model with the `bootstrap` prefix.

Using example 1 from [R] `bootstrap`, we need many more replications for the confidence interval types other than the normal based, so let’s rerun the estimation command. We will reset the random-number seed—in case we wish to reproduce the results—increase the number of replications, and save the bootstrap distribution as a dataset called `bsauto.dta`.

```stata
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. set seed 1
. bootstrap _b, reps(1000) saving(bsauto) bca: regress mpg weight gear foreign
(output omitted)
. estat bootstrap, all
```

(N) normal confidence interval
(P) percentile confidence interval
(BC) bias-corrected confidence interval
(BCa) bias-corrected and accelerated confidence interval

The estimated standard errors here differ from our previous estimates using only 100 replications by, respectively, 8%, 3%, 11%, and 6%; see example 1 of [R] `bootstrap`. So much for our advice that 50–200 replications are good enough to estimate standard errors. Well, the more replications the better—that advice you should believe.
Which of the methods to compute confidence intervals should we use? If the statistic is unbiased, the percentile ($P$) and bias-corrected ($BC$) methods should give similar results. The bias-corrected confidence interval will be the same as the percentile confidence interval when the observed value of the statistic is equal to the median of the bootstrap distribution. Thus, for unbiased statistics, the two methods should give similar results as the number of replications becomes large. For biased statistics, the bias-corrected method should yield confidence intervals with better coverage probability (closer to the nominal value of 95% or whatever was specified) than the percentile method. For statistics with variances that vary as a function of the parameter of interest, the bias-corrected and accelerated method ($BC_a$) will typically have better coverage probability than the others.

When the bootstrap distribution is approximately normal, all of these methods should give similar confidence intervals as the number of replications becomes large. If we examine the normality of these bootstrap distributions using, say, the `pnorm` command (see [R] diagnostic plots), we see that they closely follow a normal distribution. Thus here, the normal approximation would also be a valid choice. The chief advantage of the normal-approximation method is that it (supposedly) requires fewer replications than the other methods. Of course, it should be used only when the bootstrap distribution exhibits normality.

We can load `bsauto.dta` containing the bootstrap distributions for these coefficients:

```
. use bsauto
  (bootstrap: regress)
. describe *
```

We can now run other commands, such as `pnorm`, on the bootstrap distributions. As with all standard estimation commands, we can use the `bootstrap` command to replay its output table. The default variable names assigned to the statistics in `exp_list` are `_bs_1`, `_bs_2`, ..., and each variable is labeled with the associated expression. The naming convention for the extended expressions `_b` and `_se` is to prepend `_b_` and `_se_`, respectively, onto the name of each element of the coefficient vector. Here the first coefficient is `_b[weight]`, so `bootstrap` named it `_b_weight`.

`depvar` and `indepvars` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

Bootstrap, by, jackknife, rolling, statsby, and xi are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

fweights and iweights are allowed; see [U] 11.1.6 weight.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Description

`boxcox` finds the maximum likelihood estimates of the parameters of the Box–Cox transform, the coefficients on the independent variables, and the standard deviation of the normally distributed errors for a model in which `depvar` is regressed on `indepvars`. You can fit the following models:
### Option Estimates

</tr>
</tbody>
</table>

Any variable to be transformed must be strictly positive.

### Options

- `noconstant`, see [R] estimation options.

```
model(lhsonly | rhsonly | lambda | theta) specifies which of the four models to fit.
```

- `model(lhsonly)` applies the Box–Cox transform to `depvar` only. `model(lhsonly)` is the default.
- `model(rhsonly)` applies the transform to the `indepvars` only.
- `model(lambda)` applies the transform to both `depvar` and `indepvars`, and they are transformed by the same parameter.
- `model(theta)` applies the transform to both `depvar` and `indepvars`, but this time, each side is transformed by a separate parameter.

- `notrans(varlist)` specifies that the variables in `varlist` be included as nontransformed independent variables.

### Reporting

- `level(#)`, see [R] estimation options.

```
lrtest specifies that a likelihood-ratio test of significance be performed and reported for each independent variable.
```

### Maximization

- `nolog` suppresses the iteration log when fitting the full model.
- `nologlr` suppresses the iteration log when fitting the restricted models required by the `lrtest` option.

```
maximize_options: `iterate(#)` and `from(init_specs)`; see [R] maximize.
```

Remarks and examples

Remarks are presented under the following headings:

- Introduction
- Theta model
- Lambda model
- Left-hand-side-only model
- Right-hand-side-only model

Introduction

The Box–Cox transform

\[ y^{(\lambda)} = \frac{y^\lambda - 1}{\lambda} \]

has been widely used in applied data analysis. Box and Cox (1964) developed the transformation and argued that the transformation could make the residuals more closely normal and less heteroskedastic. Cook and Weisberg (1982) discuss the transform in this light. Because the transform embeds several popular functional forms, it has received some attention as a method for testing functional forms, in particular,

\[
y^{(\lambda)} = \begin{cases} 
  y - 1 & \text{if } \lambda = 1 \\
  \ln(y) & \text{if } \lambda = 0 \\
  1 - 1/y & \text{if } \lambda = -1
\end{cases}
\]

Theta model

boxcox obtains the maximum likelihood estimates of the parameters for four different models. The most general of the models, the theta model, is

\[
y_{ij}^{(\theta)} = \beta_0 + \beta_1 x_{1ij}^{(\lambda)} + \beta_2 x_{2ij}^{(\lambda)} + \cdots + \beta_k x_{kij}^{(\lambda)} + \gamma_1 z_{1ij} + \gamma_2 z_{2ij} + \cdots + \gamma_l z_{lij} + \epsilon_j
\]

where \( \epsilon \sim N(0, \sigma^2) \). Here the dependent variable, \( y \), is subject to a Box–Cox transform with parameter \( \theta \). Each of the \( \text{indepvars} \), \( x_1, x_2, \ldots, x_k \), is transformed by a Box–Cox transform with parameter \( \lambda \). The \( z_1, z_2, \ldots, z_l \) specified in the \( \text{notrans()} \) option are independent variables that are not transformed.

Box and Cox (1964) argued that this transformation would leave behind residuals that more closely follow a normal distribution than those produced by a simple linear regression model. Bear in mind that the normality of \( \epsilon \) is assumed and that boxcox obtains maximum likelihood estimates of the \( k + l + 4 \) parameters under this assumption. boxcox does not choose \( \lambda \) and \( \theta \) so that the residuals are approximately normally distributed. If you are interested in this type of transformation to normality, see the official Stata commands \texttt{lnskew0} and \texttt{bcskew0} in [R] \texttt{lnskew0}. However, those commands work on a more restrictive model in which none of the independent variables is transformed.
Example 1

Below we fit a theta model to a nonrepresentative extract of the Second National Health and Nutrition Examination Survey (NHANES II) dataset discussed in McDowell et al. (1981).

We model individual-level diastolic blood pressure (bpdiast) as a function of the transformed variables body mass index (bmi) and cholesterol level (tcresult) and of the untransformed variables age (age) and sex (sex).

```
. use http://www.stata-press.com/data/r13/nhanes2
. boxcox bpdiast bmi tcresult, notrans(age sex) model(theta) lrtest

Test Restricted
Ho: log likelihood chi2 Prob > chi2

- theta=lambda = -1 -40162.898 775.82 0.000
- theta=lambda = 0 -39790.945 31.92 0.000
- theta=lambda = 1 -39928.606 307.24 0.000

The output is composed of the iteration logs and three distinct tables. The first table contains a standard header for a maximum likelihood estimator and a standard output table for the Box–Cox transform parameters. The second table contains the estimates of the scale-variant parameters. The third table contains the output from likelihood-ratio tests on three standard functional form specifications.

The right-hand-side and the left-hand-side transformations each add to the regression fit at the 1% significance level and are both positive but less than 1. All the variables have significant impacts on diastolic blood pressure, bpdiast. As expected, the transformed variables—the body mass index, bmi, and cholesterol level, tcresult—contribute to higher blood pressure. The last output table shows that the linear, multiplicative inverse, and log specifications are strongly rejected.

Technical note

Spitzer (1984) showed that the Wald tests of the joint significance of the coefficients of the right-hand-side variables, either transformed or untransformed, are not invariant to changes in the scale of the transformed dependent variable. Davidson and MacKinnon (1993) also discuss this point. This problem demonstrates that Wald statistics can be manipulated in nonlinear models. Lafontaine and White (1986) analyze this problem numerically, and Phillips and Park (1988) analyze it by using Edgeworth expansions. See Drukker (2000b) for a more detailed discussion of this issue. Because the parameter estimates and their Wald tests are not scale invariant, no Wald tests or confidence intervals are reported for these parameters. However, when the lrtest option is specified, likelihood-ratio tests are performed and reported. Schleselman (1971) showed that, if a constant is included in the model, the parameter estimates of the Box–Cox transforms are scale invariant. For this reason, we strongly recommend that you not use the noconstant option.

The lrtest option does not perform a likelihood-ratio test on the constant, so no value for this statistic is reported. Unless the data are properly scaled, the restricted model does not often converge. For this reason, no likelihood-ratio test on the constant is performed by the lrtest option. However, if you have a special interest in performing this test, you can do so by fitting the constrained model separately. If problems with convergence are encountered, rescaling the data by their means may help.
Lambda model

A less general model than the one above is called the lambda model. It specifies that the same parameter be used in both the left-hand-side and right-hand-side transformations. Specifically,

$$y_j^{(\lambda)} = \beta_0 + \beta_1 x_{1j}^{(\lambda)} + \beta_2 x_{2j}^{(\lambda)} + \cdots + \beta_k x_{kj}^{(\lambda)} + \gamma_1 z_{1j} + \gamma_2 z_{2j} + \cdots + \gamma_l z_{lj} + \epsilon_j$$

where $\epsilon \sim N(0, \sigma^2)$. Here the depvar variable, $y$, and each of the indepvars, $x_1, x_2, \ldots, x_k$, is transformed by a Box–Cox transform with the common parameter $\lambda$. Again the $z_1, z_2, \ldots, z_l$ are independent variables that are not transformed.

Left-hand-side-only model

Even more restrictive than a common transformation parameter is transforming the dependent variable only. Because the dependent variable is on the left-hand side of the equation, this model is known as the lhsonly model. Here you are estimating the parameters of the model

$$y_j^{(\theta)} = \beta_0 + \beta_1 x_{1j} + \beta_2 x_{2j} + \cdots + \beta_k x_{kj} + \epsilon_j$$

where $\epsilon \sim N(0, \sigma^2)$. Here only the depvar, $y$, is transformed by a Box–Cox transform with the parameter $\theta$. 
Example 2

In this example, we model the transform of diastolic blood pressure as a linear combination of the untransformed body mass index, cholesterol level, age, and sex.

```
. boxcox bpdiast bmi tcsresult age sex, model(lhsonly) lrtest nolog nologlr
```

</table>
```

The maximum likelihood estimate of the transformation parameter for this model is positive and significant. Once again, all the scale-variant parameters are significant, and we find a positive impact of body mass index (bmi) and cholesterol levels (tcsresult) on the transformed diastolic blood pressure (bpdiast). This model rejects the linear, multiplicative inverse, and log specifications.

Right-hand-side-only model

The fourth model leaves the depvar alone and transforms a subset of the indepvars using the parameter $\lambda$. This is the rhsonly model. In this model, the depvar, $y$, is given by

$$ y_j = \beta_0 + \beta_1 x_{1j}^{(\lambda)} + \beta_2 x_{2j}^{(\lambda)} + \cdots + \beta_k x_{kj}^{(\lambda)} + \gamma_1 z_{1j} + \gamma_2 z_{2j} + \cdots + \gamma_l z_{lj} + \epsilon_j $$

where $\epsilon \sim N(0, \sigma^2)$. Here each of the indepvars, $x_1, x_2, \ldots, x_k$, is transformed by a Box–Cox transform with the parameter $\lambda$. Again the $z_1, z_2, \ldots, z_l$ are independent variables that are not transformed.
Example 3

Now we consider a rhsonly model in which the regressors sex and age are not transformed.

```
. boxcox bpdiast bmi tcrestult, notrans(sex age) model(rhsonly) lrtest nolog > nologlr
Fitting full model
Fitting comparison models for LR tests

The maximum likelihood estimate of the transformation parameter in this model is positive and significant at the 1% level. The transformed bmi coefficient behaves as expected, and the remaining scale-variant parameters are significant at the 1% level. This model rejects the multiplicative inverse and log specifications strongly. However, we cannot reject the hypothesis that the model is linear.
Stored results

boxcox stores the following in e():

Scalars

- $e(N)$: number of observations
- $e(ll)$: log likelihood
- $e(chi2)$: LR statistic of full vs. comparison
- $e(df_m)$: full model degrees of freedom
- $e(ll0)$: log likelihood of the restricted model
- $e(df_r)$: restricted model degrees of freedom
- $e(ll_{t1})$: log likelihood of model $\lambda=\theta=1$
- $e(chi2_{t1})$: LR of $\lambda=\theta=1$ vs. full model
- $e(p_{t1})$: $p$-value of $\lambda=\theta=1$ vs. full model
- $e(ll_{tm1})$: log likelihood of model $\lambda=\theta=-1$
- $e(chi2_{tm1})$: LR of $\lambda=\theta=-1$ vs. full model
- $e(p_{tm1})$: $p$-value of $\lambda=\theta=-1$ vs. full model
- $e(ll_{t0})$: log likelihood of model $\lambda=\theta=0$
- $e(chi2_{t0})$: LR of $\lambda=\theta=0$ vs. full model
- $e(p_{t0})$: $p$-value of $\lambda=\theta=0$ vs. full model
- $e(rank)$: rank of $e(V)$
- $e(ic)$: number of iterations
- $e(rc)$: return code

Macros

- $e(cmd)$: boxcox
- $e(cmdline)$: command as typed
- $e(depvar)$: name of dependent variable
- $e(model)$: lhsonly, rhsonly, lambda, or theta
- $e(wtype)$: weight type
- $e(wexp)$: weight expression
- $e(ntrans)$: yes if nontransformed indepvars
- $e(chi2type)$: LR; type of model $\chi^2$ test
- $e(lrtest)$: lrtest, if requested
- $e(properties)$: b V
- $e(predict)$: program used to implement predict
- $e(marginsnotok)$: predictions disallowed by margins

Matrices

- $e(b)$: coefficient vector
- $e(V)$: variance–covariance matrix of the estimators (see note below)
- $e(pm)$: $p$-values for LR tests on indepvars
- $e(df)$: degrees of freedom of LR tests on indepvars
- $e(chi2m)$: LR statistics for tests on indepvars

Functions

- $e(sample)$: marks estimation sample

$e(V)$ contains all zeros, except for the elements that correspond to the parameters of the Box–Cox transform.
Methods and formulas

In the internal computations,

\[
y^{(\lambda)}(\lambda) = \begin{cases} \frac{y^{\lambda-1}}{\lambda} & \text{if } |\lambda| > 10^{-10} \\ \ln(y) & \text{otherwise} \end{cases}
\]

The unconcentrated log likelihood for the theta model is

\[
\ln L = \left(\frac{-N}{2}\right) \left\{ \ln(2\pi) + \ln(\sigma^2) \right\} + (\theta - 1) \sum_{i=1}^{N} \ln(y_i) - \left(\frac{1}{2\sigma^2}\right) \text{SSR}
\]

where

\[
\text{SSR} = \sum_{i=1}^{N} (y_i^{(\theta)} - \beta_0 + \beta_1 x_i^{(\lambda)} + \beta_2 x_i^{(\lambda)} + \cdots + \beta_k x_i^{(\lambda)} + \gamma_1 z_i + \gamma_2 z_i + \cdots + \gamma_l z_i)^2
\]

Writing the SSR in matrix form,

\[
\text{SSR} = (y^{(\theta)} - X^{(\lambda)}b' - Zg')'(y^{(\theta)} - X^{(\lambda)}b' - Zg')
\]

where \(y^{(\theta)}\) is an \(N \times 1\) vector of elementwise transformed data, \(X^{(\lambda)}\) is an \(N \times k\) matrix of elementwise transformed data, \(Z\) is an \(N \times l\) matrix of untransformed data, \(b\) is a \(1 \times k\) vector of coefficients, and \(g\) is a \(1 \times l\) vector of coefficients. Letting

\[
W_\lambda = \begin{pmatrix} X^{(\lambda)} & Z \end{pmatrix}
\]

be the horizontal concatenation of \(X^{(\lambda)}\) and \(Z\) and

\[
d' = \begin{pmatrix} b' \\ g' \end{pmatrix}
\]

be the vertical concatenation of the coefficients yields

\[
\text{SSR} = (y^{(\theta)} - W_\lambda d')'(y^{(\theta)} - W_\lambda d')
\]

For given values of \(\lambda\) and \(\theta\), the solutions for \(d'\) and \(\sigma^2\) are

\[
\hat{d}' = (W'_\lambda W_\lambda)^{-1} W'_\lambda y^{(\theta)}
\]

and

\[
\hat{\sigma}^2 = \frac{1}{N} (y^{(\theta)} - W_\lambda \hat{d}')' (y^{(\theta)} - W_\lambda \hat{d}')
\]

Substituting these solutions into the log-likelihood function yields the concentrated log-likelihood function

\[
\ln L_c = \left(\frac{-N}{2}\right) \left\{ \ln(2\pi) + 1 + \ln(\hat{\sigma}^2) \right\} + (\theta - 1) \sum_{i=1}^{N} \ln(y_i)
\]
Similar calculations yield the concentrated log-likelihood function for the lambda model,

\[
\ln L_c = \left( -\frac{N}{2} \right) \left\{ \ln(2\pi) + 1 + \ln(\hat{\sigma}^2) \right\} + (\lambda - 1) \sum_{i=1}^{N} \ln(y_i)
\]

the lhsonly model,

\[
\ln L_c = \left( -\frac{N}{2} \right) \left\{ \ln(2\pi) + 1 + \ln(\hat{\sigma}^2) \right\} + (\theta - 1) \sum_{i=1}^{N} \ln(y_i)
\]

and the rhsonly model,

\[
\ln L_c = \left( -\frac{N}{2} \right) \left\{ \ln(2\pi) + 1 + \ln(\hat{\sigma}^2) \right\}
\]

where \(\hat{\sigma}^2\) is specific to each model and is defined analogously to that in the theta model.

</table>

*Inference is valid only for hypotheses concerning $\lambda$ and $\theta$.  

### Syntax for predict

```
predict [type] newvar [if] [in] [, statistic options]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>yhat</code></td>
<td>predicted value of $y$; the default</td>
</tr>
<tr>
<td><code>residuals</code></td>
<td>residuals</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>smearing</code></td>
<td>compute statistic using smearing method; the default</td>
</tr>
<tr>
<td><code>btransform</code></td>
<td>compute statistic using back-transform method</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ... if wanted` only for the estimation sample.
Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

yhat, the default, calculates the predicted value of the dependent variable.

residuals calculates the residuals, that is, the observed value minus the predicted value.

smearing calculates the statistics yhat and residuals using the smearing method proposed by Duan (1983) (see Methods and formulas for a description of this method). smearing is the default.

btransform calculates the statistics yhat and residuals using the back-transform method (see Methods and formulas for a description of this method).

Remarks and examples

Below we present two examples that illustrate how to use the smearing and btransform options.

Example 1: Predictions with the smearing option

In this example, we calculate the predicted values of diastolic blood pressure, bpdiast, that arise from the theta model calculated in example 1 of [R] boxcox.

```
. use http://www.stata-press.com/data/r13/nhanes2
. boxcox bpdiast bmi tcresult, notrans(age sex) model(theta) lrtest
(output omitted)
. predict yhat
(statistic yhat and option smearing are assumed)
```

In the expression above, yhat is the name we gave to the estimates of the conditional expectation. Given that we did not specify any statistic or option, the corresponding defaults yhat and smearing were assumed.

As the summary table below illustrates, the mean of the dependent variable is close to the mean of the predicted value yhat. This indicates that the theta model does a good job approximating the true value of diastolic blood pressure, bpdiast.

```
. summarize bpdiast yhat

  Variable |     Obs    Mean   Std. Dev.     Min    Max
-----------|---------|---------|---------|--------|--------
bpdiast    | 10351   81.715  12.92722      35    150
yhat       | 10351   81.71406  5.983486   66.93709  110.5283
```
Similarly, we could have asked that residuals be calculated. Here we again use the default `smearing` option:

```
.predict resid, residuals
(option smearing assumed to compute residuals)
```

**Example 2: Predictions with the btransform option**

In this example, we illustrate the tradeoffs involved by using the `btransform` option as opposed to the default `smearing` option. Continuing with example 1, we compute the predicted values using the back-transform method.

```
.predict yhatb, btransform
(statistic yhat assumed)
```

We now compute the predicted values using the `smearing` option and summarize both computations.

```
.predict yhats
(statistic yhat and option smearing are assumed)
.predict yhatb
```

```
 summarize bpdiast yhats yhatb
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>bpdiast</td>
<td>10351</td>
<td>81.715</td>
<td>12.92722</td>
<td>35</td>
<td>150</td>
</tr>
<tr>
<td>yhats</td>
<td>10351</td>
<td>81.71406</td>
<td>5.983486</td>
<td>66.93709</td>
<td>110.5283</td>
</tr>
<tr>
<td>yhatb</td>
<td>10351</td>
<td>81.08018</td>
<td>5.95549</td>
<td>66.37479</td>
<td>109.7671</td>
</tr>
</tbody>
</table>

As can be seen from the mean and the standard deviation of the summary table, the predicted values using the back-transform method give biased estimates but are less variable than those coming from the smearing method. However, the efficiency loss is small compared with the bias reduction.

**Technical note**

boxcox estimates variances only for the \( \lambda \) and \( \theta \) parameters (see the technical note in [R] boxcox), so the extent to which postestimation commands can be used following boxcox is limited. Formulas used in `lincom`, `nlcom`, `test`, and `testnl` are dependent on the estimated variances. Therefore, the use of these commands is limited and generally applicable only to inferences on the \( \lambda \) and \( \theta \) coefficients.

**Methods and formulas**

The computation of the expected value of the dependent variable conditional on the regressors for the Box–Cox model does not follow the logic of the standard linear regression model because the random disturbance does not vanish from the conditional expectation and must be accounted for. To show this, we will revisit the `lhsonly` model described by

\[
y^{(\lambda)}_j = \beta_0 + \beta_1 x_{1j} + \beta_2 x_{2j} + \cdots + \beta_{(k-1)} x_{(k-1)j} + \epsilon_j
\]

where

\[
y^{(\lambda)} = \frac{y^\lambda - 1}{\lambda}
\]
and

\[
y^{(\lambda)} = \begin{cases} 
  y - 1 & \text{if } \lambda = 1 \\
  \ln(y) & \text{if } \lambda = 0 \\
  1 - 1/y & \text{if } \lambda = -1
\end{cases}
\]

For the presentation below, let \( y^{(\lambda)} \) be an \( N \times 1 \) vector of elementwise transformed data, \( X \) be an \( N \times k \) matrix of regressors, \( \beta \) be a \( k \times 1 \) vector of parameters, and \( \iota \) be an \( n \times 1 \) vector of ones.

If we were interested in \( E(y^{(\lambda)}|X) \), then the conventional logic would follow, and we would obtain predictions as \( \widehat{y}^{(\lambda)} = X\widehat{\beta} \), where \( \widehat{\beta} \) is the estimate of \( \beta \). However, to estimate the conditional expectation of \( y \), we need to isolate it on the left-hand side of the model. In the case of the \texttt{1hsonly} model, this yields

\[
y = \left\{ \lambda (X\widehat{\beta} + \epsilon) + \iota \right\}^{1/\lambda}
\]

The conditional expectation is then defined by

\[
E(y|X) = \int \{\lambda (X\beta + \epsilon) + \iota\}^{1/\lambda} \, dF(\epsilon|X)
\]

In the expression above, \( dF(\epsilon|X) \) corresponds to the cdf of \( \epsilon \) conditional on the regressors. It is also clear that the random disturbance does not vanish.

To address this issue, the default methodology used by \texttt{predict} computes this integral using the smearing method proposed by Duan (1983) to implement a two-step estimator, as was suggested by Abrevaya (2002).

In the first step, we get an estimate for \( \epsilon \) defined as

\[
\widehat{\epsilon} = y^{(\widehat{\lambda})} - X\widehat{\beta}
\]

In the second step, for each \( j \) we compute our predicted values as the sum:

\[
\widehat{y}_j = \frac{1}{N} \sum_{i=1}^{N} \{\lambda (x_{j\,i}\widehat{\beta} + \widehat{\epsilon}_i) + 1\}^{1/\widehat{\lambda}}
\]

In the expression above, \( x_{j\,i} \) is the \( j \)th row of the matrix \( X \) (in other words, the values of the covariates for individual \( j \)), and \( \widehat{\epsilon}_i \) is the residual for individual \( i \). The result of this summation gives us the conditional expectation of the dependent variable for individual \( j \). Given that this operation is performed for each individual \( j \), the methodology is computationally intensive.

The back-transform method can be understood as a naïve estimate that disregards the random disturbance. The predictions using this approach are given by

\[
\widehat{y}_j = \left( \lambda x_{j\,\widehat{\beta}} + 1 \right)^{1/\widehat{\lambda}}
\]

[R] boxcox — Box–Cox regression models

[U] 20 Estimation and postestimation commands
Syntax

brier outcomevar forecastvar [if] [in] [, group(#)]

by is allowed; see [D] by.

Menu

Statistics > Epidemiology and related > Other > Brier score decomposition

Description

brier computes the Yates, Sanders, and Murphy decompositions of the Brier Mean Probability Score. outcomevar contains 0/1 values reflecting the actual outcome of the experiment, and forecastvar contains the corresponding probabilities as predicted by, say, logit, probit, or a human forecaster.

Option

Main

group(#) specifies the number of groups that will be used to compute the decomposition. group(10) is the default.

Remarks and examples

You have a binary (0/1) response and a formula that predicts the corresponding probabilities of having observed a positive outcome (1). If the probabilities were obtained from logistic regression, there are many methods that assess goodness of fit (see, for instance, [R] estat gof). However, the probabilities might be computed from a published formula or from a model fit on another sample, both completely unrelated to the data at hand, or perhaps the forecasts are not from a formula at all. In any case, you now have a test dataset consisting of the forecast probabilities and observed outcomes. Your test dataset might, for instance, record predictions made by a meteorologist on the probability of rain along with a variable recording whether it actually rained.

The Brier score is an aggregate measure of disagreement between the observed outcome and a prediction—the average squared error difference. The Brier score decomposition is a partition of the Brier score into components that suggest reasons for discrepancy. These reasons fall roughly into three groups: 1) lack of overall calibration between the average predicted probability and the actual probability of the event in your data, 2) misfit of the data in groups defined within your sample, and 3) inability to match actual 0 and 1 responses.
Problem 1 refers to simply overstating or understating the probabilities.

Problem 2 refers to what is standardly called a goodness-of-fit test: the data are grouped, and the predictions for the group are compared with the outcomes.

Problem 3 refers to an individual-level measure of fit. Imagine that the grouped outcomes are predicted on average correctly but that within the group, the outcomes are poorly predicted.

Using logit or probit analysis to fit your data will guarantee that there is no lack of fit due to problem 1, and a good model fitter will be able to avoid problem 2. Problem 3 is inherent in any prediction exercise.

Example 1

We have data on the outcomes of 20 basketball games (win) and the probability of victory predicted by a local pundit (for).

```
. use http://www.stata-press.com/data/r13/bball
. summarize win for

Variable | Obs   | Mean  | Std. Dev. | Min  | Max
---------|-------|--------|-----------|------|-----
      win | 20    | .65    | .4893605  | 0    | 1
     for  | 20    | .4785  | .2147526  | .15  | .9

. brier win for, group(5)

Mean probability of outcome 0.6500
of forecast 0.4785
Correlation 0.5907
ROC area 0.8791  p = 0.0030
Brier score 0.1828
Spiegelhalter’s z-statistic -0.6339  p = 0.7369
Sanders-modified Brier score 0.1861
Sanders resolution 0.1400
Outcome index variance 0.2275
Murphy resolution 0.0875
Reliability-in-the-small 0.0461
Forecast variance 0.0438
Excess forecast variance 0.0285
Minimum forecast variance 0.0153
Reliability-in-the-large 0.0294
2*Forecast-Outcome-Covar 0.1179
```

The mean probabilities of forecast and outcome are simply the mean of the predicted probabilities and the actual outcomes (wins/losses). The correlation is the product-moment correlation between them.

The Brier score measures the total difference between the event (winning) and the forecast probability of that event as an average squared difference. As a benchmark, a perfect forecaster would have a Brier score of 0, a perfect misforecaster (predicts probability of win is 1 when loses and 0 when wins) would have a Brier score of 1, and a fence-sitter (forecasts every game as 50/50) would have a Brier score of 0.25. Our pundit is doing reasonably well.

Spiegelhalter’s z statistic is a standard normal test statistic for testing whether an individual Brier score is extreme. The ROC area is the area under the receiver operating curve, and the associated test is a test of whether it is greater than 0.5. The more accurate the forecast probabilities, the larger the ROC area.

The Sanders-modified Brier score measures the difference between a grouped forecast measure and the event, where the data are grouped by sorting the sample on the forecast and dividing it into
approximately equally sized groups. The difference between the modified and the unmodified score is typically minimal. For this and the other statistics that require grouping—the Sanders and Murphy resolutions and reliability-in-the-small—to be well-defined, group boundaries are chosen so as not to allocate observations with the same forecast probability to different groups. This task is done by grouping on the forecast using \texttt{xtile}, \texttt{n(\#)}, with \# being the number of groups; see \cite{D} \texttt{pctile}.

The Sanders resolution measures error that arises from statistical considerations in evaluating the forecast for a group. A group with all positive or all negative outcomes would have a Sanders resolution of 0; it would most certainly be feasible to predict exactly what happened to each member of the group. If the group had 40% positive responses, on the other hand, a forecast that assigned \( p = 0.4 \) to each member of the group would be a good one, and yet, there would be “errors” in the squared difference sense. The “error” would be \((1 - 0.4)^2\) or \((0 - 0.4)^2\) for each member. The Sanders resolution is the average across groups of such “expected” errors. The 0.1400 value in our data from an overall Brier score of 0.1828 or 0.1861 suggests that a substantial portion of the “error” in our data is inherent.

Outcome index variance is just the variance of the outcome variable. This is the expected value of the Brier score if all the forecast probabilities were merely the average observed outcome. Remember that a fence-sitter has an expected Brier score of 0.25; a smarter fence sitter (who would guess \( p = 0.65 \) for these data) would have a Brier score of 0.2275.

The Murphy resolution measures the variation in the average outcomes across groups. If all groups have the same frequency of positive outcomes, little information in any forecast is possible, and the Murphy resolution is 0. If groups differ markedly, the Murphy resolution is as large as 0.25. The 0.0875 means that there is some variation but not a lot, and 0.0875 is probably higher than in most real cases. If you had groups in your data that varied between 40% and 60% positive outcomes, the Murphy resolution would be 0.01; between 30% and 70%, it would be 0.04.

Reliability-in-the-small measures the error that comes from the average forecast within group not measuring the average outcome within group—a classical goodness-of-fit measure, with 0 meaning a perfect fit and 1 meaning a complete lack of fit. The calculated value of 0.0461 shows some amount of lack of fit. Remember, the number is squared, and we are saying that probabilities could be just more than \( \sqrt{0.0461} = 0.215 \) or 21.5% off.

Forecast variance measures the amount of discrimination being attempted—that is, the variation in the forecasted probabilities. A small number indicates a fence-sitter making constant predictions. If the forecasts were from a logistic regression model, forecast variance would tend to increase with the amount of information available. Our pundit shows considerable forecast variance of 0.0438 (standard deviation \( \sqrt{0.0438} = 0.2093 \)), which is in line with the reliability-in-the-small, suggesting that the forecaster is attempting as much variation as is available in these data.

Excess forecast variance is the amount of actual forecast variance over a theoretical minimum. The theoretical minimum—called the minimum forecast variance—corresponds to forecasts of \( p_0 \) for observations ultimately observed to be negative responses and \( p_1 \) for observations ultimately observed to be positive outcomes. Moreover, \( p_0 \) and \( p_1 \) are set to the average forecasts made for the ultimate negative and positive outcomes. These predictions would be just as good as the predictions the forecaster did make, and any variation in the actual forecast probabilities above this is useless. If this number is large, above 1%–2%, then the forecaster may be attempting more than is possible. The 0.0285 in our data suggests this possibility.

Reliability-in-the-large measures the discrepancy between the mean forecast and the observed fraction of positive outcomes. This discrepancy will be 0 for forecasts made by most statistical models—at least when measured on the same sample used for estimation—because they, by design, reproduce sample means. For our human pundit, the 0.0294 says that there is a \( \sqrt{0.0294} \), or 17-percentage-point, difference. (This difference can also be found by calculating the difference in the
averages of the observed outcomes and forecast probabilities: $0.65 - 0.4785 = 0.17$.) That difference, however, is not significant, as we would see if we typed `ttest win=for; see [R] ttest`. If these data were larger and the bias persisted, this difference would be a critical shortcoming of the forecast.

Twice the forecast-outcome covariance is a measure of how accurately the forecast corresponds to the outcome. The concept is similar to that of $R$-squared in linear regression.

Stored results

`brier` stores the following in `r()`:

Scalars

- `r(p_roc)` significance of ROC area
- `r(roc_area)` ROC area
- `r(z)` Spiegelhalter’s $z$ statistic
- `r(p)` significance of $z$ statistic
- `r(brier)` Brier score
- `r(brier_s)` Sanders-modified Brier score
- `r(sanders)` Sanders resolution
- `r(oiv)` outcome index variance
- `r(murphy)` Murphy resolution
- `r(relinsm)` reliability-in-the-small
- `r(Var_f)` forecast variance
- `r(Var_fex)` excess forecast variance
- `r(Var_fmin)` minimum forecast variance
- `r(relinla)` reliability-in-the-large
- `r(cov_2f)` $2 \times$ forecast-outcome-covariance

Methods and formulas

See Wilks (2011) or Schmidt and Griffith (2005) for a discussion of the Brier score.

Let $d_j$, $j = 1,\ldots,N$, be the observed outcomes with $d_j = 0$ or $d_j = 1$, and let $f_j$ be the corresponding forecasted probabilities that $d_j$ is 1, $0 \leq f_j \leq 1$. Assume that the data are ordered so that $f_{j+1} \geq f_j$ (`brier` sorts the data to obtain this order). Divide the data into $K$ nearly equally sized groups, with group 1 containing observations 1 through $j_2 - 1$, group 2 containing observations $j_2$ through $j_3 - 1$, and so on.

Define

- $\bar{f}_0 =$ average $f_j$ among $d_j = 0$
- $\bar{f}_1 =$ average $f_j$ among $d_j = 1$
- $\bar{f} =$ average $f_j$
- $\bar{d} =$ average $d_j$
- $\tilde{f}_k =$ average $f_j$ in group $k$
- $\tilde{d}_k =$ average $d_j$ in group $k$
- $\tilde{n}_k =$ number of observations in group $k$

The Brier score is $\sum_j (d_j - f_j)^2 / N$.

The Sanders-modified Brier score is $\sum_j (d_j - \tilde{f}_{k(j)})^2 / N$.

Let $p_j$ denote the true but unknown probability that $d_j = 1$. Under the null hypothesis that $p_j = f_j$ for all $j$, Spiegelhalter (1986) determined that the expectation and variance of the Brier score is given by the following:
\[ E(\text{Brier}) = \frac{1}{N} \sum_{j=1}^{N} f_j(1 - f_j) \]

\[ \text{Var}(\text{Brier}) = \frac{1}{N^2} \sum_{j=1}^{N} f_j(1 - f_j)(1 - 2f_j)^2 \]

Denoting the observed value of the Brier score by \( O(\text{Brier}) \), Spiegelhalter’s \( z \) statistic is given by

\[ Z = \frac{O(\text{Brier}) - E(\text{Brier})}{\sqrt{\text{Var}(\text{Brier})}} \]

The corresponding \( p \)-value is given by the upper-tail probability of \( Z \) under the standard normal distribution.

The area under the ROC curve is estimated by applying the trapezoidal rule to the empirical ROC curve. This area is Wilcoxon’s test statistic, so the corresponding \( p \)-value is just that of a one-sided Wilcoxon test of the null hypothesis that the distribution of predictions is constant across the two outcomes.

The Sanders resolution is \( \sum_k \tilde{n}_k \{ \tilde{d}_k(1 - \tilde{d}_k) \} / N \).

The outcome index variance is \( \tilde{d}(1 - \tilde{d}) \).

The Murphy resolution is \( \sum_k \tilde{n}_k (\tilde{d}_k - \bar{d})^2 / N \).

Reliability-in-the-small is \( \sum_k \tilde{n}_k (\tilde{a}_k - \tilde{f}_k)^2 / N \).

The forecast variance is \( \sum_j (f_j - \bar{f})^2 / N \).

The minimum forecast variance is \( \{ \sum_{j \in F} (f_j - \bar{f}_0)^2 + \sum_{j \in S} (f_j - \bar{f}_1)^2 \} / N \), where \( F \) is the set of observations for which \( d_j = 0 \) and \( S \) is the complemet.

The excess forecast variance is the difference between the forecast variance and the minimum forecast variance.

Reliability-in-the-large is \( (\bar{f} - \bar{d})^2 \).

Twice the outcome covariance is \( 2(\bar{f}_1 - \bar{f}_0)\bar{d}(1 - \bar{d}) \).

Glenn Wilson Brier (1913–1998) was an American meteorological statistician who, after obtaining degrees in physics and statistics, was for many years head of meteorological statistics at the U.S. Weather Bureau in Washington, DC. In the latter part of his career, he was associated with Colorado State University. Brier worked especially on verification and evaluation of predictions and forecasts, statistical decision making, the statistical theory of turbulence, the analysis of weather modification experiments, and the application of permutation techniques.
Acknowledgment

We thank Richard Goldstein for his contributions to this improved version of `brier`.

\texttt{idcluster(newvar)} & create new cluster ID variable \\
\texttt{weight(varname)} & replace \textit{varname} with frequency weights \\
\end{tabular}

Menu

Statistics > Resampling > Draw bootstrap sample

Description

\texttt{bsample} draws bootstrap samples (random samples with replacement) from the data in memory. \textit{exp} specifies the size of the sample, which must be less than or equal to the number of sampling units in the data. The observed number of units is the default when \textit{exp} is not specified.

For bootstrap sampling of the observations, \textit{exp} must be less than or equal to \texttt{N} (the number of observations in the data; see [U] 13.4 System variables (_variables)).

For stratified bootstrap sampling, \textit{exp} must be less than or equal to \texttt{N} within the strata identified by the \texttt{strata()} option.

For clustered bootstrap sampling, \textit{exp} must be less than or equal to \texttt{N_c} (the number of clusters identified by the \texttt{cluster()} option).

For stratified bootstrap sampling of clusters, \textit{exp} must be less than or equal to \texttt{N_c} within the strata identified by the \texttt{strata()} option.

Observations that do not meet the optional \texttt{if} and \texttt{in} criteria are dropped (not sampled).

Options

\texttt{strata(varlist)} specifies the variables identifying strata. If \texttt{strata()} is specified, bootstrap samples are selected within each stratum.

\texttt{cluster(varlist)} specifies the variables identifying resampling clusters. If \texttt{cluster()} is specified, the sample drawn during each replication is a bootstrap sample of clusters.
idcluster(newvar) creates a new variable containing a unique identifier for each resampled cluster. weight(varname) specifies a variable in which the sampling frequencies will be placed. varname must be an existing variable, which will be replaced. After bsample, varname can be used as an fweight in any Stata command that accepts fweights, which can speed up resampling for commands like regress and summarize. This option cannot be combined with idcluster(). By default, bsample replaces the data in memory with the sampled observations; however, specifying the weight() option causes only the specified varname to be changed.

Remarks and examples

Below is a series of examples illustrating how bsample is used with various sampling schemes.

Example 1: Bootstrap sampling

We have data on the characteristics of hospital patients and wish to draw a bootstrap sample of 200 patients. We type

```
. use http://www.stata-press.com/data/r13/bsample1
. bsample 200
. count
   200
```

Example 2: Stratified samples with equal sizes

Among the variables in our dataset is female, an indicator for the female patients. To get a bootstrap sample of 200 female patients and 200 male patients, we type

```
. use http://www.stata-press.com/data/r13/bsample1, clear
. bsample 200, strata(female)
. tabulate female

<table>
<thead>
<tr>
<th>female</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>200</td>
<td>50.00</td>
<td>50.00</td>
</tr>
<tr>
<td>female</td>
<td>200</td>
<td>50.00</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>400</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>
```
Example 3: Stratified samples with unequal sizes

To sample 300 females and 200 males, we must generate a variable that is 300 for females and 200 for males and then use this variable in `exp` when we call `bsample`.

```
. use http://www.stata-press.com/data/r13/bsample1, clear
. generate nsamp = cond(female, 300, 200)
. bsample nsamp, strata(female)
. tabulate female
```

<table>
<thead>
<tr>
<th></th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>200</td>
<td>40.00</td>
<td>40.00</td>
</tr>
<tr>
<td>female</td>
<td>300</td>
<td>60.00</td>
<td>100.00</td>
</tr>
<tr>
<td><strong>Total</strong></td>
<td><strong>500</strong></td>
<td><strong>100.00</strong></td>
<td></td>
</tr>
</tbody>
</table>

Example 4: Stratified samples with proportional sizes

Our original dataset has 2,392 males and 3,418 females.

```
. use http://www.stata-press.com/data/r13/bsample1, clear
. tabulate female
```

<table>
<thead>
<tr>
<th></th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>2,392</td>
<td>41.17</td>
<td>41.17</td>
</tr>
<tr>
<td>female</td>
<td>3,418</td>
<td>58.83</td>
<td>100.00</td>
</tr>
<tr>
<td><strong>Total</strong></td>
<td><strong>5,810</strong></td>
<td><strong>100.00</strong></td>
<td></td>
</tr>
</tbody>
</table>

To sample 10% from females and males, we type

```
. bsample round(0.1*_{N}), strata(female)
```

`bsample` requires that the specified size of the sample be an integer, so we use the `round()` function to obtain the nearest integer to $0.1 \times 2392$ and $0.1 \times 3418$. Our sample now has 239 males and 342 females:

```
. tabulate female
```

<table>
<thead>
<tr>
<th></th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>239</td>
<td>41.14</td>
<td>41.14</td>
</tr>
<tr>
<td>female</td>
<td>342</td>
<td>58.86</td>
<td>100.00</td>
</tr>
<tr>
<td><strong>Total</strong></td>
<td><strong>581</strong></td>
<td><strong>100.00</strong></td>
<td></td>
</tr>
</tbody>
</table>

Example 5: Samples satisfying a condition

For a bootstrap sample of 200 female patients, we type

```
. use http://www.stata-press.com/data/r13/bsample1, clear
. bsample 200 if female
. tabulate female
```

<table>
<thead>
<tr>
<th></th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>female</td>
<td>200</td>
<td>100.00</td>
<td>100.00</td>
</tr>
<tr>
<td><strong>Total</strong></td>
<td><strong>200</strong></td>
<td><strong>100.00</strong></td>
<td></td>
</tr>
</tbody>
</table>
Example 6: Generating frequency weights

To identify the sampled observations using frequency weights instead of dropping unsampled observations, we use the `weight()` option (we will need to supply it an existing variable name) and type

```
use http://www.stata-press.com/data/r13/bsample1, clear
set seed 1234
generate fw = .
(bs810 missing values generated)
bsonse 200 if female, weight(fw)
tabulate fw female
```

<table>
<thead>
<tr>
<th>fw</th>
<th>female</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>male</td>
<td>female</td>
<td>Total</td>
</tr>
<tr>
<td>0</td>
<td>2,392</td>
<td>3,221</td>
<td>5,613</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
<td>194</td>
<td>194</td>
</tr>
<tr>
<td>2</td>
<td>0</td>
<td>3</td>
<td>3</td>
</tr>
<tr>
<td>Total</td>
<td>2,392</td>
<td>3,418</td>
<td>5,810</td>
</tr>
</tbody>
</table>

Note that $(194 \times 1) + (3 \times 2) = 200$.

Example 7: Oversampling observations

`bsample` requires the expression in `exp` to evaluate to a number that is less than or equal to the number of observations. To sample twice as many male and female patients as there are already in memory, we must expand the data before using `bsample`. For example,

```
use http://www.stata-press.com/data/r13/bsample1, clear
set seed 1234
expand 2
(bs810 observations created)
bsonse, strata(female)
tabulate female
```

<table>
<thead>
<tr>
<th>female</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>4,784</td>
<td>41.17</td>
<td>41.17</td>
</tr>
<tr>
<td>female</td>
<td>6,836</td>
<td>58.83</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>11,620</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>
Example 8: Stratified oversampling with unequal sizes

To sample twice as many female patients as male patients, we must expand the records for the female patients because there are less than twice as many of them as there are male patients, but first put the number of observed male patients in a local macro. After expanding the female records, we generate a variable that contains the number of observations to sample within the two groups.

```
. use http://www.stata-press.com/data/r13/bsample1, clear
. set seed 1234
. count if !female
    2392
. local nmale = r(N)
. expand 2 if female
    (3418 observations created)
. generate nsamp = cond(female,2*'nmale','nmale')
. bsample nsamp, strata(female)
. tabulate female

female  Freq.  Percent  Cum.  
male      2,392  33.33     33.33
female  4,784  66.67    100.00

Total 7,176 100.00
```

Example 9: Oversampling of clusters

For clustered data, sampling more clusters than are present in the original dataset requires more than just expanding the data. To illustrate, suppose we wanted a bootstrap sample of eight clusters from a dataset consisting of five clusters of observations.

```
. use http://www.stata-press.com/data/r13/bsample2, clear
. tabstat x, stat(n mean) by(group)
Summary for variables: x
    by categories of: group
       group | N    mean
        |     |
     A     | 15  -.3073028
     B     | 10  -.00984
     C     | 11  .0810985
     D     | 11  -.1989179
     E     | 29  -.095203
        | 76  -.1153269
```

bsample will complain if we simply expand the dataset.

```
. use http://www.stata-press.com/data/r13/bsample2
. expand 3
    (152 observations created)
. bsample 8, cluster(group)
    resample size must not be greater than number of clusters
    r(498);
```
Expanding the data will only partly solve the problem. We also need a new variable that uniquely identifies the copied clusters. We use the `expandcl` command to accomplish both these tasks; see [D] `expandcl`.

```
. use http://www.stata-press.com/data/r13/bsample2, clear
. set seed 1234
. expandcl 2, generate(expgroup) cluster(group)
(76 observations created)
. tabstat x, stat(n mean) by(expgroup)
```

Summary for variables: x
by categories of: expgroup

<table>
<thead>
<tr>
<th>expgroup</th>
<th>N</th>
<th>mean</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>15</td>
<td>-.3073028</td>
</tr>
<tr>
<td>2</td>
<td>15</td>
<td>-.3073028</td>
</tr>
<tr>
<td>3</td>
<td>10</td>
<td>-.00984</td>
</tr>
<tr>
<td>4</td>
<td>10</td>
<td>-.00984</td>
</tr>
<tr>
<td>5</td>
<td>11</td>
<td>.0810985</td>
</tr>
<tr>
<td>6</td>
<td>11</td>
<td>.0810985</td>
</tr>
<tr>
<td>7</td>
<td>11</td>
<td>-.1989179</td>
</tr>
<tr>
<td>8</td>
<td>11</td>
<td>-.1989179</td>
</tr>
<tr>
<td>9</td>
<td>29</td>
<td>-.095203</td>
</tr>
<tr>
<td>10</td>
<td>29</td>
<td>-.095203</td>
</tr>
<tr>
<td>Total</td>
<td>152</td>
<td>-.1153269</td>
</tr>
</tbody>
</table>

```
. generate fw = .
(152 missing values generated)
. bsample 8, cluster(expgroup) weight(fw)
. tabulate fw group
```

<table>
<thead>
<tr>
<th>fw</th>
<th>A</th>
<th>B</th>
<th>C</th>
<th>D</th>
<th>E</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>15</td>
<td>10</td>
<td>0</td>
<td>0</td>
<td>29</td>
<td>54</td>
</tr>
<tr>
<td>1</td>
<td>15</td>
<td>10</td>
<td>22</td>
<td>22</td>
<td>0</td>
<td>69</td>
</tr>
<tr>
<td>2</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>29</td>
<td>29</td>
</tr>
<tr>
<td>Total</td>
<td>30</td>
<td>20</td>
<td>22</td>
<td>22</td>
<td>58</td>
<td>152</td>
</tr>
</tbody>
</table>
```

The results from `tabulate` on the generated frequency weight variable versus the original cluster ID (group) show us that the bootstrap sample contains one copy of cluster A, one copy of cluster B, two copies of cluster C, two copies of cluster D, and two copies of cluster E \((1 + 1 + 2 + 2 + 2 = 8)\).
Example 10: Stratified oversampling of clusters

Suppose that we have a dataset containing two strata with five clusters in each stratum, but the cluster identifiers are not unique between the strata. To get a stratified bootstrap sample with eight clusters in each stratum, we first use `expandcl` to expand the data and get a new cluster ID variable. We use `cluster(strid group)` in the call to `expandcl`; this action will uniquely identify the $2 \times 5 = 10$ clusters across the strata.

```stata
. use http://www.stata-press.com/data/r13/bsample2, clear
. set seed 1234
. tabulate group strid
    +-------------------------------------------------+
<table>
<thead>
<tr>
<th>group</th>
<th>strid</th>
<th>2</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>7</td>
<td>8</td>
</tr>
<tr>
<td>B</td>
<td>5</td>
<td>5</td>
</tr>
<tr>
<td>C</td>
<td>5</td>
<td>6</td>
</tr>
<tr>
<td>D</td>
<td>5</td>
<td>6</td>
</tr>
<tr>
<td>E</td>
<td>14</td>
<td>15</td>
</tr>
</tbody>
</table>
   +-------------------------------------------------+
   | Total | 36    | 40|
    +-------------------------------------------------+
```

Now we can use `bsample` with the expanded data, stratum ID variable, and new cluster ID variable.

```stata
. expandcl 2, generate(expgroup) cluster(strid group)
   (76 observations created)
```

```stata
. generate fw = .
   (152 missing values generated)
. bsample 8, cluster(expgroup) str(strid) weight(fw)
. by strid, sort: tabulate fw group

|-- strid = 1
<table>
<thead>
<tr>
<th>fw</th>
<th>A</th>
<th>B</th>
<th>C</th>
<th>D</th>
<th>E</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0</td>
<td>5</td>
<td>0</td>
<td>5</td>
<td>14</td>
<td>24</td>
</tr>
<tr>
<td>1</td>
<td>14</td>
<td>5</td>
<td>10</td>
<td>5</td>
<td>0</td>
<td>34</td>
</tr>
<tr>
<td>2</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>14</td>
<td>14</td>
</tr>
<tr>
<td>Total</td>
<td>14</td>
<td>10</td>
<td>10</td>
<td>10</td>
<td>28</td>
<td>72</td>
</tr>
</tbody>
</table>

|-- strid = 2
<table>
<thead>
<tr>
<th>fw</th>
<th>A</th>
<th>B</th>
<th>C</th>
<th>D</th>
<th>E</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>8</td>
<td>10</td>
<td>0</td>
<td>6</td>
<td>0</td>
<td>24</td>
</tr>
<tr>
<td>1</td>
<td>8</td>
<td>0</td>

<td>0</td>
<td>15</td>
<td>21</td>
</tr>
<tr>
<td>Total</td>
<td>16</td>
<td>10</td>
<td>12</td>
<td>12</td>
<td>30</td>
<td>80</td>
</tr>
</tbody>
</table>
```

The results from `by strid: tabulate` on the generated frequency weight variable versus the original cluster ID (`group`) show us how many times each cluster was sampled for each stratum. For stratum 1, the bootstrap sample contains two copies of cluster A, one copy of cluster B, two copies of cluster C, one copy of cluster D, and two copies of cluster E ($2 + 1 + 2 + 1 + 2 = 8$). For stratum 2, the bootstrap sample contains one copy of cluster A, zero copies of cluster B, three copies of cluster C, one copy of cluster D, and three copies of cluster E ($1 + 0 + 3 + 1 + 3 = 8$).

Statistics > Resampling > Report bootstrap results

Description

`bstat` is a programmer’s command that computes and displays estimation results from bootstrap statistics.

For each variable in `varlist` (the default is all variables), then `bstat` computes a covariance matrix, estimates bias, and constructs several different confidence intervals (CIs). The following CIs are constructed by `bstat`:
1. Normal CIs (using the normal approximation)
2. Percentile CIs
3. Bias-corrected (BC) CIs
4. Bias-corrected and accelerated (BCₐ) CIs (optional)

`estat bootstrap` displays a table of one or more of the above confidence intervals; see [R] bootstrap postestimation.

If there are bootstrap estimation results in `e()`, `bstat` replays them. If given the `using` modifier, `bstat` uses the data in `filename` to compute the bootstrap statistics while preserving the data currently in memory. Otherwise, `bstat` uses the data in memory to compute the bootstrap statistics.

The following options may be used to replay estimation results from `bstat`:

`level(#)` `notable` `noheader` `nolegend` `verbose` `title(text)`

For all other options and the qualifiers using, if, and in, `bstat` requires a bootstrap dataset.

Options

<table>
<thead>
<tr>
<th>Main</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>stat(vector)</code> specifies the observed value of each statistic (that is, the value of the statistic using the original dataset).</td>
</tr>
<tr>
<td><code>accel(vector)</code> specifies the acceleration of each statistic, which is used to construct BCₐ CIs.</td>
</tr>
<tr>
<td><code>ties</code> specifies that <code>bstat</code> adjust for ties in the replicate values when computing the median bias used to construct BC and BCₐ CIs.</td>
</tr>
<tr>
<td><code>mse</code> specifies that <code>bstat</code> compute the variance by using deviations of the replicates from the observed value of the statistics. By default, <code>bstat</code> computes the variance by using deviations from the average of the replicates.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Reporting</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>level(#)</code>; see [R] estimation options.</td>
</tr>
<tr>
<td><code>n(#)</code> specifies the number of observations from which bootstrap samples were taken. This value is used in no calculations but improves the table header when this information is not saved in the bootstrap dataset.</td>
</tr>
<tr>
<td><code>notable</code> suppresses the display of the output table.</td>
</tr>
<tr>
<td><code>noheader</code> suppresses the display of the table header. This option implies <code>nolegend</code>.</td>
</tr>
<tr>
<td><code>nolegend</code> suppresses the display of the table legend.</td>
</tr>
<tr>
<td><code>verbose</code> specifies that the full table legend be displayed. By default, coefficients and standard errors are not displayed.</td>
</tr>
<tr>
<td><code>title(text)</code> specifies a title to be displayed above the table of bootstrap results; the default title is Bootstrap results.</td>
</tr>
</tbody>
</table>

`display_options: cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see [R] estimation options.`
Remarks and examples

Remarks are presented under the following headings:

- Bootstrap datasets
- Creating a bootstrap dataset

Bootstrap datasets

Although `bstat` allows you to specify the observed value and acceleration of each bootstrap statistic via the `stat()` and `accel()` options, programmers may be interested in what `bstat` uses when these options are not supplied.

When working from a bootstrap dataset, `bstat` first checks the data characteristics (see `[P] char`) that it understands:

- `_dta[bs_version]` identifies the version of the bootstrap dataset. This characteristic may be empty (not defined), 2, or 3; otherwise, `bstat` will quit and display an error message. This version tells `bstat` which other characteristics to look for in the bootstrap dataset.

  `bstat` uses the following characteristics from version 3 bootstrap datasets:

  - `_dta[N]`
  - `_dta[N_strata]`
  - `_dta[N_cluster]`
  - `_dta[command]`
  - `varname[observed]`
  - `varname[acceleration]`
  - `varname[expression]`

  `bstat` uses the following characteristics from version 2 bootstrap datasets:

  - `_dta[N]`
  - `_dta[N_strata]`
  - `_dta[N_cluster]`
  - `varname[observed]`
  - `varname[acceleration]`

  An empty bootstrap dataset version implies that the dataset was created by the `bstrap` command in a version of Stata earlier than Stata 8. Here `bstat` expects `varname[bstrap]` to contain the observed value of the statistic identified by `varname` (`varname[observed]` in version 2). All other characteristics are ignored.

- `_dta[N]` is the number of observations in the observed dataset. This characteristic may be overruled by specifying the `n()` option.

- `_dta[N_strata]` is the number of strata in the observed dataset.

- `_dta[N_cluster]` is the number of clusters in the observed dataset.

- `_dta[command]` is the command used to compute the observed values of the statistics.

  `varname[observed]` is the observed value of the statistic identified by `varname`. To specify a different value, use the `stat()` option.

  `varname[acceleration]` is the estimate of acceleration for the statistic identified by `varname`. To specify a different value, use the `accel()` option.

  `varname[expression]` is the expression or label that describes the statistic identified by `varname`.
Creating a bootstrap dataset

Suppose that we are interested in obtaining bootstrap statistics by resampling the residuals from a regression (which is not possible with the `bootstrap` command). After loading some data, we run a regression, save some results relevant to the `bstat` command, and save the residuals in a new variable, `res`.

```stata
use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
regress mpg weight length
```

<table>

</tbody>
</table>

| Coef. Std. Err. t P>|t| [95% Conf. Interval] |
|---------------------|---------------------|---------------------|---------------------|
| weight              | -.0038515           | .001586             | -2.43               | 0.018   | -.0070138 -.0006891 |
| length              | -.0795935           | .0553577            | -1.44               | 0.155   | -.1899736 .0307867  |
| _cons               | 47.88487            | 6.08787             | 7.87                | 0.000   | 35.746 60.02374     |

Instead of programming this resampling inside a loop, it is much more convenient to write a short program and use the `simulate` command; see `[R] simulate`. In the following, `mysim_r` requires the user to specify a coefficient vector and a residual variable. `mysim_r` then retrieves the list of predictor variables (removing `_cons` from the list), generates a new temporary response variable with the resampled residuals, and regresses the new response variable on the predictors.
We can now give `mysim_r` a test run, but we first set the random-number seed (to reproduce results).

```stata
set seed 54321
mym_r b, res(res)
```

(74 real changes made)

<table>

</table>

|     | Coef.  | Std. Err.  | t    | P>|t| | [95% Conf. Interval] |
|-----|--------|------------|------|------|----------------------|
| weight | -.0059938 | .0013604 | -4.41 | 0.000 | -.0087064 -.0032813 |
| length | -.0127875 | .0474837 | -0.27 | 0.788 | -.1074673 .0818924 |
| _cons  | 42.23195 | 5.22194 | 8.09 | 0.000 | 31.8197 52.6442 |

Now that we have a program that will compute the results we want, we can use `simulate` to generate a bootstrap dataset and `bstat` to display the results.

```stata
set seed 54321
simulate, reps(200) nodots: mysim_r b, res(res)
command: mysim_r b, res(res)
bstat, stat(b) n('n')
```

Bootstrap results

<table>
<thead>
<tr>
<th></th>
<th>Observed</th>
<th>Bootstrap</th>
<th>Normal-based</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Coef.</td>
<td>Std. Err.</td>
<td>z</td>
</tr>
<tr>
<td>_b_weight</td>
<td>-.0038515</td>
<td>.0015715</td>
<td>-2.45</td>
</tr>
<tr>
<td>_b_length</td>
<td>-.0795935</td>
<td>.0552415</td>
<td>-1.44</td>
</tr>
<tr>
<td>_b_cons</td>
<td>47.88487</td>
<td>6.150069</td>
<td>7.79</td>
</tr>
</tbody>
</table>

Finally, we see that `simulate` created some of the data characteristics recognized by `bstat`. All we need to do is correctly specify the version of the bootstrap dataset, and `bstat` will automatically use the relevant data characteristics.

See Poi (2004) for another example of residual resampling.
Stored results

*bstat* stores the following in **e()**:

Scalars

- `e(N)` sample size
- `e(N_reps)` number of complete replications
- `e(N_misreps)` number of incomplete replications
- `e(N_strata)` number of strata
- `e(N_clust)` number of clusters
- `e(k_aux)` number of auxiliary parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_exp)` number of standard expressions
- `e(k_exp)` number of extended expressions (i.e., `_b`)
- `e(k_extra)` number of extra equations beyond the original ones from `e(b)`
- `e(level)` confidence level for bootstrap CIs
- `e(bs_version)` version for bootstrap results
- `e(rank)` rank of `e(V)`

Macros

- `e(cmd)` `bstat`
- `e(command)` from `_dta[command]`
- `e(cmdline)` command as typed
- `e(title)` title in estimation output
- `e(exp#)` expression for the `#`th statistic
- `e(prefix)` bootstrap
- `e(ties)` ties, if specified
- `e(mse)` mse, if specified
- `e(vce)` bootstrap
- `e(vcetype)` title used to label Std. Err.
- `e(properties)` `b V`

Matrices

- `e(b)` observed statistics
- `e(b_bs)` bootstrap estimates
- `e(reps)` number of nonmissing results
- `e(bias)` estimated biases
- `e(se)` estimated standard errors
- `e(z0)` median biases
- `e(accel)` estimated accelerations
- `e(ci_normal)` normal-approximation CIs
- `e(ci_percentile)` percentile CIs
- `e(ci_bc)` bias-corrected CIs
- `e(ci_bca)` bias-corrected and accelerated CIs
- `e(V)` bootstrap variance–covariance matrix

Syntax

centile [varlist] [if] [in] [, options]

options Description

Main
  centile(numlist) report specified centiles; default is centile(50)

Options
  cci binomial exact; conservative confidence interval
  normal normal, based on observed centiles
  meansd normal, based on mean and standard deviation
  level(#) set confidence level; default is level(95)

by is allowed; see [D] by.

Menu

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Centiles with CIs

Description

centile estimates specified centiles and calculates confidence intervals. If no varlist is specified, centile calculates centiles for all the variables in the dataset. If centile() is not specified, medians (centile(50)) are reported.

By default, centile uses a binomial method for obtaining confidence intervals that makes no assumptions about the underlying distribution of the variable.

Options

Main

centile(numlist) specifies the centiles to be reported. The default is to display the 50th centile.

Specifying centile(5) requests that the fifth centile be reported. Specifying centile(5 50 95) requests that the 5th, 50th, and 95th centiles be reported. Specifying centile(10(10)90) requests that the 10th, 20th, ..., 90th centiles be reported; see [U] 11.1.8 numlist.

Options

cci (conservative confidence interval) forces the confidence limits to fall exactly on sample values.

Confidence intervals displayed with the cci option are slightly wider than those with the default (nocci) option.
normal causes the confidence interval to be calculated by using a formula for the standard error of a normal-distribution quantile given by Kendall and Stuart (1969, 237). The normal option is useful when you want empirical centiles—that is, centiles based on sample order statistics rather than on the mean and standard deviation—and are willing to assume normality.

meansd causes the centile and confidence interval to be calculated based on the sample mean and standard deviation, and it assumes normality.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see \[R\] level.

## Remarks and examples

The \( q \)th centile of a continuous random variable, \( X \), is defined as the value of \( C_q \), which fulfills the condition \( \Pr(X \leq C_q) = q/100 \). The value of \( q \) must be in the range \( 0 < q < 100 \), though \( q \) is not necessarily an integer. By default, \texttt{centile} estimates \( C_q \) for the variables in \texttt{varlist} and for the values of \( q \) given in \texttt{centile(numlist)}. It makes no assumptions about the distribution of \( X \), and, if necessary, uses linear interpolation between neighboring sample values. Extreme centiles (for example, the 99th centile in samples smaller than 100) are fixed at the minimum or maximum sample value. An “exact” confidence interval for \( C_q \) is also given, using the binomial-based method described below in \textit{Methods and formulas} and in Conover (1999, 143–148). Again linear interpolation is used to improve the accuracy of the estimated confidence limits, but extremes are fixed at the minimum or maximum sample value.

You can prevent \texttt{centile} from interpolating when calculating binomial-based confidence intervals by specifying \texttt{cci}. The resulting intervals are generally wider than with the default; that is, the coverage (confidence level) tends to be greater than the nominal value (given as usual by \texttt{level(#)}, by default 95%).

If the data are believed to be normally distributed (a common case), there are two alternative methods for estimating centiles. If \texttt{normal} is specified, \( C_q \) is calculated, as just described, but its confidence interval is based on a formula for the standard error (se) of a normal-distribution quantile given by Kendall and Stuart (1969, 237). If \texttt{meansd} is alternatively specified, \( C_q \) is estimated as \( \overline{x} + z_q \times s \), where \( \overline{x} \) and \( s \) are the sample mean and standard deviation, and \( z_q \) is the \( q \)th centile of the standard normal distribution (for example, \( z_{95} = 1.645 \)). The confidence interval is derived from the se of the estimate of \( C_q \).

### Example 1

Using \texttt{auto.dta}, we estimate the 5th, 50th, and 95th centiles of the \texttt{price} variable:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. format price %8.2fc
. centile price, centile(5 50 95)

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Percentile</th>
<th>Centile</th>
<th>______</th>
<th>Binom. Interp.</th>
<th>______</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
<td>[95% Conf. Interval]</td>
<td></td>
<td></td>
</tr>
<tr>
<td>price</td>
<td>74</td>
<td>5</td>
<td>3,727.75</td>
<td>3,291.23</td>
<td>3,914.16</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td>50</td>
<td>5,006.50</td>
<td>4,593.57</td>
<td>5,717.90</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td>95</td>
<td>13,498.00</td>
<td>11,061.53</td>
<td>15,865.30</td>
<td></td>
</tr>
</tbody>
</table>
```

\texttt{summarize} produces somewhat different results from \texttt{centile}; see \textit{Methods and formulas}.
The confidence limits produced by using the cci option are slightly wider than those produced without this option:

```
. centile price, c(5 50 95) cci
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Percentile</th>
<th>Centile</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>price</td>
<td>74</td>
<td>5</td>
<td>3,727.75</td>
<td>3,291.00 3,955.00</td>
</tr>
<tr>
<td></td>
<td>50</td>
<td>5006.50</td>
<td>4,589.00</td>
<td>5,215.60 5,919.00</td>
</tr>
<tr>
<td></td>
<td>95</td>
<td>13,498.00</td>
<td>10,372.00</td>
<td>15,906.00</td>
</tr>
</tbody>
</table>

If we are willing to assume that price is normally distributed, we could include either the normal or the meansd option:

```
. centile price, c(5 50 95) normal
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Percentile</th>
<th>Centile</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>price</td>
<td>74</td>
<td>5</td>
<td>3,727.75</td>
<td>3,211.19 4,244.31</td>
</tr>
<tr>
<td></td>
<td>50</td>
<td>5006.50</td>
<td>4,096.68</td>
<td>5,046.68 5,916.32</td>
</tr>
<tr>
<td></td>
<td>95</td>
<td>13,498.00</td>
<td>5,426.81</td>
<td>21,569.19</td>
</tr>
</tbody>
</table>

```
. centile price, c(5 50 95) meansd
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Percentile</th>
<th>Centile</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>price</td>
<td>74</td>
<td>5</td>
<td>1,313.77</td>
<td>278.93 2,348.61</td>
</tr>
<tr>
<td></td>
<td>50</td>
<td>6,165.26</td>
<td>5,493.24</td>
<td>6,837.27</td>
</tr>
<tr>
<td></td>
<td>95</td>
<td>11,016.75</td>
<td>9,981.90</td>
<td>12,051.59</td>
</tr>
</tbody>
</table>

With the normal option, the centile estimates are, by definition, the same as before. The confidence intervals for the 5th and 50th centiles are similar to the previous ones, but the interval for the 95th centile is different. The results using the meansd option also differ from both previous sets of estimates.

We can use sktest (see [R] sktest) to check the correctness of the normality assumption:

```
. sktest price
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Pr(Skewness)</th>
<th>Pr(Kurtosis)</th>
<th>adj chi2(2)</th>
<th>Prob&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>price</td>
<td>74</td>
<td>0.0000</td>
<td>0.0127</td>
<td>21.77</td>
<td>0.0000</td>
</tr>
</tbody>
</table>
sktest reveals that `price` is definitely not normally distributed, so the normal assumption is not reasonable, and the `normal` and `meansd` options are not appropriate for these data. We should rely on the results from the default choice, which does not assume normality. If the data are normally distributed, however, the precision of the estimated centiles and their confidence intervals will be ordered (best) `meansd` > `normal` > [default] (worst). The `normal` option is useful when we really do want empirical centiles (that is, centiles based on sample order statistics rather than on the mean and standard deviation) but are willing to assume normality.

### Stored results

`centile` stores the following in `r()`:

**Scalars**
- `r(N)` number of observations
- `r(n_cent)` number of centiles requested
- `r(c_#)` value of `#` centile
- `r(lb_#)` `#`-requested centile lower confidence bound
- `r(ub_#)` `#`-requested centile upper confidence bound

**Macros**
- `r(centiles)` centiles requested

### Methods and formulas

Methods and formulas are presented under the following headings:

- **Default case**
- **Normal case**
- **meansd case**

#### Default case

The calculation is based on the method of Mood and Graybill (1963, 408). Let \(x_1 \leq x_2 \leq \cdots \leq x_n\) be a sample of size \(n\) arranged in ascending order. Denote the estimated \(q\)th centile of the \(x\)'s as \(c_q\). We require that \(0 < q < 100\). Let \(R = (n + 1)q/100\) have integer part \(r\) and fractional part \(f\); that is, \(r = \text{int}(R)\) and \(f = R - r\). (If \(R\) is itself an integer, then \(r = R\) and \(f = 0\).) Note that \(0 \leq r \leq n\). For convenience, define \(x_0 = x_1\) and \(x_{n+1} = x_n\). \(C_q\) is estimated by

\[
c_q = x_r + f \times (x_{r+1} - x_r)
\]

that is, \(c_q\) is a weighted average of \(x_r\) and \(x_{r+1}\). Loosely speaking, a (conservative) \(p\)% confidence interval for \(C_q\) involves finding the observations ranked \(t\) and \(u\), which correspond, respectively, to the \(\alpha = (100 - p)/200\) and \(1 - \alpha\) quantiles of a binomial distribution with parameters \(n\) and \(q/100\), that is, \(B(n, q/100)\). More precisely, define the \(i\)th value \((i = 0, \ldots, n)\) of the cumulative binomial distribution function as \(F_i = \text{Pr}(S \leq i)\), where \(S\) has distribution \(B(n, q/100)\). For convenience, let \(F_{-1} = 0\) and \(F_{n+1} = 1\). \(t\) is found such that \(F_t \leq \alpha\) and \(F_{t+1} > \alpha\), and \(u\) is found such that \(1 - F_u \leq \alpha\) and \(1 - F_{u-1} > \alpha\).

With the `cci` option in force, the (conservative) confidence interval is \((x_{t+1}, x_{u+1})\), and its actual coverage probability is \(F_u - F_t\).
The default case uses linear interpolation on the \( F_i \) as follows. Let
\[
g = (\alpha - F_t) / (F_{t+1} - F_t) \\
h = \{\alpha - (1 - F_u)\} / \{(1 - F_{u-1}) - (1 - F_u)\} \\
= (\alpha - 1 + F_u) / (F_u - F_{u-1})
\]
The interpolated lower and upper confidence limits \((c_{qL}, c_{qU})\) for \( C_q \) are
\[
c_{qL} = x_{t+1} + g \times (x_{t+2} - x_{t+1}) \\
c_{qU} = x_{u+1} - h \times (x_{u+1} - x_u)
\]
Suppose that we want a 95% confidence interval for the median of a sample of size 13. \( n = 13, q = 50, p = 95, \alpha = 0.025, R = 14 \times 50/100 = 7, \) and \( f = 0 \). Therefore, the median is the 7th observation. Some example data, \( x_i \), and the values of \( F_i \) are as follows:

<table>
<thead>
<tr>
<th>( i )</th>
<th>( F_i )</th>
<th>( 1 - F_i )</th>
<th>( x_i )</th>
<th>( i )</th>
<th>( F_i )</th>
<th>( 1 - F_i )</th>
<th>( x_i )</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0.0001</td>

<td>15</td>
<td>11</td>
<td>0.9983</td>
<td>0.0017</td>
<td>77</td>
</tr>
<tr>
<td>5</td>
<td>0.2905</td>
<td>0.7095</td>
<td>23</td>
<td>12</td>
<td>0.9999</td>
<td>0.0001</td>
<td>104</td>
</tr>
<tr>
<td>6</td>
<td>0.5000</td>
<td>0.5000</td>
<td>28</td>
<td>13</td>
<td>1.0000</td>
<td>0.0000</td>
<td>211</td>
</tr>
</tbody>
</table>

The median is \( x_7 = 33 \). Also, \( F_2 \leq 0.025 \) and \( F_3 > 0.025 \), so \( t = 2 \); \( 1 - F_{10} \leq 0.025 \) and \( 1 - F_9 > 0.025 \), so \( u = 10 \). The conservative confidence interval is therefore
\[
(c_{50L}, c_{50U}) = (x_{t+1}, x_{u+1}) = (x_3, x_{11}) = (10, 77)
\]
with actual coverage \( F_{10} - F_2 = 0.9888 - 0.0112 = 0.9776 \) (97.8% confidence). For the interpolation calculation, we have
\[
g = (0.025 - 0.0112) / (0.0461 - 0.0112) = 0.395 \\
h = (0.025 - 1 + 0.9888) / (0.9888 - 0.9539) = 0.395
\]
So,
\[
c_{50L} = x_3 + 0.395 \times (x_4 - x_3) = 10 + 0.395 \times 5 = 11.98 \\
c_{50U} = x_{11} - 0.395 \times (x_{11} - x_{10}) = 77 - 0.395 \times 18 = 69.89
\]

**Normal case**

The value of \( c_q \) is as above. Its se is given by the formula
\[
s_q = \sqrt{q(100 - q)} / \left\{ 100 \sqrt{n} Z(c_q; \bar{x}, s) \right\}
\]
where \( \bar{x} \) and \( s \) are the mean and standard deviation of the \( x_i \), and
\[
Z(Y; \mu, \sigma) = \left( 1 / \sqrt{2\pi\sigma^2} \right) e^{-(Y-\mu)^2 / 2\sigma^2}
\]
is the density function of a normally distributed variable \( Y \) with mean \( \mu \) and standard deviation \( \sigma \). The confidence interval for \( C_q \) is \((c_q - z_{100(1-\alpha)} s_q, c_q + z_{100(1-\alpha)} s_q)\).
The value of $c_q$ is $\bar{x} + z_q \times s$. Its se is given by the formula

$$s_q^* = s \sqrt{1/n + z_q^2/(2n - 2)}$$

The confidence interval for $C_q$ is $(c_q - z_{100(1-\alpha)} \times s_q^*, c_q + z_{100(1-\alpha)} \times s_q^*)$.

**cii for variable distributed as Poisson**

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Poisson CI calculator

### Description

**ci** computes standard errors and confidence intervals for each of the variables in *varlist*.

**cii** is the immediate form of **ci**; see [U] 19 Immediate commands for a general discussion of immediate commands.

In the binomial and Poisson variants of **cii**, the second number specified (_#succ_ or _#events_) must be an integer or between 0 and 1. If the number is between 0 and 1, Stata interprets it as the fraction of successes or events and converts it to an integer number representing the number of successes or events. The computation then proceeds as if two integers had been specified.

### Options

- **binomial** tells **ci** that the variables are 0/1 variables and that binomial confidence intervals will be calculated. (**cii** produces binomial confidence intervals when only two numbers are specified.)
- **poisson** specifies that the variables (or numbers for **cii**) are Poisson-distributed counts; exact Poisson confidence intervals will be calculated.
exposure(\textit{varname}) is used only with \textit{poisson}. You do not need to specify \textit{poisson} if you specify \textit{exposure(): poisson} is assumed. \textit{varname} contains the total exposure (typically a time or an area) during which the number of events recorded in \textit{varlist} were observed.

\textit{exact}, \textit{wald}, \textit{wilson}, \textit{agresti}, and \textit{jeffreys} specify that variables are 0/1 and specify how binomial confidence intervals are to be calculated.

\textit{exact} is the default and specifies exact (also known in the literature as Clopper–Pearson [1934]) binomial confidence intervals.

\textit{wald} specifies calculation of Wald confidence intervals.

\textit{wilson} specifies calculation of Wilson confidence intervals.

\textit{agresti} specifies calculation of Agresti–Coull confidence intervals.

\textit{jeffreys} specifies calculation of Jeffreys confidence intervals.

See Brown, Cai, and DasGupta (2001) for a discussion and comparison of the different binomial confidence intervals.

\textit{total} is for use with the \textit{by} prefix. It requests that, in addition to output for each \textit{by}-group, output be added for all groups combined.

\textit{separator(\#)} specifies how often separation lines should be inserted into the output. The default is \textit{separator(5)}, meaning that a line is drawn after every five variables. \textit{separator(10)} would draw the line after every 10 variables. \textit{separator(0)} suppresses the separation line.

\textit{level(\#)} specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by \textit{set level}; see \textasciitilde R \texttt{level}.

### Remarks and examples

Remarks are presented under the following headings:

- Ordinary confidence intervals
- Binomial confidence intervals
- Poisson confidence intervals
- Immediate form
- Video examples

#### Ordinary confidence intervals

- **Example 1**

Without the \textit{binomial} or \textit{poisson} options, \textit{ci} produces “ordinary” confidence intervals, meaning those that are correct if the variable is distributed normally, and \textit{asymptotically} correct for all other distributions satisfying the conditions of the central limit theorem.

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. ci mpg price
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.297</td>
<td>.672551</td>
<td>19.9569 22.63769</td>
</tr>
<tr>
<td>price</td>
<td>74</td>
<td>6165.25</td>
<td>342.8719</td>
<td>5481.914 6848.6</td>
</tr>
</tbody>
</table>
The standard error of the mean of mpg is 0.67, and the 95% confidence interval is [19.96, 22.64]. We can obtain wider confidence intervals, 99%, by typing

```
. ci mpg price, level(99)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[99% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6725511</td>
<td>19.51849 23.07611</td>
</tr>
<tr>
<td>price</td>
<td>74</td>
<td>6165.257</td>
<td>342.8719</td>
<td>5258.405 7072.108</td>
</tr>
</tbody>
</table>

Example 2

by() breaks out the confidence intervals according to by-group; total adds an overall summary. For instance,

```
. ci mpg, by(foreign) total
```

<table>
<thead>
<tr>
<th>-&gt; foreign = Domestic</th>
</tr>
</thead>
<tbody>
<tr>
<td>Variable</td>
</tr>
<tr>
<td>mpg</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>-&gt; foreign = Foreign</th>
</tr>
</thead>
<tbody>
<tr>
<td>Variable</td>
</tr>
<tr>
<td>mpg</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>-&gt; Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Variable</td>
</tr>
<tr>
<td>mpg</td>
</tr>
</tbody>
</table>

Technical note

You can control the formatting of the numbers in the output by specifying a display format for the variable; see [U] 12.5 Formats: Controlling how data are displayed. For instance,

```
. format mpg %9.2f
. ci mpg
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.30</td>
<td>0.67</td>
<td>19.96 22.64</td>
</tr>
</tbody>
</table>

Binomial confidence intervals

Example 3

We have data on employees, including a variable marking whether the employee was promoted last year.
. use http://www.stata-press.com/data/r13/promo
. ci promoted, binomial

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>promoted</td>
<td>20</td>
<td>.1</td>
<td>.067082</td>
<td>.0123485 .3169827</td>
</tr>
</tbody>
</table>

The above interval is the default for binomial data, known equivalently as both the exact binomial and the Clopper–Pearson interval.

Nominally, the interpretation of a 95% confidence interval is that under repeated samples or experiments, 95% of the resultant intervals would contain the unknown parameter in question. However, for binomial data, the actual coverage probability, regardless of method, usually differs from that interpretation. This result occurs because of the discreteness of the binomial distribution, which produces only a finite set of outcomes, meaning that coverage probabilities are subject to discrete jumps and the exact nominal level cannot always be achieved. Therefore, the term exact confidence interval refers to its being derived from the binomial distribution, the distribution exactly generating the data, rather than resulting in exactly the nominal coverage.

For the Clopper–Pearson interval, the actual coverage probability is guaranteed to be greater than or equal to the nominal confidence level, here 95%. Because of the way it is calculated—see Methods and formulas—it may also be interpreted as follows: If the true probability of being promoted were 0.012, the chances of observing a result as extreme or more extreme than the result observed (20 × 0.1 = 2 or more promotions) would be 2.5%. If the true probability of being promoted were 0.317, the chances of observing a result as extreme or more extreme than the result observed (two or fewer promotions) would be 2.5%.

Example 4

The Clopper–Pearson interval is desirable because it guarantees nominal coverage; however, by dropping this restriction, you may obtain accurate intervals that are not as conservative. In this vein, you might opt for the Wilson (1927) interval,

. ci promoted, binomial wilson

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>promoted</td>
<td>20</td>
<td>.1</td>
<td>.067082</td>
<td>.0278665 .3010336</td>
</tr>
</tbody>
</table>

the Agresti–Coull (1998) interval,

. ci promoted, binomial agresti

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>promoted</td>
<td>20</td>
<td>.1</td>
<td>.067082</td>
<td>.0156562 .3132439</td>
</tr>
</tbody>
</table>

or the Bayesian-derived Jeffreys interval (Brown, Cai, and DasGupta 2001),

. ci promoted, binomial jeffreys

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>promoted</td>
<td>20</td>
<td>.1</td>
<td>.067082</td>
<td>.0213725 .2838533</td>
</tr>
</tbody>
</table>
Picking the best interval is a matter of balancing accuracy (coverage) against precision (average interval length) and depends on sample size and success probability. Brown, Cai, and DasGupta (2001) recommend the Wilson or Jeffreys interval for small sample sizes (≤40) yet favor the Agresti–Coull interval for its simplicity, decent performance for sample sizes less than or equal to 40, and performance comparable to Wilson/Jeffreys for sample sizes greater than 40. They also deem the Clopper–Pearson interval to be “wastefully conservative and [...] not a good choice for practical use”, unless of course one requires, at a minimum, the nominal coverage level.

Finally, the binomial Wald confidence interval is obtained by specifying the binomial and wald options. The Wald interval is the one taught in most introductory statistics courses and for the above is simply, for level $1 - \alpha$, Mean $\pm z_\alpha$(Std. Err.), where $z_\alpha$ is the $1 - \alpha/2$ quantile of the standard normal. Because its overall poor performance makes it impractical, the Wald interval is available mainly for pedagogical purposes. The binomial Wald interval is also similar to the interval produced by treating binary data as normal data and using ci without the binomial option, with two exceptions. First, when binomial is specified, the calculation of the standard error uses denominator $n$ rather than $n - 1$, used for normal data. Second, confidence intervals for normal data are based on the $t$ distribution rather than the standard normal. Of course, both discrepancies vanish as sample size increases.

### Technical note

Let’s repeat example 3, but this time with data in which there are no promotions over the observed period:

```
  . use http://www.stata-press.com/data/r13/promonone
  . ci promoted, binomial
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>promoted</td>
<td>20</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

(*) one-sided, 97.5% confidence interval

The confidence interval is [0, 0.168], and this is the confidence interval that most books publish. It is not, however, a true 95% confidence interval because the lower tail has vanished. As Stata notes, it is a one-sided, 97.5% confidence interval. If you wanted to put 5% in the right tail, you could type `ci promoted, binomial level(90)`.

### Technical note

`ci` with the binomial option ignores any variables that do not take on the values 0 and 1 exclusively. For instance, with our automobile dataset,

```
  . use http://www.stata-press.com/data/r13/auto
  (1978 Automobile Data)
  . ci mpg foreign, binomial
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>74</td>
<td>.2972973</td>
<td>.0531331</td>
<td>0.196584 - 0.4148353</td>
</tr>
</tbody>
</table>

We also requested the confidence interval for mpg, but Stata ignored us. It does that so you can type `ci, binomial` and obtain correct confidence intervals for all the variables that are 0/1 in your data.
Example 5

We have data on the number of bacterial colonies on a Petri dish. The dish has been divided into 36 small squares, and the number of colonies in each square has been counted. Each observation in our dataset represents a square on the dish. The variable `count` records the number of colonies in each square counted, which varies from 0 to 5.

```
use http://www.stata-press.com/data/r13/petri
.ci count, poisson
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Exposure</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>count</td>
<td>36</td>
<td>2.33333</td>
<td>.2545875</td>
<td>1.861158, 2.888825</td>
</tr>
</tbody>
</table>

`ci` reports that the average number of colonies per square is 2.33. If the expected number of colonies per square were as low as 1.86, the probability of observing 2.33 or more colonies per square would be 2.5%. If the expected number were as large as 2.89, the probability of observing 2.33 or fewer colonies per square would be 2.5%.

Technical note

The number of “observations”—how finely the Petri dish is divided—makes no difference. The Poisson distribution is a function only of the count. In example 4, we observed a total of $2.33 \times 36 = 84$ colonies and a confidence interval of $[1.86 \times 36, 2.89 \times 36] = [67, 104]$. We would obtain the same $[67, 104]$ confidence interval if our dish were divided into, say, 49 squares, rather than 36.

For the counts, it is not even important that all the squares be of the same size. For rates, however, such differences do matter, but in an easy-to-calculate way. Rates are obtained from counts by dividing by exposure, which is typically a number multiplied by either time or an area. For our Petri dishes, we divide by an area to obtain a rate, but if our example were cast in terms of being infected by a disease, we might divide by person-years to obtain the rate. Rates are convenient because they are easier to compare: we might have 2.3 colonies per square inch or 0.0005 infections per person-year.

So, let’s assume that we wish to obtain the number of colonies per square inch, and, moreover, that not all the “squares” on our dish are of equal size. We have a variable called `area` that records the area of each “square”:

```
.use http://www.stata-press.com/data/r13/petri
.ci count, exposure(area)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Exposure</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>count</td>
<td>3</td>
<td>28</td>
<td>3.055051</td>
<td>22.3339, 34.66591</td>
</tr>
</tbody>
</table>

The rates are now in more familiar terms. In our sample, there are 28 colonies per square inch and the 95% confidence interval is $[22.3, 34.7]$. When we did not specify `exposure()`, `ci` assumed that each observation contributed 1 to exposure.
Technical note

As with the binomial option, if there were no colonies on our dish, *ci* would calculate a one-sided confidence interval:

```
use http://www.stata-press.com/data/r13/petrinone
-ci count, poisson
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Exposure</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>count</td>
<td>36</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

(*) one-sided, 97.5% confidence interval

Immediate form

Example 6

We are reading a soon-to-be-published paper by a colleague. In it is a table showing the number of observations, mean, and standard deviation of 1980 median family income for the Northeast and West. We correctly think that the paper would be much improved if it included the confidence intervals. The paper claims that for 166 cities in the Northeast, the average of median family income is $19,509 with a standard deviation of $4,379:

For the Northeast:

```
cii 166 19509 4379
```

<table>
<thead>
<tr>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>166</td>
<td>19509</td>
<td>339.8763</td>
<td>18837.93  20180.07</td>
</tr>
</tbody>
</table>

For the West:

```
cii 256 22557 5003
```

<table>
<thead>
<tr>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>256</td>
<td>22557</td>
<td>312.6875</td>
<td>21941.22  23172.78</td>
</tr>
</tbody>
</table>

Example 7

We flip a coin 10 times, and it comes up heads only once. We are shocked and decide to obtain a 99% confidence interval for this coin:

```
cii 10 1, level(99)
```

<table>
<thead>
<tr>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[99% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>10</td>
<td>1.0</td>
<td>0.0948683</td>
<td>0.0005011  0.5442871</td>
</tr>
</tbody>
</table>
Example 8

The number of reported traffic accidents in Santa Monica over a 24-hour period is 27. We need know nothing else:

```
cii 1 27, poisson
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Exposure</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>27</td>
<td>5.196152</td>
<td>17.79317</td>
<td>17.79317 39.28358</td>
</tr>
</tbody>
</table>

Methods and formulas

Methods and formulas are presented under the following headings:

Ordinary
Binomial
Poisson

Ordinary

Define $n$, $\bar{x}$, and $s^2$ as, respectively, the number of observations, (weighted) average, and (unbiased) estimated variance of the variable in question; see [R] summarize.

The standard error of the mean, $s_\mu$, is defined as $\sqrt{s^2/n}$.

Let $\alpha$ be $1 - l/100$, where $l$ is the significance level specified by the user. Define $t_\alpha$ as the two-sided $t$ statistic corresponding to a significance level of $\alpha$ with $n - 1$ degrees of freedom; $t_\alpha$ is obtained from Stata as `invttail(n-1,0.5*alpha)`. The lower and upper confidence bounds are, respectively, $\bar{x} - s_\mu t_\alpha$ and $\bar{x} + s_\mu t_\alpha$. 
Binomial

Given \( k \) successes of \( n \) trials, the estimated probability is \( \hat{p} = k/n \) with standard error \( \sqrt{\hat{p}(1 - \hat{p})/n} \). \( \text{ci} \) calculates the exact (Clopper–Pearson) confidence interval \([p_1, p_2]\) such that

\[
\Pr(K \geq k|p = p_1) = \alpha/2
\]

and

\[
\Pr(K \leq k|p = p_2) = \alpha/2
\]

where \( K \) is distributed as binomial\((n,p)\). The endpoints may be obtained directly by using Stata’s \text{invbinomial()}\ function. If \( k = 0 \) or \( k = n \), the calculation of the appropriate tail is skipped.

The Wald interval is \( \hat{p} \pm z_{\alpha} \sqrt{\hat{p}(1 - \hat{p})/n} \), where \( z_{\alpha} \) is the \( 1 - \alpha/2 \) quantile of the standard normal. The interval is obtained by inverting the acceptance region of the large-sample Wald test of \( H_0: p = p_0 \) versus the two-sided alternative. That is, the confidence interval is the set of all \( p_0 \) such that

\[
\left| \frac{\hat{p} - p_0}{\sqrt{n^{-1}\hat{p}(1 - \hat{p})}} \right| \leq z_{\alpha}
\]

The Wilson interval is a variation on the Wald interval, using the null standard error \( \sqrt{n^{-1}p_0(1 - p_0)} \) in place of the estimated standard error \( \sqrt{n^{-1}\hat{p}(1 - \hat{p})} \) in the above expression. Inverting this acceptance region is more complicated yet results in the closed form

\[
\frac{k + z_{\alpha}^2/2}{n + z_{\alpha}^2/2} \pm \frac{z_{\alpha}n^{1/2}}{n + z_{\alpha}^2/2} \left\{ \hat{p}(1 - \hat{p}) + \frac{z_{\alpha}^2}{4n} \right\}^{1/2}
\]

The Agresti–Coull interval is basically a Wald interval that borrows its center from the Wilson interval. Defining \( \tilde{k} = k + z_{\alpha}^2/2 \), \( \tilde{n} = n + z_{\alpha}^2 \), and (hence) \( \tilde{p} = \tilde{k}/\tilde{n} \), the Agresti–Coull interval is

\[
\tilde{p} \pm z_{\alpha} \sqrt{\tilde{p}(1 - \tilde{p})/\tilde{n}}
\]

When \( \alpha = 0.05 \), \( z_{\alpha} \) is near enough to 2 that \( \tilde{p} \) can be thought of as a typical estimate of proportion where two successes and two failures have been added to the sample (Agresti and Coull 1998). This typical estimate of proportion makes the Agresti–Coull interval an easy-to-present alternative for introductory statistics students.

The Jeffreys interval is a Bayesian interval and is based on the Jeffreys prior, which is the Beta\((1/2,1/2)\) distribution. Assigning this prior to \( p \) results in a posterior distribution for \( p \) that is Beta with parameters \( k+1/2 \) and \( n-k+1/2 \). The Jeffreys interval is then taken to be the \( 1 - \alpha/2 \) central posterior probability interval, namely, the \( \alpha/2 \) and \( 1 - \alpha/2 \) quantiles of the Beta\((k+1/2, n-k+1/2)\) distribution. These quantiles may be obtained directly by using Stata’s \text{invibeta()}\ function.

Poisson

Given the total cases, \( k \), the estimate of the expected count \( \lambda \) is \( k \), and its standard error is \( \sqrt{k} \). \( \text{ci} \) calculates the exact confidence interval \([\lambda_1, \lambda_2]\) such that

\[
\Pr(K \geq k|\lambda = \lambda_1) = \alpha/2
\]
Pr(K ≤ k | \lambda = \lambda_2) = \alpha/2

where K is Poisson with mean \lambda. Solution is by Newton’s method. If k = 0, the calculation of \lambda_1 is skipped. All values are then reported as rates, which are the above numbers divided by the total exposure.

Harold Jeffreys (1891–1989) was born near Durham, England, and spent more than 75 years studying and working at the University of Cambridge, principally on theoretical and observational problems in geophysics, astronomy, mathematics, and statistics. He developed a systematic Bayesian approach to inference in his monograph *Theory of Probability*.

Edwin Bidwell (E. B.) Wilson (1879–1964) majored in mathematics at Harvard and studied and taught at Yale and MIT before returning to Harvard in 1922. He worked in mathematics, physics, and statistics. His method for binomial intervals can be considered a precursor, for a particular problem, of Neyman’s concept of confidence intervals.

Jerzy Neyman (1894–1981) was born in Bendery, Russia, now Moldavia. He studied and then taught at Kharkov University, moving from physics to mathematics. In 1921, Neyman moved to Poland, where he worked in statistics at Bydgoszcz and then Warsaw. Neyman received a Rockefeller Fellowship to work with Karl Pearson at University College London. There, he collaborated with Egon Pearson, Karl’s son, on the theory of hypothesis testing. Life in Poland became progressively more difficult, and Neyman returned to UCL to work there from 1934 to 1938. At this time, he published on the theory of confidence intervals. He then was offered a post in California at Berkeley, where he settled. Neyman established an outstanding statistics department and remained highly active in research, including applications in astronomy, meteorology, and medicine. He was one of the great statisticians of the 20th century.

Acknowledgment

We thank Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal* for his assistance with the jeffreys and wilson options.

clogit — Conditional (fixed-effects) logistic regression

Syntax

clogit depvar [indepvars] [if] [in] [weight], group(varname) [options]

Description

Model

*group(varname)  matched group variable
offset(varname)   include varname in model with coefficient constrained to 1
constraints(constraints)  apply specified linear constraints
collinear         keep collinear variables

SE/Robust

vce(vcetype)  vcetype may be oim, robust, cluster clustvar, opg, bootstrap, or jackknife
nonest           do not check that panels are nested within clusters

Reporting

level(#)         set confidence level; default is level(95)
                or report odds ratios
nocnsreport     do not display constraints
display_options control column formats, row spacing, line width, display of omitted
                variables and base and empty cells, and factor-variable labeling

Maximization

maximize_options control the maximization process; seldom used
coeflegend      display legend instead of statistics

*group(varname) is required.

indepvars may contain factor variables; see [U] 11.4.3 Factor variables.

bootstrap, by, fp, jackknife, mfp, mi estimate, nestreg, rolling, statsby, stepwise, and svy are allowed; see [U] 11.1.10 Prefix commands.
vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
vce(), nonest, and weights are not allowed with the svy prefix; see [SVY] svy.

fweights, iweights, and pweights are allowed (see [U] 11.1.6 weight), but they are interpreted to apply to groups
as a whole, not to individual observations. See Use of weights below.

coeftest does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
clogit — Conditional (fixed-effects) logistic regression

Menu
Statistics > Categorical outcomes > Conditional logistic regression

Description
clogit fits what biostatisticians and epidemiologists call conditional logistic regression for matched case-control groups (see, for example, Hosmer, Lemeshow, and Sturdivant [2013, chap. 7]) and what economists and other social scientists call fixed-effects logit for panel data (see, for example, Chamberlain [1980]). Computationally, these models are the same. depvar equal to nonzero and nonmissing (typically depvar equal to one) indicates a positive outcome, whereas depvar equal to zero indicates a negative outcome.

See [R] asclogit if you want to fit McFadden’s choice model (McFadden 1974). Also see [R] logistic for a list of related estimation commands.

Options

**Model**

- `group(varname)` is required; it specifies an identifier variable (numeric or string) for the matched groups. `strata(varname)` is a synonym for `group()`.
- `offset(varname), constraints(constraints), collinear; see [R] estimation options.`

**SE/Robust**

- `vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.
- `nocnsreport; see [R] estimation options.`

**Reporting**

- `level(#); see [R] estimation options.`
- `display_options: nolabel, vsquish, noemptycells, baselevels, allbaselevels, nolfvlabel, fvwrap(#), fvwrapparallelstyle, cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.`

**Maximization**

- `maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.`

Setting the optimization type to `technique(bhhh)` resets the default `vcetype` to `vce(opg).`
The following option is available with `clogit` but is not shown in the dialog box: `coeflegend`; see [R] estimation options.

Remarks and examples

Remarks are presented under the following headings:

- **Introduction**
- **Matched case–control data**
- **Use of weights**
- **Fixed-effects logit**

**Introduction**

`clogit` fits maximum likelihood models with a dichotomous dependent variable coded as 0/1 (more precisely, `clogit` interprets 0 and not 0 to indicate the dichotomy). Conditional logistic analysis differs from regular logistic regression in that the data are grouped and the likelihood is calculated relative to each group; that is, a conditional likelihood is used. See Methods and formulas at the end of this entry.

Biostatisticians and epidemiologists fit these models when analyzing matched case–control studies with 1:1 matching, 1:k_2i matching, or k_1i:k_2i matching, where i denotes the ith matched group for i = 1, 2, ..., n, where n is the total number of groups. `clogit` fits a model appropriate for all of these matching schemes or for any mix of the schemes because the matching k_1i:k_2i can vary from group to group. `clogit` always uses the true conditional likelihood, not an approximation. Biostatisticians and epidemiologists sometimes refer to the matched groups as “strata”, but we will stick to the more generic term “group”.

Economists and other social scientists fitting fixed-effects logit models have data that look exactly like the data biostatisticians and epidemiologists call k_1i:k_2i matched case–control data. In terms of how the data are arranged, k_1i:k_2i matching means that in the ith group, the dependent variable is 1 a total of k_1i times and 0 a total of k_2i times. There are a total of T_i = k_1i + k_2i observations for the ith group. This data arrangement is what economists and other social scientists call “panel data”, “longitudinal data”, or “cross-sectional time-series data”.

So no matter what terminology you use, the computation and the use of the `clogit` command is the same. The following example shows how your data should be arranged to use `clogit`.

**Example 1**

Suppose that we have grouped data with the variable `id` containing a unique identifier for each group. Our outcome variable, `y`, contains 0s and 1s. If we were biostatisticians, `y = 1` would indicate a case, `y = 0` would be a control, and `id` would be an identifier variable that indicates the groups of matched case–control subjects.

If we were economists, `y = 1` might indicate that a person was unemployed at any time during a year and `y = 0`, that a person was employed all year, and `id` would be an identifier variable for persons.
If we list the first few observations of this dataset, it looks like

```
use http://www.stata-press.com/data/r13/clogitid
list y x1 x2 id in 1/11
```

<table>
<thead>
<tr>

Pretending that we are biostatisticians, we describe our data as follows. The first group (id = 1014) consists of four matched persons: 1 case (y = 1) and three controls (y = 0), that is, 1:3 matching. The second group has 1:2 matching, and the third 2:2.

Pretending that we are economists, we describe our data as follows. The first group consists of 4 observations (one per year) for person 1014. This person had a period of unemployment during 1 year of 4. The second person had a period of unemployment during 1 year of 3, and the third had a period of 2 years of 4.

Our independent variables are x1 and x2. To fit the conditional (fixed-effects) logistic model, we type

```
clogit y x1 x2, group(id)
```

```
note: multiple positive outcomes within groups encountered.
```

```
Iteration 0:  log likelihood = -123.42828
Iteration 1:  log likelihood = -123.41386
Iteration 2:  log likelihood = -123.41386
```

```
Conditional (fixed-effects) logistic regression
Number of obs = 369
LR chi2(2) = 9.07
Prob > chi2 = 0.0107
Log likelihood = -123.41386
Pseudo R2 = 0.0355
```

| y | Coef.         | Std. Err. | z   | P>|z| | [95% Conf. Interval] |

⚠️ Technical note

The message “note: multiple positive outcomes within groups encountered” at the top of the clogit output for the previous example merely informs us that we have $k_{1i} : k_{2i}$ matching with $k_{1i} > 1$ for at least one group. If your data should be $1 : k_{2i}$ matched, this message tells you that there is an error in the data somewhere.

We can see the distribution of $k_{1i}$ and $T_i = k_{1i} + k_{2i}$ for the data of the example 1 by using the following steps:
. by id, sort: gen k1 = sum(y)
. by id: replace k1 = . if _n < _N
(303 real changes made, 303 to missing)
. by id: gen T = sum(y<.)
. by id: replace T = . if _n < _N
(303 real changes made, 303 to missing)
. tabulate k1

</table>

We see that \( k_{1i} \) ranges from 1 to 4 and \( T_i \) ranges from 2 to 10 for these data.

Technical note

For \( k_{1i} \); \( k_{2i} \) matching (and hence in the general case of fixed-effects logit), \texttt{clogit} uses a recursive algorithm to compute the likelihood, which means that there are no limits on the size of \( T_i \). However, computation time is proportional to \( \sum T_i \min(k_{1i}, k_{2i}) \), so \texttt{clogit} will take roughly 10 times longer to fit a model with 10:10 matching than one with 1:10 matching. But \texttt{clogit} is fast, so computation becomes an issue only when \( \min(k_{1i}, k_{2i}) \) is around 100 or more. See \textit{Methods and formulas} for details.

Matched case–control data

Here we give a more detailed example of matched case–control data.

Example 2

Hosmer, Lemeshow, and Sturdivant (2013, 24) present data on matched pairs of infants, each pair having one with low birthweight and another with regular birthweight. The data are matched on age of the mother. Several possible maternal exposures are considered: race (three categories), smoking status, presence of hypertension, presence of uterine irritability, previous preterm delivery, and weight at the last menstrual period.
We list the case–control indicator variable, `low`; the match identifier variable, `pairid`; and two of the covariates, `lwt` and `smoke`, for the first 10 observations.

```stata
. list low lwt smoke pairid in 1/10

<table>
<thead>
<tr>
<th>low</th>
<th>lwt</th>
<th>smoke</th>
<th>pairid</th>
</tr>
</thead>
<tbody>

| other| .9750      | .6817263  | -0.04 | 0.971| .2476522 3.838573  |

Smoking, previous preterm delivery, hypertension, uterine irritability, and possibly the mother’s weight all contribute to low birthweight. Race of black and race of other are statistically insignificant when compared with the race of white omitted group, although the race of black effect is large. We can test the joint statistical significance of race being black (2.race) and race being other (3.race) by using test:

. test 2.race 3.race  
( 1) [low]2.race = 0  
( 2) [low]3.race = 0  
chi2( 2) = 0.88  
Prob > chi2 = 0.6436  

For a more complete description of test, see [R] test. test presents results in coefficients rather than odds ratios. Jointly testing that the coefficients on 2.race and 3.race are 0 is equivalent to jointly testing that the odds ratios are 1.  

Here one case was matched to one control, that is, 1:1 matching. From clogit’s point of view, that was not important—$k_1$ cases could have been matched to $k_2$ controls ($k_1:k_2$ matching), and we would have fit the model in the same way. Furthermore, the matching can change from group
to group, which we have denoted as \( k_{1i} : k_{2i} \) matching, where \( i \) denotes the group. clogit does not care. To fit the conditional logistic regression model, we specified the group(varname) option, group(pairid). The case and control are stored in separate observations. clogit knew that they were linked (in the same group) because the related observations share the same value of pairid.

**Technical note**

clogit provides a way to extend McNemar’s test to multiple controls per case \((1: k_{2i} \text{ matching})\) and to multiple controls matched with multiple cases \((k_{1i} : k_{2i} \text{ matching})\).

In Stata, McNemar’s test is calculated by the mcc command; see [ST] epitab. The mcc command, however, requires that the matched case and control appear in one observation, so the data will need to be manipulated from 1 to 2 observations per stratum before using clogit. Alternatively, if you begin with clogit’s 2-observations-per-group organization, you will have to change it to 1 observation per group if you wish to use mcc. In either case, reshape provides an easy way to change the organization of the data. We will demonstrate its use below, but we direct you to [D] reshape for a more thorough discussion.

In example 2, we used clogit to analyze the relationship between low birthweight and various characteristics of the mother. Assume that we now want to assess the relationship between low birthweight and smoking, ignoring the mother’s other characteristics. Using clogit, we obtain the following results:

```
clogit low smoke, group(pairid) or
```

```
Iteration 0: log likelihood = -35.425931
Iteration 1: log likelihood = -35.419283
Iteration 2: log likelihood = -35.419282
```

```
Conditional (fixed-effects) logistic regression
Log likelihood = -35.419282
Number of obs = 112
LR chi2(1) = 6.79
Prob > chi2 = 0.0091
Pseudo R2 = 0.0875
```

| low | Odds Ratio | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|-----|------------|-----------|-------|------|---------------------|
| smoke| 2.75       | 1.135369  | 2.45  | 0.014| 1.224347 to 6.176763 |

Let’s compare our estimated odds ratio and 95% confidence interval with that produced by mcc. We begin by reshaping the data:

```
keep low smoke pairid
reshape wide smoke, i(pairid) j(low 0 1)
```

We now have the variables smoke0 (formed from smoke and low = 0), recording 1 if the control mother smoked and 0 otherwise; and smoke1 (formed from smoke and low = 1), recording 1 if the case mother smoked and 0 otherwise. We can now use mcc:
Both methods estimated the same odds ratio, and the 95% confidence intervals are similar. \texttt{clogit} produced a confidence interval of \([1.22, 6.18]\), whereas \texttt{mcc} produced a confidence interval of \([1.18, 7.14]\).

**Use of weights**

With \texttt{clogit}, weights apply to groups as a whole, not to individual observations. For example, if there is a group in your dataset with a frequency weight of 3, there are a total of three groups in your sample with the same values of the dependent and independent variables as this one group. Weights must have the same value for all observations belonging to the same group; otherwise, an error message will be displayed.

**Example 3**

We use the example from the above discussion of the \texttt{mcc} command. Here we have a total of 56 matched case–control groups, each with one case matched to one control. We had 8 matched pairs in which both the case and the control are exposed, 22 pairs in which the case is exposed and the control is unexposed, 8 pairs in which the case is unexposed and the control is exposed, and 18 pairs in which they are both unexposed.

With weights, it is easy to enter these data into Stata and run \texttt{clogit}. 

```plaintext
.use example3
clogit smokel smoke0
cases | exposed unexposed total
|----------|----------|--------|
exposed   | 8        | 22     | 30     |

Fixed-effects logit

The fixed-effects logit model can be written as

\[ \Pr(y_{it} = 1 \mid x_{it}) = F(\alpha_i + x_{it}\beta) \]

where \( F \) is the cumulative logistic distribution

\[ F(z) = \frac{\exp(z)}{1 + \exp(z)} \]

\( i = 1, 2, \ldots, n \) denotes the independent units (called “groups” by clogit), and \( t = 1, 2, \ldots, T_i \) denotes the observations for the \( i \)th unit (group).

Fitting this model by using a full maximum-likelihood approach leads to difficulties, however. When \( T_i \) is fixed, the maximum likelihood estimates for \( \alpha_i \) and \( \beta \) are inconsistent (Andersen 1970; Chamberlain 1980). This difficulty can be circumvented by looking at the probability of \( y_i = (y_{i1}, \ldots, y_{iT_i}) \) conditional on \( \sum_{t=1}^{T_i} y_{it} \). This conditional probability does not involve the \( \alpha_i \), so they are never estimated when the resulting conditional likelihood is used. See Hamerle and Ronning (1995) for a succinct and lucid development. See Methods and formulas for the estimation equation.
Example 4

We are studying unionization of women in the United States by using the union dataset; see \texttt{[XT] \texttt{xt}}. We fit the fixed-effects logit model:

```
. use http://www.stata-press.com/data/r13/union, clear
   (NLS Women 14-24 in 1968)
. clogit union age grade not_smsa south black, group(idcode)
   note: multiple positive outcomes within groups encountered.
   note: 2744 groups (14165 obs) dropped because of all positive or
        all negative outcomes.
   note: black omitted because of no within-group variance.
```

We received three messages at the top of the output. The first one, “multiple positive outcomes within
groups encountered”, we expected. Our data do indeed have multiple positive outcomes (\texttt{union} = 1)
in many groups. (Here a group consists of all the observations for a particular individual.)

The second message tells us that 2,744 groups were “dropped” by \texttt{clogit}. When either \texttt{union} = 0
or \texttt{union} = 1 for all observations for an individual, this individual’s contribution to the log-likelihood
is zero. Although these are perfectly valid observations in every sense, they have no effect on the
estimation, so they are not included in the total “Number of obs”. Hence, the reported “Number of
obs” gives the effective sample size of the estimation. Here it is 12,035 observations—only 46% of
the total 26,200.

We can easily check that there are indeed 2,744 groups with \texttt{union} either all 0 or all 1. We will
generate a variable that contains the fraction of observations for each individual who has \texttt{union} = 1.
Because $2481 + 263 = 2744$, we confirm what clogit did.

The third warning message from clogit said “black omitted because of no within-group variance”. Obviously, race stays constant for an individual across time. Any such variables are collinear with the $\alpha_i$ (that is, the fixed effects), and just as the $\alpha_i$ drop out of the conditional likelihood, so do all variables that are unchanging within groups. Thus they cannot be estimated with the conditional fixed-effects model.

There are several other estimators implemented in Stata that we could use with these data:

cloglog ..., vce(cluster idcode)
logit ..., vce(cluster idcode)
probit ..., vce(cluster idcode)
scobit ..., vce(cluster idcode)
xtcloglog ...
xtgee ..., family(binomial) link(logit) corr(exchangeable)
xtlogit ...
xtprobit ...

clogit stores the following in e():

Scalars
- \( e(N) \): number of observations
- \( e(N\_drop) \): number of observations dropped because of all positive or all negative outcomes
- \( e(N\_group\_drop) \): number of groups dropped because of all positive or all negative outcomes
- \( e(k) \): number of parameters
- \( e(k\_eq) \): number of equations in \( e(b) \)
- \( e(k\_eq\_model) \): number of equations in overall model test
- \( e(k\_dv) \): number of dependent variables
- \( e(df\_m) \): model degrees of freedom
- \( e(r2\_p) \): pseudo-\( R^2 \)-squared
- \( e(ll) \): log likelihood
- \( e(ll0) \): log likelihood, constant-only model
- \( e(N\_clust) \): number of clusters
- \( e(chi2) \): \( \chi^2 \) test
- \( e(p) \): significance
- \( e(rank) \): rank of \( e(V) \)
- \( e(ic) \): number of iterations
- \( e(rc) \): return code
- \( e(converged) \): 1 if converged, 0 otherwise

Macros
- \( e(cmd) \): clogit
- \( e(cmdline) \): command as typed
- \( e(depvar) \): name of dependent variable
- \( e(group) \): name of group() variable
- \( e(multiple) \): multiple if multiple positive outcomes within group
- \( e(wtype) \): weight type
- \( e(wexp) \): weight expression
- \( e(title) \): title in estimation output
- \( e(clustvar) \): name of cluster variable
- \( e(offset) \): linear offset variable
- \( e(chi2type) \): Wald or LR; type of model \( \chi^2 \) test
- \( e(vce) \): \( vce \)type specified in vce()
- \( e(vcetype) \): title used to label Std. Err.
- \( e(opt) \): type of optimization
- \( e(which) \): \text{max} or \text{min}; whether optimizer is to perform maximization or minimization
- \( e(ml\_method) \): type of \text{ml} method
- \( e(user) \): name of likelihood-evaluator program
- \( e(technique) \): maximization technique
- \( e(properties) \): \text{b V}
### Methods and formulas

Let \( i = 1, 2, \ldots, n \) denote the groups and let \( t = 1, 2, \ldots, T_i \) denote the observations for the \( i \)th group. Let \( y_{it} \) be the dependent variable taking on values 0 or 1. Let \( y_i = (y_{i1}, \ldots, y_{iT_i}) \) be the outcomes for the \( i \)th group as a whole. Let \( x_{it} \) be a row vector of covariates. Let

\[
k_{1i} = \sum_{t=1}^{T_i} y_{it}
\]

be the observed number of ones for the dependent variable in the \( i \)th group. Biostatisticians would say that there are \( k_{1i} \) cases matched to \( k_{2i} = T_i - k_{1i} \) controls in the \( i \)th group.

We consider the probability of a possible value of \( y_i \) conditional on \( \sum_{t=1}^{T_i} y_{it} = k_{1i} \) (Hamerle and Ronning 1995, eq. 8.33; Hosmer, Lemeshow, and Sturdivant 2013, eq. 7.4),

\[
\Pr(y_i \mid \sum_{t=1}^{T_i} y_{it} = k_{1i}) = \frac{\exp\left(\sum_{t=1}^{T_i} y_{it} x_{it} \beta\right)}{\sum_{d_i \in S_i} \exp\left(\sum_{t=1}^{T_i} d_{it} x_{it} \beta\right)}
\]

where \( d_{it} \) is equal to 0 or 1 with \( \sum_{t=1}^{T_i} d_{it} = k_{1i} \), and \( S_i \) is the set of all possible combinations of \( k_{1i} \) ones and \( k_{2i} \) zeros. Clearly, there are \( \binom{T_i}{k_{1i}} \) such combinations, but we need not count all of these combinations to compute the denominator of the above equation. It can be computed recursively.

Denote the denominator by

\[
f_i(T_i, k_{1i}) = \sum_{d_i \in S_i} \exp\left(\sum_{t=1}^{T_i} d_{it} x_{it} \beta\right)
\]

Consider, computationally, how \( f_i \) changes as we go from a total of 1 observation in the group to 2 observations to 3, etc. Doing this, we derive the recursive formula

\[
f_i(T, k) = f_i(T - 1, k) + f_i(T - 1, k - 1) \exp(x_i T \beta)
\]

where we define \( f_i(T, 0) = 0 \) if \( T < k \) and \( f_i(T, 0) = 1 \).
The conditional log-likelihood is

$$\ln L = \sum_{i=1}^{n} \left\{ \sum_{t=1}^{T_i} y_{it} x_{it} \beta - \log f_i(T_i, k_{1i}) \right\}$$

The derivatives of the conditional log-likelihood can also be computed recursively by taking derivatives of the recursive formula for $f_i$.

Computation time is roughly proportional to

$$p^2 \sum_{i=1}^{n} T_i \min(k_{1i}, k_{2i})$$

where $p$ is the number of independent variables in the model. If $\min(k_{1i}, k_{2i})$ is small, computation time is not an issue. But if it is large—say, 100 or more—patience may be required.

If $T_i$ is large for all groups, the bias of the unconditional fixed-effects estimator is not a concern, and we can confidently use `logit` with an indicator variable for each group (provided, of course, that the number of groups does not exceed `matsize`; see [R] `matsize`).

This command supports the clustered version of the Huber/White/sandwich estimator of the variance using `vce(robust)` and `vce(cluster clustvar)`. See [P] `robust`, particularly Maximum likelihood estimators and Methods and formulas. Specifying `vce(robust)` is equivalent to specifying `vce(cluster groupvar)`, where `groupvar` is the variable for the matched groups.

`clogit` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] variance estimation.

</tbody>
</table>

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample)` ... if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when `if e(sample)` is not specified.

Starred statistics are available for multiple controls per case-matching design only. They are not available if `vce(robust)`, `vce(cluster clustvar)`, or `pweights` were specified with `clogit`.

dbeta, dx2, gdbeta, gdx2, hat, and rstandard are not available if `constraints()` was specified with `clogit`.

Menu for predict

```
Statistics > Postestimation > Predictions, residuals, etc.
```

Options for predict

Main

pc1, the default, calculates the probability of a positive outcome conditional on one positive outcome within group.

pu0 calculates the probability of a positive outcome, assuming that the fixed effect is zero.

xb calculates the linear prediction.

stdp calculates the standard error of the linear prediction.

dbeta calculates the Delta-β influence statistic, a standardized measure of the difference in the coefficient vector that is due to deletion of the observation.

dx2 calculates the Delta-χ² influence statistic, reflecting the decrease in the Pearson chi-squared that is due to deletion of the observation.

gdbeta calculates the approximation to the Pregibon stratum-specific Delta-β influence statistic, a standardized measure of the difference in the coefficient vector that is due to deletion of the entire stratum.
_gdx2_ calculates the approximation to the Pregibon stratum-specific Delta-$\chi^2$ influence statistic, reflecting the decrease in the Pearson chi-squared that is due to deletion of the entire stratum.

_hat_ calculates the Hosmer and Lemeshow leverage or the diagonal element of the hat matrix.

_residuals_ calculates the Pearson residuals.

_rstandard_ calculates the standardized Pearson residuals.

_score_ calculates the equation-level score, $\partial \ln L / \partial (x_{it} \beta)$.

_nooffset_ is relevant only if you specified _offset(varname)_ for _clogit_. It modifies the calculations made by _predict_ so that they ignore the offset variable; the linear prediction is treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_j$. This option cannot be specified with _dbeta_, _dx2_, _gdbeta_, _gdx2_, _hat_, and _rstandard_.

### Remarks and examples

_predict_ may be used after _clogit_ to obtain predicted values of the index $x_{it} \beta$. Predicted probabilities for conditional logistic regression must be interpreted carefully. Probabilities are estimated for each group as a whole, not for individual observations. Furthermore, the probabilities are conditional on the number of positive outcomes in the group (that is, the number of cases and the number of controls), or it is assumed that the fixed effect is zero. _predict_ may also be used to obtain influence and lack of fit statistics for an individual observation and for the whole group, to compute Pearson, standardized Pearson residuals, and leverage values.

_predict_ may be used for both within-sample and out-of-sample predictions.

#### Example 1

Suppose that we have $1:k_{2i}$ matched data and that we have previously fit the following model:

```
    . use http://www.stata-press.com/data/r13/clogitid
    . clogit y x1 x2, group(id)
    (output omitted)
```

To obtain the predicted values of the index, we could type _predict idx, xb_ to create a new variable called _idx_. From _idx_, we could then calculate the predicted probabilities. Easier, however, would be to type

```
    . predict phat
    (option pc1 assumed; probability of success given one success within group)
```

_phrat_ would then contain the predicted probabilities.

As noted previously, the predicted probabilities are really predicted probabilities for the group as a whole (that is, they are the predicted probability of observing $y_{it} = 1$ and $y_{it'} = 0$ for all $t' \neq t$). Thus, if we want to obtain the predicted probabilities for the estimation sample, it is important that, when we make the calculation, predictions be restricted to the same sample on which we estimated the data. We cannot predict the probabilities and then just keep the relevant ones because the entire sample determines each probability. Thus, assuming that we are not attempting to make out-of-sample predictions, we type

```
    . predict phat2 if e(sample)
    (option pc1 assumed; probability of success given one success within group)
```
Methods and formulas

Recall that $i = 1, \ldots, n$ denote the groups and $t = 1, \ldots, T_i$ denote the observations for the $i$th group.

predict produces probabilities of a positive outcome within group conditional on there being one positive outcome (pc1),

$$\Pr \left( y_{it} = 1 \left| \sum_{t=1}^{T_i} y_{it} = 1 \right. \right) = \frac{\exp(x_{it}\beta)}{\sum_{t=1}^{T_i} \exp(x_{it}\beta)}$$

or predict calculates the unconditional $pu_0$:

$$\Pr(y_{it} = 1) = \frac{\exp(x_{it}\beta)}{1 + \exp(x_{it}\beta)}$$

Let $N = \sum_{j=1}^{n} T_j$ denote the total number of observations, $p$ denote the number of covariates, and $\hat{\theta}_{it}$ denote the conditional predicted probabilities of a positive outcome (pc1).

For the multiple control per case (1 : $k_{2i}$) matching, Hosmer, Lemeshow, and Sturdivant (2013, 248–251) propose the following diagnostics:

The Pearson residual is

$$r_{it} = \frac{(y_{it} - \hat{\theta}_{it})}{\sqrt{\hat{\theta}_{it}}}$$

The leverage (hat) value is defined as

$$h_{it} = \frac{\hat{\theta}_{it}\tilde{x}_{it}^T(\tilde{X}^T U \tilde{X})^{-1}\tilde{x}_{it}}{\hat{\theta}_{it}}$$

where $\tilde{x}_{it} = x_{it} - \sum_{j=1}^{T_i} x_{ij}\hat{\theta}_{ij}$ is the $1 \times p$ row vector of centered by a weighted stratum-specific mean covariate values, $U_N = \text{diag}\{\hat{\theta}_{it}\}$, and the rows of $\tilde{X}_{N \times p}$ are composed of $\tilde{x}_{it}$ values.

The standardized Pearson residual is

$$r_{sit} = \frac{r_{it}}{\sqrt{1 - h_{it}}}$$

The lack of fit and influence diagnostics for an individual observation are (respectively) computed as

$$\Delta \chi^2_{it} = r_{sit}^2$$

and

$$\Delta \hat{\beta}_{it} = \Delta \chi^2_{it} \frac{h_{it}}{1 - h_{it}}$$

The lack of fit and influence diagnostics for the groups are the group-specific totals of the respective individual diagnostics shown above.

cloglog — Complementary log-log regression

Syntax

cloglog depvar [indepvars] [if] [in] [weight] [, options]

options Description

Model
   noconstant suppress constant term
   offset(varname) include varname in model with coefficient constrained to 1
   asis retain perfect predictor variables
   constraints(constraints) apply specified linear constraints
   collinear keep collinear variables

SE/Robust
   vce(vcetype) vcetype may be oim, robust, cluster clustvar, opg, bootstrap, or jackknife

Reporting
   level(#) set confidence level; default is level(95)
   eform report exponentiated coefficients
   noconsreport do not display constraints
   display_options control column formats, row spacing, line width, display of omitted
   variables and base and empty cells, and factor-variable labeling

Maximization
   maximize_options control the maximization process; seldom used
   coeflegend display legend instead of statistics

indeps may contain factor variables; see [U] 11.4.3 Factor variables.
depvar and indeps may contain time-series operators; see [U] 11.4.4 Time-series varlists.
bootstrap, by, fp, jackknife, mi estimate, nestreg, rolling, statsby, stepwise, and svy are allowed; see [U] 11.1.10 Prefix commands.
vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
vce() and weights are not allowed with the svy prefix; see [SVY] svy.
fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.
coeflegend does not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
Menu

Statistics > Binary outcomes > Complementary log-log regression

Description

cloglog fits maximum-likelihood complementary log-log models.

See [R] logistic for a list of related estimation commands.

Options

**Model**

- `noconstant`, `offset(varname)`; see [R] estimation options.
- `asis` forces retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see [R] probit.
- `constraints(constraints)`, `collinear`; see [R] estimation options.

**SE/Robust**

- `vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] `vce_option`.

**Reporting**

- `level(#)`; see [R] estimation options.
- `eform` displays the exponentiated coefficients and corresponding standard errors and confidence intervals.
- `nocnsreport`; see [R] estimation options.

**display_options**: `nomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fwrap(#)`, `fwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] estimation options.

**Maximization**

- `maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] maximize. These options are seldom used.

Setting the optimization type to `technique(bhhh)` resets the default `vcetype` to `vce(opg)`.

The following option is available with cloglog but is not shown in the dialog box:
- `coeflegend`; see [R] estimation options.
Remarks and examples

Remarks are presented under the following headings:

Introduction to complementary log-log regression
Robust standard errors

Introduction to complementary log-log regression

cloglog fits maximum likelihood models with dichotomous dependent variables coded as 0/1 (or, more precisely, coded as 0 and not 0).

Example 1

We have data on the make, weight, and mileage rating of 22 foreign and 52 domestic automobiles. We wish to fit a model explaining whether a car is foreign based on its weight and mileage. Here is an overview of our data:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. keep make mpg weight foreign
. describe
Contains data from http://www.stata-press.com/data/r13/auto.dta
obs: 74 1978 Automobile Data
vars: 4 13 Apr 2013 17:45
size: 1,702 (_dta has notes)

 storage display value
variable name type format label variable label
make str18 %-18s Make and Model
mpg int %8.0g Mileage (mpg)
weight int %8.0g Weight (lbs.)
foreign byte %8.0g origin Car type
```

Sorted by:  foreign
Note: dataset has changed since last saved

```
. inspect foreign
foreign: Car type

```

(2 unique values)

foreign is labeled and all values are documented in the label.

The variable foreign takes on two unique values, 0 and 1. The value 0 denotes a domestic car, and 1 denotes a foreign car.
The model that we wish to fit is

$$\Pr(\text{foreign} = 1) = F(\beta_0 + \beta_1 \text{weight} + \beta_2 \text{mpg})$$

where $F(z) = 1 - \exp\{-\exp(z)\}$.

To fit this model, we type

```
cloglog foreign weight mpg
```

Iteration 0:  log likelihood = -34.054593
Iteration 1:  log likelihood = -27.869915
Iteration 2:  log likelihood = -27.742997
Iteration 3:  log likelihood = -27.742769
Iteration 4:  log likelihood = -27.742769

We find that heavier cars are less likely to be foreign and that cars yielding better gas mileage are also less likely to be foreign, at least when holding the weight of the car constant.

See [R] maximize for an explanation of the output.

Technical note

Stata interprets a value of 0 as a negative outcome (failure) and treats all other values (except missing) as positive outcomes (successes). Thus, if your dependent variable takes on the values 0 and 1, 0 is interpreted as failure and 1 as success. If your dependent variable takes on the values 0, 1, and 2, 0 is still interpreted as failure, but both 1 and 2 are treated as successes.

If you prefer a more formal mathematical statement, when you type cloglog y x, Stata fits the model

$$\Pr(y_j \neq 0 \mid x_j) = 1 - \exp\{-\exp(x_j \beta)\}$$

Robust standard errors

If you specify the vce(robust) option, cloglog reports robust standard errors, as described in [U] 20.21 Obtaining robust variance estimates. For the model of foreign on weight and mpg, the robust calculation increases the standard error of the coefficient on mpg by 44%:
Without `vce(robust)`, the standard error for the coefficient on `mpg` was reported to be 0.076, with a resulting confidence interval of $[-0.29, 0.01]$.

The `vce(cluster clustvar)` option can relax the independence assumption required by the complementary log-log estimator to being just independence between clusters. To demonstrate this ability, we will switch to a different dataset.

We are studying unionization of women in the United States by using the `union` dataset; see `[XT] xt`. We fit the following model, ignoring that women are observed an average of 5.9 times each in this dataset:

```stata
. use http://www.stata-press.com/data/r13/union, clear
(NLS Women 14-24 in 1968)
. cloglog union age grade not_smsa south##c.year
```

Without `vce(robust)`, the standard error for the coefficient on `mpg` was reported to be 0.076, with a resulting confidence interval of $[-0.29, 0.01]$.

The `vce(cluster clustvar)` option can relax the independence assumption required by the complementary log-log estimator to being just independence between clusters. To demonstrate this ability, we will switch to a different dataset.

We are studying unionization of women in the United States by using the `union` dataset; see `[XT] xt`. We fit the following model, ignoring that women are observed an average of 5.9 times each in this dataset:

```stata
. use http://www.stata-press.com/data/r13/union, clear
(NLS Women 14-24 in 1968)
. cloglog union age grade not_smsa south##c.year
```
The reported standard errors in this model are probably meaningless. Women are observed repeatedly, and so the observations are not independent. Looking at the coefficients, we find a large southern effect against unionization and a different time trend for the south. The `vce(cluster clustvar)` option provides a way to fit this model and obtains correct standard errors:

```plaintext
cloglog union age grade not_smsa south##c.year, vce(cluster id) nolog

Complementary log-log regression
Number of obs = 26200
Zero outcomes = 20389
Nonzero outcomes = 5811
Wald chi2(6) = 160.76
Log pseudolikelihood = -13540.607 Prob > chi2 = 0.0000
(Std. Err. adjusted for 4434 clusters in idcode)

Robust

| _cons     | -1.488278  | 0.4468005  | -3.33 | 0.001 | -2.363991 - 0.6125652 |
```

The coefficient estimates are similar, but these standard errors are smaller than those produced by `cloglog, vce(cluster clustvar)` This finding is as we would expect. If the within-panel correlation assumptions are valid, the population-averaged estimator should be more efficient.
In addition to this estimator, we may use the `xtgee` command to fit a panel estimator (with complementary log-log link) and any number of assumptions on the within-idcode correlation.

`cloglog`, `vce(cluster clustvar)` is robust to assumptions about within-cluster correlation. That is, it inefficiently sums within cluster for the standard-error calculation rather than attempting to exploit what might be assumed about the within-cluster correlation (as do the `xtgee` population-averaged models).

### Stored results

`cloglog` stores the following in `e()`:

**Scalars**
- `e(N)` number of observations
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_dv)` number of dependent variables
- `e(N_f)` number of zero outcomes
- `e(N_s)` number of nonzero outcomes
- `e(df_m)` model degrees of freedom
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(p)` significance
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

**Macros**
- `e(cmd)` `cloglog`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(offset)` linear offset variable
- `e(chi2type)` Wald or LR; type of model $\chi^2$ test
- `e(vcetype)` vcetype specified in `vce()`
- `e(vce)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` max or min; whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of ml method
- `e(user)` name of likelihood-evaluator program
- `e(technique)` maximization technique
- `e(properties)` `b V`
- `e(predict)` program used to implement predict
- `e(asbalanced)` factor variables fvset as asbalanced
- `e(asobserved)` factor variables fvset as asobserved

**Matrices**
- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(ilog)` iteration log (up to 20 iterations)
- `e(gradient)` gradient vector
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

**Functions**
- `e(sample)` marks estimation sample
Methods and formulas

Complementary log-log analysis (related to the gompit model, so named because of its relationship to the Gompertz distribution) is an alternative to logit and probit analysis, but it is unlike these other estimators in that the transformation is not symmetric. Typically, this model is used when the positive (or negative) outcome is rare.

The log-likelihood function for complementary log-log is

$$\ln L = \sum_{j \in S} w_j \ln F(x_j \beta) + \sum_{j \not\in S} w_j \ln \{1 - F(x_j \beta)\}$$

where $S$ is the set of all observations $j$ such that $y_j \neq 0$, $F(z) = 1 - \exp \{- \exp(z)\}$, and $w_j$ denotes the optional weights. $\ln L$ is maximized as described in \textbf{[R] maximize}.

We can fit a gompit model by reversing the success–failure sense of the dependent variable and using \texttt{cloglog}.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \textbf{[P] _robust}, particularly \textit{Maximum likelihood estimators} and \textit{Methods and formulas}. The scores are calculated as $u_j = [\exp(x_j \beta) \exp \{- \exp(x_j \beta)\} / F(x_j \beta)]x_j$ for the positive outcomes and $\{- \exp(x_j \beta)\}x_j$ for the negative outcomes.

\texttt{cloglog} also supports estimation with survey data. For details on VCEs with survey data, see \textbf{[SVY] variance estimation}.

Acknowledgment

We thank Joseph Hilbe of Arizona State University for providing the inspiration for the \texttt{cloglog} command (Hilbe 1996, 1998).

1 `forecast` is not appropriate with `mi` or `svy` estimation results.
2 `lrtest` is not appropriate with `svy` estimation results.
Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>probability of a positive outcome; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td>score</td>
<td>first derivative of the log likelihood with respect to $x_j\beta$</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

- **Main**
  - `pr`, the default, calculates the probability of a positive outcome.
  - `xb` calculates the linear prediction.
  - `stdp` calculates the standard error of the linear prediction.
  - `score` calculates the equation-level score, $\frac{\partial \ln L}{\partial (x_j\beta)}$.
  - `nooffset` is relevant only if you specified `offset(\text{varname})` for `cloglog`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $x_j\beta$ rather than as $x_j\beta + \text{offset}_j$.

Remarks and examples

Once you have fit a model, you can obtain the predicted probabilities by using the `predict` command for both the estimation sample and other samples; see [U] 20 Estimation and postestimation commands and [R] `predict`. Here we will make only a few comments.

- `predict` without arguments calculates the predicted probability of a positive outcome. With the `xb` option, it calculates the linear combination $x_j\beta$, where $x_j$ are the independent variables in the $j$th observation and $\beta$ is the estimated parameter vector.

- With the `stdp` option, `predict` calculates the standard error of the linear prediction, which is not adjusted for replicated covariate patterns in the data.

> Example 1

In example 1 in [R] `cloglog`, we fit the complementary log-log model `cloglog foreign weight mpg`. To obtain predicted probabilities,
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. cloglog foreign weight mpg
   (output omitted)
. predict p
   (option pr assumed; Pr(foreign))
. summarize foreign p

|             | mse1 force MSE to be 1 |
|             | coeflegend display legend instead of statistics |

*"constraints(constraints)" is required.

**indevars** may contain factor variables; see [U] 11.4.3 Factor variables.

**depvar** and **indevars** may contain time-series operators; see [U] 11.4.4 Time-series varlists.

bootstrap, by, fp, jackknife, mi estimate, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.

vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate.

With the fp prefix (see [R] fp), constraints cannot be specified for the variable containing fractional polynomial terms.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

aweights are not allowed with the jackknife prefix; see [R] jackknife.

vce(), mse1, and weights are not allowed with the svy prefix; see [SVY] svy.

aweights, fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.

mse1 and coeflegend do not appear in the dialog.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

308
Menu

Statistics  >  Linear models and related  >  Constrained linear regression

Description
cnsreg fits constrained linear regression models.

Options

- **Model**
  - constraints(constraints), collinear, noconstant; see [R] estimation options.

- **SE/Robust**
  - vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (ols), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.
    - vce(ols), the default, uses the standard variance estimator for ordinary least-squares regression.

- **Reporting**
  - level(#); see [R] estimation options.
  - nocnsreport; see [R] estimation options.

  *display_options:* noomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%)fmt, pformat(%)fmt, sformat(%)fmt, and nolstretch; see [R] estimation options.

The following options are available with cnsreg but are not shown in the dialog box:

- **mse1** is used only in programs and ado-files that use cnsreg to fit models other than constrained linear regression. mse1 sets the mean squared error to 1, thus forcing the variance–covariance matrix of the estimators to be \((X'DX)^{-1}\) (see Methods and formulas in [R] regress) and affecting calculated standard errors. Degrees of freedom for \(t\) statistics are calculated as \(n\) rather than \(n - p + c\), where \(p\) is the total number of parameters (prior to restrictions and including the constant) and \(c\) is the number of constraints.

- mse1 is not allowed with the svy prefix.

- coeflegend; see [R] estimation options.

Remarks and examples

For a discussion of constrained linear regression, see Greene (2012, 121–122); Hill, Griffiths, and Lim (2011, 231–233); or Davidson and MacKinnon (1993, 17).
Example 1: One constraint

In principle, we can obtain constrained linear regression estimates by modifying the list of independent variables. For instance, if we wanted to fit the model

\[ \text{mpg} = \beta_0 + \beta_1 \text{price} + \beta_2 \text{weight} + u \]

and constrain \( \beta_1 = \beta_2 \), we could write

\[ \text{mpg} = \beta_0 + \beta_1 (\text{price} + \text{weight}) + u \]

and run a regression of \( \text{mpg} \) on \( \text{price} + \text{weight} \). The estimated coefficient on the sum would be the constrained estimate of \( \beta_1 \) and \( \beta_2 \). Using \texttt{cnsreg}, however, is easier:

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. constraint 1 price = weight
. cnsreg mpg price weight, constraint(1)
```

```
+---------------------------------------------+
|                    |    |    |            |               |               |
|                    | Coef. | Std. Err. | t    | P>|t|   | [95% Conf. Interval] |
| Price             |  .0009875 |  .0001611 | -6.13 |   0.000 |   -.0013086   -.0006664 |
| Weight            |  .0009875 |  .0001611 | -6.13 |   0.000 |   -.0013086   -.0006664 |
| Constant          |  30.36718 |  1.577958 | 19.24 |   0.000 |    27.22158    33.51278 |
+---------------------------------------------+
```

We define constraints by using the \texttt{constraint} command; see \texttt{[R] constraint}. We fit the model with \texttt{cnsreg} and specify the constraint number or numbers in the \texttt{constraints()} option.

Just to show that the results above are correct, here is the result of applying the constraint by hand:

```
. generate x = price + weight
. regress mpg x
```

```
+--------------------------------------------------+
|                        |   |    |            |               |               |
|                        | Coef. | Std. Err. | t   | P>|t|   | [95% Conf. Interval] |
| Price                 |  .0009875 |  .0001611 | -6.13 |   0.000 |   -.0013086   -.0006664 |
| Constant              |  30.36718 |  1.577958 | 19.24 |   0.000 |    27.22158    33.51278 |
+--------------------------------------------------+
```
Example 2: Multiple constraints

Models can be fit subject to multiple simultaneous constraints. We simply define the constraints and then include the constraint numbers in the `constraints()` option. For instance, say that we wish to fit the model

\[ \text{mpg} = \beta_0 + \beta_1 \text{price} + \beta_2 \text{weight} + \beta_3 \text{displ} + \beta_4 \text{gear\_ratio} + \beta_5 \text{foreign} + \beta_6 \text{length} + u \]

subject to the constraints

\[ \beta_1 = \beta_2 = \beta_3 = \beta_6 \]

\[ \beta_4 = -\beta_5 = \beta_0 / 20 \]

(This model, like the one in example 1, is admittedly senseless.) We fit the model by typing

```
. constraint 1 price=weight
. constraint 2 displ=weight
. constraint 3 length=weight
. constraint 5 gear\_ratio = -foreign
. constraint 6 gear\_ratio = _cons/20
. cnsreg mpg price weight displ gear\_ratio foreign length, c(1-3,5-6)
```

```
Constrained linear regression
Number of obs = 74
F( 2, 72) = 785.20
Prob > F = 0.0000
Root MSE = 4.6823

( 1) price - weight = 0
( 2) - weight + displacement = 0
( 3) - weight + length = 0
( 4) gear\_ratio + foreign = 0
( 5) gear\_ratio - .05*_cons = 0

| mpg         | Coef.    | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|-------------|----------|-----------|-------|------|----------------------|
| price       | -.000923 | .0001534  | -6.02 | 0.000 | -.0012288 to -.0006172 |
| weight      | -.000923 | .0001534  | -6.02 | 0.000 | -.0012288 to -.0006172 |
| displ       | -.000923 | .0001534  | -6.02 | 0.000 | -.0012288 to -.0006172 |
| gear\_ratio | 1.326114 | .0687589  | 19.29 | 0.000 | 1.189046 to 1.463183  |
| foreign     | -1.326114| .0687589  | -19.29| 0.000 | -1.463183 to -1.189046|
| length      | -.000923 | .0001534  | -6.02 | 0.000 | -.0012288 to -.0006172 |
| _cons       | 26.52229 | 1.375178  | 19.29 | 0.000 | 23.78092 to 29.26365  |
```

There are many ways we could have specified the `constraints()` option (which we abbreviated `c()` above). We typed `c(1-3,5-6)`, meaning that we want constraints 1 through 3 and 5 and 6; those numbers correspond to the constraints we defined. The only reason we did not use the number 4 was to emphasize that constraints do not have to be consecutively numbered. We typed `c(1-3,5-6)`, but we could have typed `c(1,2,3,5,6)` or `c(1-3,5,6)` or `c(1-2,3,5,6)` or even `c(1-6)`, which would have worked as long as constraint 4 was not defined. If we had previously defined a constraint 4, then `c(1-6)` would have included it.
**Stored results**

`cnsreg` stores the following in `e()`:

**Scalars**
- `e(N)` number of observations
- `e(df_m)` model degrees of freedom
- `e(df_r)` residual degrees of freedom
- `e(F)` $F$ statistic
- `e(rmse)` root mean squared error
- `e(ll)` log likelihood
- `e(N_clust)` number of clusters
- `e(rank)` rank of `e(V)`

**Macros**
- `e(cmd)` `cnsreg`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(vce)` `vcetype` specified in `vce()`
- `e(vctype)` title used to label Std. Err.
- `e(properties)` `b V`
- `e(predict)` program used to implement predict
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

**Matrices**
- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

**Functions**
- `e(sample)` marks estimation sample

**Methods and formulas**

Let $n$ be the number of observations, $p$ be the total number of parameters (prior to restrictions and including the constant), and $c$ be the number of constraints. The coefficients are calculated as $b' = T\{(T'X'WXT)^{-1}(T'X'Wy - T'X'WXa')\} + a'$, where $T$ and $a$ are as defined in `[P] makecns`, and $W = I$ if no weights are specified. If weights are specified, let $v$: $1 \times n$ be the specified weights. If `fweight` frequency weights are specified, $W = \text{diag}(v)$. If analytic weights are specified, then $W = \text{diag}[v/(1'v)(1'1)]$, meaning that the weights are normalized to sum to the number of observations.

The mean squared error is $s^2 = (y'Wy - 2b'X'Wy + b'X'WXb)/(n - p + c)$. The variance–covariance matrix is $s^2T(T'X'WXT)^{-1}T'$.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See `[P] _robust`, particularly `Introduction` and `Methods and formulas`.

`cnsreg` also supports estimation with survey data. For details on VCEs with survey data, see `[SVY] variance estimation`.

### Description

The following postestimation commands are available after `cnsreg`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>contrast</td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td>estat ic</td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td>estat summarize</td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td>estat vce</td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td>estat (svy)</td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td>estimates</td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td>forecast(^1)</td>
<td>dynamic forecasts and simulations</td>
</tr>
<tr>
<td>lincom</td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td>linktest</td>
<td>link test for model specification</td>
</tr>
<tr>
<td>lrtest(^2)</td>
<td>likelihood-ratio test</td>
</tr>
<tr>
<td>margins</td>
<td>marginal means, predictive margins, marginal effects, and average marginal effects</td>
</tr>
<tr>
<td>marginsplot</td>
<td>graph the results from margins (profile plots, interaction plots, etc.)</td>
</tr>
<tr>
<td>nlcom</td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td>predict</td>
<td>predictions, residuals, influence statistics, and other diagnostic measures</td>
</tr>
<tr>
<td>predictnl</td>
<td>point estimates, standard errors, testing, and inference for generalized predictions</td>
</tr>
<tr>
<td>pwcompare</td>
<td>pairwise comparisons of estimates</td>
</tr>
<tr>
<td>suest</td>
<td>seemingly unrelated estimation</td>
</tr>
<tr>
<td>test</td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td>testnl</td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

\(^1\) `forecast` is not appropriate with `mi` or `svy` estimation results.

\(^2\) `lrtest` is not appropriate with `svy` estimation results.
Syntax for predict

```
predict [type] newvar [if] [in] [ , statistic ]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>xb</code></td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td><code>residuals</code></td>
<td>residuals</td>
</tr>
<tr>
<td><code>stdp</code></td>
<td>standard error of the prediction</td>
</tr>
<tr>
<td><code>stdf</code></td>
<td>standard error of the forecast</td>
</tr>
<tr>
<td><code>pr(a,b)</code></td>
<td>$\Pr(a &lt; y_j &lt; b)$</td>
</tr>
<tr>
<td><code>e(a,b)</code></td>
<td>$E(y_j</td>
</tr>
<tr>
<td><code>ystar(a,b)</code></td>
<td>$E(y^<em>_j)$, $y^</em>_j = \max{a, \min(y_j, b)}$</td>
</tr>
<tr>
<td><code>score</code></td>
<td>equivalent to residuals</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

`stdf` is not allowed with `svy` estimation results.

where $a$ and $b$ may be numbers or variables; $a$ missing ($a \geq .$) means $-\infty$, and $b$ missing ($b \geq .$) means $+\infty$; see [U] 12.2.1 Missing values.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

<table>
<thead>
<tr>
<th>Main</th>
<th>xb, the default, calculates the linear prediction.</th>
</tr>
</thead>
<tbody>
<tr>
<td>residuals</td>
<td>calculates the residuals, that is, $y_j - \mathbf{x}_j \mathbf{b}$.</td>
</tr>
<tr>
<td>stdp</td>
<td>calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.</td>
</tr>
</tbody>
</table>
| stdf | calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by `stdf` are always larger than those produced by `stdp`; see Methods and formulas in [R] regress postestimation.
| `pr(a,b)` | calculates $\Pr(a < \mathbf{x}_j \mathbf{b} + u_j < b)$, the probability that $y_j | \mathbf{x}_j$ would be observed in the interval $(a,b)$. |

$a$ and $b$ may be specified as numbers or variable names; $lb$ and $ub$ are variable names; `pr(20,30)` calculates $\Pr(20 < \mathbf{x}_j \mathbf{b} + u_j < 30)$; `pr(lb,ub)` calculates $\Pr(lb < \mathbf{x}_j \mathbf{b} + u_j < ub)$; and `pr(20,ub)` calculates $\Pr(20 < \mathbf{x}_j \mathbf{b} + u_j < ub)$.

$a$ missing ($a \geq .$) means $-\infty$; `pr(.,30)` calculates $\Pr(-\infty < \mathbf{x}_j \mathbf{b} + u_j < 30)$; `pr(lb,30)` calculates $\Pr(-\infty < \mathbf{x}_j \mathbf{b} + u_j < 30)$ in observations for which $lb \geq .$. and calculates $\Pr(lb < \mathbf{x}_j \mathbf{b} + u_j < 30)$ elsewhere.
\( b \) missing (\( b \geq . \)) means \(+\infty\); \( \text{pr}(20, .) \) calculates \( \Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20) \); 
\( \text{pr}(20, ub) \) calculates \( \Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20) \) in observations for which \( ub \geq . \) and calculates \( \Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < ub) \) elsewhere.

\( \text{e}(a,b) \) calculates \( E(\mathbf{x}_j\mathbf{b} + u_j | a < \mathbf{x}_j\mathbf{b} + u_j < b) \), the expected value of \( y_j|\mathbf{x}_j \) conditional on \( y_j|\mathbf{x}_j \) being in the interval \( (a,b) \), meaning that \( y_j|\mathbf{x}_j \) is truncated. \( a \) and \( b \) are specified as they are for \( \text{pr}() \).

\( \text{ystar}(a,b) \) calculates \( E(y_j^*) \), where \( y_j^* = a \) if \( \mathbf{x}_j\mathbf{b} + u_j \leq a \), \( y_j^* = b \) if \( \mathbf{x}_j\mathbf{b} + u_j \geq b \), and \( y_j^* = \mathbf{x}_j\mathbf{b} + u_j \) otherwise, meaning that \( y_j^* \) is censored. \( a \) and \( b \) are specified as they are for \( \text{pr}() \).

\text{score} is equivalent to \text{residuals} for linear regression models.

[U] 20 Estimation and postestimation commands
**Syntax**

*Define constraints*

\[
\text{constraint} \ [\text{define}] \ # \ [\text{exp}=\text{exp} | \text{coefficientlist}]
\]

*List constraints*

\[
\text{constraint} \ \text{dir} \ [\text{numlist} | \text{all}]
\]

\[
\text{constraint} \ \text{list} \ [\text{numlist} | \text{all}]
\]

*Drop constraints*

\[
\text{constraint} \ \text{drop} \ \{\text{numlist} | \text{all}\}
\]

*Programmer’s commands*

\[
\text{constraint} \ \text{get} \ #
\]

\[
\text{constraint} \ \text{free}
\]

where \text{coefficientlist} is as defined in [R] \text{test} and \# is restricted to the range 1–1,999, inclusive.

**Menu**

Statistics > Other > Manage constraints

**Description**

\text{constraint} defines, lists, and drops linear constraints. Constraints are for use by models that allow constrained estimation.

Constraints are defined by the \text{constraint} command. The currently defined constraints can be listed by either \text{constraint list} or \text{constraint dir}; both do the same thing. Existing constraints can be eliminated by \text{constraint drop}.

\text{constraint get} and \text{constraint free} are programmer’s commands. \text{constraint get} returns the contents of the specified constraint in macro \text{r(contents)} and returns in scalar \text{r(defined)} 0 or 1—1 being returned if the constraint was defined. \text{constraint free} returns the number of a free (unused) constraint in macro \text{r(free)}.
Remarks and examples

Using constraints is discussed in [R] cnsreg, [R] mlogit, and [R] reg3; this entry is concerned only with practical aspects of defining and manipulating constraints.

Example 1

Constraints are numbered from 1 to 1,999, and we assign the number when we define the constraint:

```
. use http://www.stata-press.com/data/r13/sysdsn1
(Health insurance data)
. constraint 2 [indemnity]2.site = 0
```

The currently defined constraints can be listed by `constraint list`:

```
. constraint list
  2: [indemnity]2.site = 0
```

`constraint drop` drops constraints:

```
. constraint drop 2
. constraint list
```

The empty list after `constraint list` indicates that no constraints are defined. Below we demonstrate the various syntaxes allowed by `constraint`:

```
. constraint 1 [Indemnity]
. constraint 10 [Indemnity]: 1.site 2.site
. constraint 11 [Indemnity]: 3.site
. constraint 21 [Prepaid=Uninsure]: nonwhite
. constraint 30 [Prepaid]
. constraint 31 [Insure]
. constraint list
  1: [Indemnity]
  10: [Indemnity]: 1.site 2.site
  11: [Indemnity]: 3.site
  21: [Prepaid=Uninsure]: nonwhite
  30: [Prepaid]
  31: [Insure]
. constraint drop 21-25, 31
. constraint list
  1: [Indemnity]
  10: [Indemnity]: 1.site 2.site
  11: [Indemnity]: 3.site
  30: [Prepaid]
. constraint drop _all
. constraint list
```

Technical note

The `constraint` command does not check the syntax of the constraint itself because a constraint can be interpreted only in the context of a model. Thus `constraint` is willing to define constraints that later will not make sense. Any errors in the constraints will be detected and mentioned at the time of estimation.

[R] cnsreg — Constrained linear regression
Syntax

contrast termlist [ , options ]

where termlist is a list of factor variables or interactions that appear in the current estimation results. The variables may be typed with or without contrast operators, and you may use any factor-variable syntax:

See the operators (op.) table below for the list of contrast operators.

options Description

Main
overall add a joint hypothesis test for all specified contrasts
asobserved treat all factor variables as observed
lincom treat user-defined contrasts as linear combinations

Equations
equation(eqspec) perform contrasts in termlist for equation eqspec
atequations perform contrasts in termlist within each equation

Advanced
emptycells(empspec) treatment of empty cells for balanced factors
noestimcheck suppress estimability checks

Reporting
level(#) confidence level; default is level(95)
mcompare(method) adjust for multiple comparisons; default is mcompare(noadjust)
noeffects suppress table of individual contrasts
cieffects show effects table with confidence intervals
pveffects show effects table with \( p \)-values
effects show effects table with confidence intervals and \( p \)-values
nowald suppress table of Wald tests
noatlevels report only the overall Wald test for terms that use the within \( @ \) or nested | operator

nosvyadjust compute unadjusted Wald tests for survey results
sort sort the individual contrast values in each term
post post contrasts and their VCEs as estimation results
display_options control column formats, row spacing, line width, and factor-variable labeling
eform_option report exponentiated contrasts
df(#) use \( t \) distribution with \( \# \) degrees of freedom for computing \( p \)-values and confidence intervals

df(#) does not appear in the dialog box.

</tr>
</tbody>
</table>
A, B, C, and D represent any factor variable in the current estimation results.
x and y represent any continuous variable in the current estimation results.

* r. and g. represent any contrast operator. See the table below.

* c. specifies that a variable be treated as continuous; see [U] 11.4.3 Factor variables.

Operators are allowed on any factor variable that does not appear to the right of @ or |. Operators decompose the effects of the associated factor variable into one-degree-of-freedom effects (contrasts).

Higher-level interactions are allowed anywhere an interaction operator (#) appears in the table.

Time-series operators are allowed if they were used in the estimation.

_eqns designates the equations in manova, mlogit, mprobit, and mvreg and can be specified anywhere a factor variable appears.

/ is allowed only after anova, cnsreg, manova, mvreg, or regress.

<table>
<thead>
<tr>
<th>operators (op.)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>r.</td>
<td>differences from the reference (base) level; the default</td>
</tr>
<tr>
<td>a.</td>
<td>differences from the next level (adjacent contrasts)</td>
</tr>
<tr>
<td>ar.</td>
<td>differences from the previous level (reverse adjacent contrasts)</td>
</tr>
</tbody>
</table>

As-balanced operators

| g.              | differences from the balanced grand mean |
| h.              | differences from the balanced mean of subsequent levels (Helmert contrasts) |
| j.              | differences from the balanced mean of previous levels (reverse Helmert contrasts) |
| p.              | orthogonal polynomial in the level values |
| q.              | orthogonal polynomial in the level sequence |

As-observed operators

| gw.            | differences from the observation-weighted grand mean |
| hw.            | differences from the observation-weighted mean of subsequent levels |
| jw.            | differences from the observation-weighted mean of previous levels |
| pw.            | observation-weighted orthogonal polynomial in the level values |
| qw.            | observation-weighted orthogonal polynomial in the level sequence |

One or more individual contrasts may be selected by using the op#. or op(numlist). syntax. For example, a3.A selects the adjacent contrast for level 3 of A, and p(1/2).B selects the linear and quadratic effects of B. Also see Orthogonal polynomial contrasts and Beyond linear models.

Custom contrasts

| {A numlist}     | user-defined contrast on the levels of factor A |
| {A#B numlist}   | user-defined contrast on the levels of the interaction between A and B |

Custom contrasts may be part of a term, such as {A numlist}#B, {A numlist}@B, {A numlist}|B, {A#B numlist}, and {A numlist}#{B numlist}. The same is true of higher-order custom contrasts, such as {A#B numlist}@C, {A#B numlist}#r.C, and {A#B numlist}#c.x.

Higher-order interactions with at most eight factor variables are allowed with custom contrasts.

### Description

**contrast** tests linear hypotheses and forms contrasts involving factor variables and their interactions from the most recently fit model. The tests include ANOVA-style tests of main effects, simple effects, interactions, and nested effects. **contrast** can use named contrasts to decompose these effects into comparisons against reference categories, comparisons of adjacent levels, comparisons against the grand mean, orthogonal polynomials, and such. Custom contrasts may also be specified.

**contrast** can be used with `svy` estimation results; see `[SVY] svy postestimation`.

Contrasts can also be computed for margins of linear and nonlinear responses; see `[R] margins, contrast`.

### Options

**Main**

- `overall` specifies that a joint hypothesis test over all terms be performed.
- `asobserved` specifies that factor covariates be evaluated using the cell frequencies observed in the estimation sample. The default is to treat all factor covariates as though there were an equal number of observations in each level.
- `lincom` specifies that user-defined contrasts be treated as linear combinations. The default is to require that all user-defined contrasts sum to zero. (Summing to zero is part of the definition of a contrast.)

**Equations**

- `equation(eqspec)` specifies the equation from which contrasts are to be computed. The default is to compute contrasts from the first equation.
- `atequations` specifies that the contrasts be computed within each equation.

**Advanced**

- `emptycells(empspec)` specifies how empty cells are handled in interactions involving factor variables that are being treated as balanced.
  - `emptycells(strict)` is the default; it specifies that contrasts involving empty cells be treated as not estimable.
  - `emptycells(reweight)` specifies that the effects of the observed cells be increased to accommodate any missing cells. This makes the contrast estimable but changes its interpretation.
noestimcheck specifies that contrast not check for estimability. By default, the requested contrasts are checked and those found not estimable are reported as such. Nonestimability is usually caused by empty cells. If noestimcheck is specified, estimates are computed in the usual way and reported even though the resulting estimates are manipulable, which is to say they can differ across equivalent models having different parameterizations.

Reporting

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

mcompare(method) specifies the method for computing \( p \)-values and confidence intervals that account for multiple comparisons within a factor-variable term.

Most methods adjust the comparisonwise error rate, \( \alpha_c \), to achieve a prespecified experimentwise error rate, \( \alpha_e \).

mcompare(noadjust) is the default; it specifies no adjustment.

\[ \alpha_c = \alpha_e \]

mcompare(bonferroni) adjusts the comparisonwise error rate based on the upper limit of the Bonferroni inequality

\[ \alpha_e \leq m \alpha_c \]

where \( m \) is the number of comparisons within the term.

The adjusted comparisonwise error rate is

\[ \alpha_c = \frac{\alpha_e}{m} \]

mcompare(sidak) adjusts the comparisonwise error rate based on the upper limit of the probability inequality

\[ \alpha_e \leq 1 - (1 - \alpha_e)^m \]

where \( m \) is the number of comparisons within the term.

The adjusted comparisonwise error rate is

\[ \alpha_c = 1 - (1 - \alpha_e)^{1/m} \]

This adjustment is exact when the \( m \) comparisons are independent.

mcompare(scheffe) controls the experimentwise error rate using the \( F \) or \( \chi^2 \) distribution with degrees of freedom equal to the rank of the term.

mcompare(method adjustall) specifies that the multiple-comparison adjustments count all comparisons across all terms rather than performing multiple comparisons term by term. This leads to more conservative adjustments when multiple variables or terms are specified in marginslist. This option is compatible only with the bonferroni and sidak methods.

noeffects suppresses the table of individual contrasts with confidence intervals. This table is produced by default when the mcompare() option is specified or when a term in termlist implies all individual contrasts.

cieffects specifies that a table containing a confidence interval for each individual contrast be reported.

pveffects specifies that a table containing a \( p \)-value for each individual contrast be reported.

effects specifies that a single table containing a confidence interval and \( p \)-value for each individual contrast be reported.
The following option is available with `contrast` but is not shown in the dialog box:

`df(#)` specifies that the $t$ distribution with # degrees of freedom be used for computing $p$-values and confidence intervals. The default is to use $e(df,r)$ degrees of freedom or the standard normal distribution if $e(df,r)$ is missing.
Remarks and examples

Remarks are presented under the following headings:

Introduction

One-way models
- Estimated cell means
- Testing equality of cell means
- Reference category contrasts
- Reverse adjacent contrasts
- Orthogonal polynomial contrasts

Two-way models
- Estimated interaction cell means
- Simple effects
- Interaction effects
- Main effects
- Partial interaction effects

Three-way and higher-order models
- Contrast operators
  - Differences from a reference level (r.)
  - Differences from the next level (a.)
  - Differences from the previous level (ar.)
  - Differences from the grand mean (g.)
  - Differences from the mean of subsequent levels (h.)
  - Differences from the mean of previous levels (j.)
  - Orthogonal polynomials (p. and q.)

User-defined contrasts
- Empty cells
- Empty cells, ANOVA style
- Nested effects
- Multiple comparisons
- Unbalanced data
  - Using observed cell frequencies
  - Weighted contrast operators
- Testing factor effects on slopes
- Chow tests
- Beyond linear models
- Multiple equations
- Video example

Introduction

`contrast` performs ANOVA-style tests of main effects, interactions, simple effects, and nested effects. It can easily decompose these tests into constituent contrasts using either named contrasts (codings) or user-specified contrasts. Comparing levels of factor variables—whether as main effects, interactions, or simple effects—is as easy as adding a contrast operator to the variable. The operators can compare each level with the previous level, each level with a reference level, each level with the mean of previous levels, and more.

`contrast` tests and estimates contrasts. A contrast of the parameters $\mu_1, \mu_2, \ldots, \mu_p$ is a linear combination $\sum_i c_i \mu_i$ whose $c_i$ sum to zero. A difference of population means that $\mu_1 - \mu_2$ is a contrast, as are most other comparisons of population or model quantities (Coster 2005). Some contrasts may be estimated with `lincom`, but `contrast` is much more powerful. `contrast` can handle multiple contrasts simultaneously, and the command’s contrast operators make it easy to specify complicated linear combinations.

Both the contrast operation and the creation of the margins for comparison can be performed as though the data were balanced (typical for experimental designs) or using the observed frequencies in the estimation sample (typical for observational studies). `contrast` can perform these analyses on the results of almost all of Stata’s estimators, not just the linear-models estimators.
Most of \texttt{contrast}'s computations can be considered comparisons of estimated cell means from a model fit. Tests of interactions are tests of whether the cell means for the interaction are all equal. Tests of main effects are tests of whether the marginal cell means for the factor are all equal. More focused comparisons of cell means (for example, is level 2 equal to level 1) are specified using contrast operators. More formally, all of \texttt{contrast}'s computations are comparisons of conditional expectations; cell means are one type of conditional expectation.

All contrasts can also easily be graphed; see \texttt{[R] marginsplot}.

\texttt{contrast} is a flexible tool for understanding the effects of categorical covariates. If your model contains categorical covariates, and especially if it contains interactions, you will want to use \texttt{contrast}.

\subsection*{One-way models}

Suppose we have collected data on cholesterol levels for individuals from five age groups. To study the effect of age group on cholesterol, we can begin by fitting a one-way model using \texttt{regress}:

\begin{verbatim}
. use http://www.stata-press.com/data/r13/cholesterol
(Artificial cholesterol data)
. label list ages
ages:
  1 10-19
  2 20-29
  3 30-39
  4 40-59
  5 60-79
. regress chol i.agegrp

Source | SS      df    MS
-------------+---------+---------+
Model       | 14943.4 | 4       3735.8
Residual   | 7468.2  | 70      106.7
Total      | 22411.6 | 74      302.9

Number of obs = 75
F(  4,   70) = 35.0
Prob > F    = 0.000
R-squared   = 0.667
Adj R-squared = 0.648
Root MSE    = 10.3

| chol | Coef.  | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|------|--------|-----------|-------|------|---------------------|
| agegrp|        |           |       |      |                     |
| 20-29| 8.203575| 3.771628  | 2.18  | 0.033| .6812991           |
| 30-39| 21.54105| 3.771628  | 5.71  | 0.000| 14.01878           |
| 40-59| 30.15067| 3.771628  | 7.99  | 0.000| 22.6284           |
| 60-79| 38.76221| 3.771628  | 10.28 | 0.000| 31.23993           |
| _cons| 180.5198| 2.666944  | 67.69 | 0.000| 175.2007           |
\end{verbatim}
Estimated cell means

`margins` will show us the estimated cell means for each age group based on our fitted model:

```
. margins agegrp
Adjusted predictions                        Number of obs = 75
Model VCE      : OLS
Expression : Linear prediction, predict()

<table>
<thead>
<tr>
<th></th>
<th>Delta-method</th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Margin</td>
<td>Std. Err.</td>
<td>t</td>
<td>P&gt;</td>
<td>[95% Conf. Interval]</td>
</tr>
<tr>
<td>agegrp</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>10-19</td>
<td>180.5198</td>
<td>2.666944</td>
<td>67.69</td>
<td>0.000</td>
<td>175.2007 - 185.8388</td>
</tr>
<tr>
<td>20-29</td>
<td>188.7233</td>
<td>2.666944</td>
<td>70.76</td>
<td>0.000</td>
<td>183.4043 - 194.0424</td>
</tr>
<tr>
<td>30-39</td>
<td>202.0608</td>
<td>2.666944</td>
<td>75.76</td>
<td>0.000</td>
<td>196.7418 - 207.3799</td>
</tr>
<tr>
<td>40-59</td>
<td>210.6704</td>
<td>2.666944</td>
<td>78.99</td>
<td>0.000</td>
<td>205.3514 - 215.9895</td>
</tr>
<tr>
<td>60-79</td>
<td>219.282</td>
<td>2.666944</td>
<td>82.22</td>
<td>0.000</td>
<td>213.9629 - 224.601</td>
</tr>
</tbody>
</table>
```

We can graph those means with `marginsplot`:

```
. marginsplot
   Variables that uniquely identify margins: agegrp
```

![Adjusted Predictions of agegrp with 95% CIs](image-url)
Testing equality of cell means

Are all the means equal? That is to say is there an effect of age group on cholesterol level? We can answer that by asking `contrast` to test whether the means of the age groups are identical.

```
. contrast agegrp
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegrp</td>
<td>4</td>
<td>35.02</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td>70</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

The means are clearly different. We could have obtained this same test directly had we fit our model using `anova` rather than `regress`.

```
. anova chol agegrp
Number of obs = 75  R-squared = 0.6668
Root MSE = 10.329  Adj R-squared = 0.6477

         Source | Partial SS | df | MS          | F     | Prob > F
-------------|------------|----|-------------|-------|----------
         Model | 14943.3997 | 4  | 3735.84993  | 35.02 | 0.0000   
   agegrp   | 14943.3997 | 4  | 3735.84993  | 35.02 | 0.0000   
Residual  | 7468.21971 | 70 | 106.688853  |       |          
     Total | 22411.6194 | 74 | 302.859722  |       |          
```

Achieving a more direct test result is why we recommend using `anova` instead of `regress` for models where our focus is on the categorical covariates. The models fit by `anova` and `regress` are identical; they merely parameterize the effects differently. The results of `contrast` will be identical regardless of which command is used to fit the model. If, however, we were fitting models whose responses are nonlinear functions of the covariates, such as logistic regression, then there would be no analogue to `anova`, and we would appreciate `contrast`s ability to quickly test main effects and interactions.
Reference category contrasts

Now that we know that the overall effect of age group is statistically significant, we can explore the effects of each age group. One way to do that is to use the reference category operator, \( r \):

```
. contrast r.agegrp
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(20-29 vs 10-19)</td>
<td>1</td>
<td>4.73</td>
<td>0.0330</td>
</tr>
<tr>
<td>(30-39 vs 10-19)</td>
<td>1</td>
<td>32.62</td>
<td>0.0000</td>
</tr>
<tr>
<td>(40-59 vs 10-19)</td>
<td>1</td>
<td>63.91</td>
<td>0.0000</td>
</tr>
<tr>
<td>(60-79 vs 10-19)</td>
<td>1</td>
<td>105.62</td>
<td>0.0000</td>
</tr>
<tr>
<td>Joint</td>
<td>4</td>
<td>35.02</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Denominator    70
```

The cell mean of each age group is compared against the base age group (ages 10–19). The first table shows that each difference is significant. The second table gives an estimate and confidence interval for each contrast. These are the comparisons that linear regression gives with a factor covariate and no interactions. The contrasts are identical to the coefficients from our linear regression.

Reverse adjacent contrasts

We have far more flexibility with \( \text{contrast} \). Age group is ordinal, so it is interesting to compare each age group with the preceding age group (rather than against one reference group). We specify that analysis by using the reverse adjacent operator, \( \text{ar} \):

```
. contrast ar.agegrp
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(20-29 vs 10-19)</td>
<td>1</td>
<td>4.73</td>
<td>0.0330</td>
</tr>
<tr>
<td>(30-39 vs 20-29)</td>
<td>1</td>
<td>12.51</td>
<td>0.0007</td>
</tr>
<tr>
<td>(40-59 vs 30-39)</td>
<td>1</td>
<td>5.21</td>
<td>0.0255</td>
</tr>
<tr>
<td>(60-79 vs 40-59)</td>
<td>1</td>
<td>5.21</td>
<td>0.0255</td>
</tr>
<tr>
<td>Joint</td>
<td>4</td>
<td>35.02</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Denominator    70
```
The 20–29 age group’s cholesterol level is 8.2 points higher than the 10–19 age group’s cholesterol level; the 30–39 age group’s level is 13.3 points higher than the 20–29 age group’s level; and so on. Each age group is statistically different from the preceding age group at the 5% level.

Orthogonal polynomial contrasts

The relationship between age group and cholesterol level looked almost linear in our graph. We can examine that relationship further by using the orthogonal polynomial operator, p.: 

```
. contrast p.agegrp, noeffects
```

Conversely, the marginal linear predictions

```
Margins : asbalanced
```

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(linear)</td>
<td>1</td>
<td>139.11</td>
<td>0.0000</td>
</tr>
<tr>
<td>(quadratic)</td>
<td>1</td>
<td>0.15</td>
<td>0.6962</td>
</tr>
<tr>
<td>(cubic)</td>
<td>1</td>
<td>0.37</td>
<td>0.5448</td>
</tr>
<tr>
<td>(quartic)</td>
<td>1</td>
<td>0.43</td>
<td>0.5153</td>
</tr>
<tr>
<td>Joint</td>
<td>4</td>
<td>35.02</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td>70</td>
<td></td>
</tr>
</tbody>
</table>

Only the linear effect is statistically significant.

We can even perform the joint test that all effects beyond linear are zero. We do that by selecting all polynomial contrasts above linear—that is, polynomial contrasts 2, 3, and 4.

```
. contrast p(2 3 4).agegrp, noeffects
```

Conversely, the marginal linear predictions

```
Margins : asbalanced
```

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(quadratic)</td>
<td>1</td>
<td>0.15</td>
<td>0.6962</td>
</tr>
<tr>
<td>(cubic)</td>
<td>1</td>
<td>0.37</td>
<td>0.5448</td>
</tr>
<tr>
<td>(quartic)</td>
<td>1</td>
<td>0.43</td>
<td>0.5153</td>
</tr>
<tr>
<td>Joint</td>
<td>3</td>
<td>0.32</td>
<td>0.8129</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td>70</td>
<td></td>
</tr>
</tbody>
</table>

The joint test has three degrees of freedom and is clearly insignificant. A linear effect of age group seems adequate for this model.
Two-way models

Suppose we are investigating the effects of different dosages of a blood pressure medication and believe that the effects may be different for men and women. We can fit the following ANOVA model for \texttt{bpchange}, the change in diastolic blood pressure. Change is defined as the after measurement minus the before measurement, so that negative values of \texttt{bpchange} correspond to decreases in blood pressure.

```stata
. use http://www.stata-press.com/data/r13/bpchange
(Artificial blood pressure data)
. label list gender
   gender:
   1 male
   2 female
. anova bpchange dose##gender
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>1411.9087</td>
<td>5</td>
<td>282.38174</td>
<td>131.09</td>
<td>0.0000</td>
</tr>
<tr>
<td>dose</td>
<td>963.481795</td>
<td>2</td>
<td>481.740897</td>
<td>223.64</td>
<td>0.0000</td>
</tr>
<tr>
<td>gender</td>
<td>355.118817</td>
<td>1</td>
<td>355.118817</td>
<td>164.85</td>
<td>0.0000</td>
</tr>
<tr>
<td>dose#gender</td>
<td>93.3080926</td>
<td>2</td>
<td>46.6540463</td>
<td>21.66</td>
<td>0.0000</td>
</tr>
<tr>
<td>Residual</td>
<td>51.699253</td>
<td>24</td>
<td>2.15413554</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>1463.60796</td>
<td>29</td>
<td>50.4692399</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Estimated interaction cell means

Everything is significant, including the interaction. So increasing dosage is effective and differs by gender. Let’s explore the effects. First, let’s look at the estimated cell mean of blood pressure change for each combination of gender and dosage.

```stata
. margins dose#gender
```

<table>
<thead>
<tr>
<th>dose#gender</th>
<th>Delta-method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Margin</td>
<td>Std. Err.</td>
</tr>
<tr>
<td>250#male</td>
<td>-7.35384</td>
</tr>
<tr>
<td>250#female</td>
<td>3.706567</td>
</tr>
<tr>
<td>500#male</td>
<td>-13.73386</td>
</tr>
<tr>
<td>500#female</td>
<td>-6.584167</td>
</tr>
<tr>
<td>750#male</td>
<td>-16.82108</td>
</tr>
<tr>
<td>750#female</td>
<td>-14.38795</td>
</tr>
</tbody>
</table>

Our data are balanced, so these results will not be affected by the many different ways that \texttt{margins} can compute cell means. Moreover, because our model consists of only \texttt{dose} and \texttt{gender}, these are also the point estimates for each combination.
We can graph the results:

```
. marginsplot
Variables that uniquely identify margins: dose gender
```

![Adjusted Predictions of dose#gender with 95% CIs](image)

The lines are not parallel, which we expected because the interaction term is significant. Males experience a greater decline in blood pressure at every dosage level, but the effect of increasing dosage is greater for females. In fact, it is not clear if we can tell the difference between male and female response at the maximum dosage.

**Simple effects**

We can contrast the male and female responses within dosage to see the simple effects of gender. Because there are only two levels in gender, the choice of contrast operator is largely irrelevant. Aside from orthogonal polynomials, all operators produce the same estimates, although the effects can change signs.

```
. contrast r.gender@dose
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>

<tr>
<td>(female vs male)</td>
<td>750</td>
<td>2.433124</td>
<td>.5173031 4.348944</td>
</tr>
</tbody>
</table>
```
The effect for males is about 11 points higher than for females at a dosage of 250, and that shrinks to 2.4 points higher at the maximum dosage of 750.

We can form the simple effects the other way by contrasting the effect of dose at each level of gender:

\[
.\text{contrast ar.dose@gender}
\]

Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
<tr>
<td>(750 vs 500) male</td>
<td>1</td>
<td>11.06</td>
<td>0.0028</td>
</tr>
<tr>
<td>(750 vs 500) female</td>
<td>1</td>
<td>70.68</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Joint | 4  | 122.65| 0.0000|

Denominator 24

Contrast Std. Err. [95% Conf. Interval]

dose@gender
(500 vs 250) male | -6.380018 | 0.9282533 | -8.295839 -4.464198 |
(500 vs 250) female | -10.29073 | 0.9282533 | -12.20655 -8.374914 |
(750 vs 500) male | -3.087217 | 0.9282533 | -5.003038 -1.171396 |
(750 vs 500) female | -7.803784 | 0.9282533 | -9.719605 -5.887963 |

Here we use the ar. reverse adjacent contrast operator so that first we are comparing a dosage of 500 with a dosage of 250, and then we are comparing 750 with 500. We see that increasing the dosage has a larger effect on females—10.3 points when going from 250 to 500 compared with 6.4 points for males, and 7.8 points when going from 500 to 750 versus 3.1 points for males.

**Interaction effects**

By specifying contrast operators on both factors, we can decompose the interaction effect into separate interaction contrasts.

\[
.\text{contrast ar.dose#r.gender}

</tr>
</tbody>
</table>

Joint | 2  | 21.66| 0.0000|

Denominator 24
Look for departures from zero to indicate an interaction effect between dose and gender. Both contrasts are significantly different from zero. Of course, we already knew the overall interaction was significant from our ANOVA results. The effect of increasing dose from 250 to 500 is 3.9 points greater in females than in males, and the effect of increasing dose from 500 to 750 is 4.7 points greater in females than in males. The confidence intervals for both estimates easily exclude zero, meaning that there is an interaction effect.

The joint test of these two interaction effects reproduces the test of interaction effects in the \texttt{anova} output. We can see that the $F$ statistic of 21.66 matches the statistic from our original ANOVA results.

### Main effects

We can perform tests of the main effects by listing each variable individually in \texttt{contrast}.

```plaintext
. contrast dose gender

Contrasts of marginal linear predictions
Margins : asbalanced

|        | df |   F   |  P>|F|
|--------|----|-------|------|
| dose   | 2  | 223.64| 0.0000|
| gender | 1  | 164.85| 0.0000|

Denominator | 24
```

The $F$ tests are equivalent to the tests of main effects in the \texttt{anova} output. This is true only for linear models. \texttt{contrast} provides an easy way to obtain main effects and other ANOVA-style tests for models whose responses are not linear in the parameters—logistic, probit, glm, etc.

If we include contrast operators on the variables, we can also decompose the main effects into individual contrasts:

```plaintext
. contrast ar.dose r.gender

Contrasts of marginal linear predictions
Margins : asbalanced

|        | df |   F   |  P>|F|
|--------|----|-------|------|
| dose (500 vs 250) | 1  | 161.27| 0.0000|
|         |   | 68.83 | 0.0000|
| Joint   | 2  | 223.64| 0.0000|
| gender  | 1  | 164.85| 0.0000|

Denominator | 24
```
Contrast Std. Err. [95% Conf. Interval]
---
**dose**  
(500 vs 250)  -8.335376  .6563742  -9.690066  -6.980687  
(750 vs 500)  -5.4455  .6563742  -6.80019  -4.090811  
**gender**  
(female vs male)  6.881074  .5359273  5.774974  7.987173

By specifying the `ar.` operator on `dose`, we decompose the main effect for dose into two one-degree-of-freedom contrasts, comparing the marginal mean of blood pressure change for each dosage level with that of the previous level. Because `gender` has only two levels, we cannot decompose this main effect any further. However, specifying a contrast operator on `gender` allowed us to calculate the difference in the marginal means for women and men.

**Partial interaction effects**

At this point, we have looked at the total interaction effects and at the main effects of each variable. The partial interaction effects are a midpoint between these two types of effects where we collect the individual interaction effects along the levels of one of the variables and perform a joint test of those interactions. If we think of the interaction effects as forming a table, with the levels of one factor variable forming the rows and the levels of the other forming the columns, partial interaction effects are joint tests of the interactions in a row or a column. To perform these tests, we specify a contrast operator on only one of the variables in our interaction. For this particular model, these are not very interesting because our variables have only two and three levels. Therefore, the tests of the partial interaction effects reproduce the tests that we obtained for the total interaction effects. We specify a contrast operator only on `dose` to decompose the overall test for interaction effects into joint tests for each `ar.dose` contrast:

```
. contrast ar.dose#gender
```

Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>dose#gender</strong></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(500 vs 250) (joint)</td>
<td>1</td>
<td>8.87</td>
<td>0.0065</td>
</tr>
<tr>
<td>(750 vs 500) (joint)</td>
<td>1</td>
<td>12.91</td>
<td>0.0015</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>21.66</td>
<td>0.0000</td>
</tr>
<tr>
<td><strong>Denominator</strong></td>
<td>24</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The first row is a joint test of all the interaction effects involving the (500 vs 250) comparison of dosages. The second row is a joint test of all the interaction effects involving the (750 vs 500) comparison. If we look back at our output in Interaction effects, we can see that there was only one of each of these interaction effects. Therefore, each test labeled (joint) has only one degree-of-freedom.

We could have instead included a contrast operator on `gender` to compute the partial interaction effects along the other dimension:
Here we obtain a joint test of all the interaction effects involving the (female vs male) comparison for gender. Because gender has only two levels, the (female vs male) contrast is the only reference category contrast possible. Therefore, we obtain a single joint test of all the interaction effects. Clearly, the partial interaction effects are not interesting for this particular model. However, if our factors had more levels, the partial interaction effects would produce tests that are not available in the total interaction effects. For example, if our model included factors for four dosage levels and three races, then typing

```
. contrast ar.dose#race
```

would produce three joint tests, one for each of the reverse adjacent contrasts for dosage. Each of these tests would be a two-degree-of-freedom test because race has three levels.

### Three-way and higher-order models

All the contrasts and tests that we reviewed above for two-way models can be used with models that have more terms. For instance, we could fit a three-way full factorial model by using the `anova` command:

```
. use http://www.stata-press.com/data/r13/cont3way
. anova y race##sex##group
```

We could then test the simple effects of race within each level of the interaction between sex and group:

```
. contrast race@sex#group
```

To see the reference category contrasts that decompose these simple effects, type

```
. contrast r.race@sex#group
```

We could test the three-way interaction effects by typing

```
. contrast race#sex#group
```

or the interaction effects for the interaction of race and sex by typing

```
. contrast race#sex
```

To see the individual reference category contrasts that decompose this interaction effect, type

```
. contrast r.race#r.sex
```
We could even obtain joint tests for the interaction of `race` and `sex` within each level of `group` by typing

```
contrast race#sex@group
```

For tests of the main effects of each factor, we can type

```
contrast race sex group
```

We can calculate the individual reference category contrasts that decompose these main effects:

```
contrast r.race r.sex r.group
```

For the partial interaction effects, we could type

```
contrast r.race#group
```

to obtain a joint test of the two-way interaction effects of `race` and `group` for each of the individual `r.race` contrasts.

We could type

```
contrast r.race#sex#group
```

to obtain a joint test of all the three-way interaction terms for each of the individual `r.race` contrasts.

### Contrast operators

`contrast` recognizes a set of contrast operators that are used to specify commonly used contrasts. When these operators are used, `contrast` will report a test for each individual contrast in addition to the joint test for the term. We have already seen a few of these, like `r.` and `ar.`, in the previous examples. Here we will take a closer look at each of the unweighted operators.

Here we use the cholesterol dataset and the one-way ANOVA model from the example in *One-way models:*

```
use http://www.stata-press.com/data/r13/cholesterol
(Artificial cholesterol data)
. anova chol agegrp
(output omitted)
```

The `margins` command reports the estimated cell means, \(\hat{\mu}_1, \ldots, \hat{\mu}_5\), for each of the five age groups.

```
. margins agegrp
Adjusted predictions                       Number of obs =      75

</tbody>
</table>
Contrast operators provide an easy way to make certain types of comparisons of these cell means. We use the ordinal factor `agegrp` to demonstrate these operators because some types of contrasts are only meaningful when the levels of the factor have a natural ordering. We demonstrate these contrast operators using a one-way model; however, they are equally applicable to main effects, simple effects, and interactions for more complicated models.

Differences from a reference level (\(r\.\))

The \(r\.\) operator specifies that each level of the attached factor variable be compared with a reference level. These are referred to as reference-level or reference-category contrasts (or effects), and \(r\.\) is the reference-level operator.

In the following, we use the \(r\.\) operator to test the effect of each category of age group when that category is compared with a reference category.

```plaintext

</tbody>
</table>
```

In the first table, the row labeled \((20-29 \text{ vs } 10-19)\) is a test of \(\mu_2 = \mu_1\), a test that the mean cholesterol levels for the 10–19 age group and the 20–29 age group are equal. The tests in the next three rows are defined similarly. The row labeled `Joint` provides the joint test for these four hypotheses, which is just the test of the main effects of age group.

The second table provides the contrasts of each category with the reference category along with confidence intervals. The contrast in the row labeled \((20-29 \text{ vs } 10-19)\) is the difference in the cell means of the second age group and the first age group, \(\hat{\mu}_2 - \hat{\mu}_1\).

The first level of a factor is the default reference level, but we can specify a different reference level by using the `b.` operator; see [U] 11.4.3.2 Base levels. Here we use the last age group, (60–79), instead of the first as the reference category. We also include the `nowald` option so that only the table of contrasts and their confidence intervals is produced.
. contrast rb5.agegrp, nowald

</tbody>
</table>

Now the first row is labeled (10–19 vs 60–79) and is the difference in the cell means of the first and fifth age groups.

**Differences from the next level (a.)**

The a. operator specifies that each level of the attached factor variable be compared with the next level. These are referred to as adjacent contrasts (or effects), and a. is the adjacent operator. This operator is only meaningful with factor variables that have a natural ordering in the levels.

We can use the a. operator to perform tests that each level of age group differs from the next adjacent level.

. contrast a.agegrp

</tr>
</tbody>
</table>

In the first table, the row labeled (10–19 vs 20–29) tests the effect of belonging to the 10–19 age group instead of the 20–29 age group. Likewise, the rows labeled (20–29 vs 30–39), (30–39 vs 40–59), and (40–59 vs 60–79) are tests for the effects of being in the younger of the two age groups instead of the older one.

In the second table, the contrast in the row labeled (10–19 vs 20–29) is the difference in the cell means of the first and second age groups, \( \hat{\mu}_1 - \hat{\mu}_2 \). The contrasts in the other rows are defined similarly.
Differences from the previous level (ar.)

The ar. operator specifies that each level of the attached factor variable be compared with the previous level. These are referred to as reverse adjacent contrasts (or effects), and ar. is the reverse adjacent operator. As with the a. operator, this operator is only meaningful with factor variables that have a natural ordering in the levels.

In the following, we use the ar. operator to report tests for the individual reverse adjacent effects of agegrp.

```
. contrast ar.agegrp

```

Here the Wald tests in the first table for the individual reverse adjacent effects are equivalent to the tests for the adjacent effects in the previous example. However, if we compare values of the contrasts in the bottom tables, we see the difference between the r. and the ar. operators. This time, the contrast in the first row is labeled (20–29 vs 10–19) and is the difference in the cell means of the second and first age groups, \( \hat{\mu}_2 - \hat{\mu}_1 \). This is the estimated effect of belonging to the 20–29 age group instead of the 10–19 age group. The remaining rows make similar comparisons to the previous level.

Differences from the grand mean (g.)

The g. operator specifies that each level of a factor variable be compared with the grand mean of all levels. For this operator, the grand mean is computed using a simple average of the cell means.
Here are the grand mean effects of `agegrp`:

```
. contrast g.agegrp
Contrasts of marginal linear predictions

```

There are five age groups in our estimation sample. Thus the row labeled (10-19 vs mean) tests $\mu_1 = (\mu_1 + \mu_2 + \mu_3 + \mu_4 + \mu_5)/5$. The row labeled (20-29 vs mean) tests $\mu_2 = (\mu_1 + \mu_2 + \mu_3 + \mu_4 + \mu_5)/5$. The remaining rows perform similar tests for the third, fourth, and fifth age groups. In our example, the means for all age groups except the 30–39 age group are statistically different from the grand mean.

**Differences from the mean of subsequent levels (h.)**

The h. operator specifies that each level of the attached factor variable be compared with the mean of subsequent levels. These are referred to as Helmert contrasts (or effects), and h. is the Helmert operator. For this operator, the mean is computed using a simple average of the cell means. This operator is only meaningful with factor variables that have a natural ordering in the levels.

Here are the Helmert contrasts for `agegrp`:

```
. contrast h.agegrp

```
The row labeled $(10-19 \text{ vs } >10-19)$ tests $\mu_1 = (\mu_2 + \mu_3 + \mu_4 + \mu_5)/4$, that is, that the cell mean for the youngest age group is equal to the average of the cell means for the older age groups. The row labeled $(20-29 \text{ vs } >20-29)$ tests $\mu_2 = (\mu_3 + \mu_4 + \mu_5)/3$. The tests in the other rows are defined similarly.

**Differences from the mean of previous levels (j.)**

The j. operator specifies that each level of the attached factor variable be compared with the mean of the previous levels. These are referred to as reverse Helmert contrasts (or effects), and j. is the reverse Helmert operator. For this operator, the mean is computed using a simple average of the cell means. This operator is only meaningful with factor variables that have a natural ordering in the levels.

Here are the reverse Helmert contrasts of `agegrp`:

```
. contrast j.agegrp
Contrasts of marginal linear predictions
Margins : asbalanced

                  df   F    P>F
agegrp
(20-29 vs 10-19)  1   4.73  0.0330
(30-39 vs <30-39) 1  28.51  0.0000
(40-59 vs <40-59) 1  43.18  0.0000
(60-79 vs <60-79) 1  63.65  0.0000
Joint             4  35.02  0.0000
Denominator      70
```

The row labeled $(20-29 \text{ vs } 10-19)$ tests $\mu_2 = \mu_1$, that is, that the cell means for the 20–29 and the 10–19 age groups are equal. The row labeled $(30-39 \text{ vs } <30-39)$ tests $\mu_3 = (\mu_1 + \mu_2)/2$, that is, that the cell mean for the 30–39 age group is equal to the average of the cell means for the 10–19 and 20–29 age groups. The tests in the remaining rows are defined similarly.
Orthogonal polynomials (p. and q.)

The p. and q. operators specify that orthogonal polynomials be applied to the attached factor variable. Orthogonal polynomial contrasts allow us to partition the effects of a factor variable into linear, quadratic, cubic, and higher-order polynomial components. The p. operator applies orthogonal polynomials using the values of the factor variable. The q. operator applies orthogonal polynomials using the level indices. If the level values of the factor variable are equally spaced, as with our agegrp variable, then the p. and q. operators yield the same result. These operators are only meaningful with factor variables that have a natural ordering in the levels.

Because agegrp has five levels, contrast can test the linear, quadratic, cubic, and quartic effects of agegrp.

```
. contrast p.agegrp, noeffects
Contrasts of marginal linear predictions

</tbody>
</table>
```

The row labeled (linear) tests the linear effect of agegrp, the only effect that appears to be significant in this case.

The labels for our agegrp variable show the age ranges that correspond to each level.

```
. label list ages
ages:
  1 10-19
  2 20-29
  3 30-39
  4 40-59
  5 60-79
```

Notice that these groups do not have equal widths. Now let’s refit our model using the agemidpt variable. The values of agemidpt indicate the midpoint of each age group that was defined by the agegrp variable and are, therefore, not equally spaced.

```
. anova chol agemidpt
Number of obs = 75  R-squared = 0.6668
Root MSE = 10.329  Adj R-squared = 0.6477

Using the values of the midpoints, the quadratic effect is also significant at the 5% level.

⚠️ Technical note

We used the `noeffects` option when working with orthogonal polynomial contrasts. Apart from perhaps the sign of the contrast, the values of the individual contrasts are not meaningful for orthogonal polynomial contrasts. In addition, many textbooks provide tables with contrast coefficients that can be used to compute orthogonal polynomial contrasts where the levels of a factor are equally spaced. If we use these coefficients and calculate the contrasts manually with user-defined contrasts, as described below, the Wald tests for the polynomial terms will be equivalent, but the values of the individual contrasts will not necessarily match those that we obtain when using the polynomial contrast operator. When we use one of these contrast operators, an algorithm is used to calculate the coefficients of the polynomial contrast that will allow for unequal spacing in the levels of the factor as well as in the weights for the cell frequencies (when using `pw.` or `qw.`), as described in Methods and formulas.
User-defined contrasts

In the previous examples, we performed tests using contrast operators. When there is not a contrast operator available to calculate the contrast in which we are interested, we can specify custom contrasts.

Here we fit a one-way model for cholesterol on the factor `race`, which has three levels:

```
. label list race
race:
   1 black
   2 white
   3 other
. anova chol race
```

```
Number of obs = 75    R-squared = 0.0299
Root MSE = 17.3775    Adj R-squared = 0.0029

Source | Partial SS   df MS      F     Prob > F
----------|-------------|--------|-----|--------|
Model     | 669.278235  2 334.639117 1.11 0.3357
race      | 669.278235  2 334.639117 1.11 0.3357
Residual | 21742.3412  72 301.976961
Total     | 22411.6194  74 302.859722
```

`margins` calculates the estimated cell mean cholesterol level for each race:

```
. margins race
Adjusted predictions                           Number of obs = 75
Expression : Linear prediction, predict()

|            | Delta-method | Margin | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|------------|--------------|--------|-----------|-------|-----|---------------------|
| race       |              |        |           |       |     |                     |
| black      | 204.4279     | 3.475497 | 58.82     | 0.000 | 197.4996 | 211.3562           |
| white      | 197.6132     | 3.475497 | 56.86     | 0.000 | 190.6849 | 204.5415           |
| other      | 198.7127     | 3.475497 | 57.18     | 0.000 | 191.7844 | 205.6409           |
```

Suppose we want to test the following linear combination:

\[
\sum_{i=1}^{3} c_i \mu_i
\]

where \( \mu_i \) is the cell mean of `chol` when `race` is equal to its \( i \)th level (the means estimated using `margins` above). Assuming the \( c_i \) elements sum to zero, this linear combination is a contrast. We can specify this type of custom contrast by using the following syntax:

\[
\{ \text{race } c_1 \ c_2 \ c_3 \}
\]

The null hypothesis for the test of the main effects of `race` is

\[
H_{0,\text{race}}: \mu_1 = \mu_2 = \mu_3
\]
Although $H_{0,\text{race}}$ can be tested using any of several different contrasts on the cell means, we will test it by comparing the second and third cell means with the first. To test that the cell means for blacks and whites are equal, $\mu_1 = \mu_2$, we can specify the contrast
\[
\{\text{race} \ -1 \ 1 \ 0\}
\]
To test that the cell means for blacks and other races are equal, $\mu_1 = \mu_3$, we can specify the contrast
\[
\{\text{race} \ -1 \ 0 \ 1\}
\]
We can use both in a single call to \texttt{contrast}.

\[
. \ \texttt{contrast \ \{race \ -1 \ 1 \ 0\} \ \{race \ -1 \ 0 \ 1\}}
\]

Contrasts of marginal linear predictions

<td>4.915095</td>
<td>-16.61278</td>
</tr>
<tr>
<td>(2)</td>
<td>-5.715261</td>
<td>4.915095</td>
<td>-15.51332</td>
</tr>
</tbody>
</table>

The row labeled (1) is the test for $\mu_1 = \mu_2$, the first specified contrast. The row labeled (2) is the test for $\mu_1 = \mu_3$, the second specified contrast. The row labeled Joint is the overall test for the main effects of race.

Now let’s fit a model with two factors, race and age group:

\[
. \ \texttt{anova \ chol \ race##agegrp}
\]

\[
\begin{array}{llll}
\text{Source} & \text{Partial SS} & \text{df} & \text{MS} & \text{F} & \text{Prob > F} \\
\text{Model} & 16861.438 & 14 & 1204.38843 & 13.02 & 0.0000 \\
\text{race} & 669.278235 & 2 & 334.639117 & 3.62 & 0.0329 \\
\text{agegrp} & 14943.3997 & 4 & 3735.84993 & 40.39 & 0.0000 \\
\text{race#agegrp} & 1248.76005 & 8 & 156.095006 & 1.69 & 0.1201 \\
\text{Residual} & 5550.18143 & 60 & 92.5030238 & & \\
\text{Total} & 22411.6194 & 74 & 302.859722 & & \\
\end{array}
\]

The null hypothesis for the test of the main effects of race is now
\[
H_{0,\text{race}}: \mu_{1i} = \mu_{2i} = \mu_{3i}
\]
where $\mu_{i}$ is the marginal mean of chol when race is equal to its $i$th level.
We can use the same syntax as above to perform this test by specifying contrasts on the marginal means of `race`:

```
. contrast \{race -1 1 0\} \{race -1 0 1\}
```

Contrasts of marginal linear predictions

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

Now we are interested in testing the following linear combination of these cell means:

\[
\sum_{i=1}^{3} \sum_{j=1}^{5} c_{ij} \mu_{ij}
\]
We can specify this type of custom contrast using the following syntax:

\{race\#agegrp \ c_{11} \ c_{12} \ \ldots \ c_{15} \ c_{21} \ c_{22} \ \ldots \ c_{25} \ c_{31} \ c_{32} \ \ldots \ c_{35}\}

Because the marginal means of chol for each level of race are linear combinations of the cell means, we can compose the test for the main effects of race in terms of the cell means directly. The constraint that the marginal means for blacks and whites are equal, \(\mu_1 = \mu_2\), translates to the following constraint on the cell means:

\[\frac{1}{5}(\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15}) = \frac{1}{5}(\mu_{21} + \mu_{22} + \mu_{23} + \mu_{24} + \mu_{25})\]

Ignoring the common factor, we can specify this contrast as

\{race\#agegrp -1 -1 -1 -1 -1 1 1 1 1 1 0 0 0 0 0\}

contrast will fill in the trailing zeros for us if we neglect to specify them, so

\{race\#agegrp -1 -1 -1 -1 1 1 1 1 1\}

is also allowed. The other constraint, \(\mu_1 = \mu_3\), translates to

\[\frac{1}{5}(\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15}) = \frac{1}{5}(\mu_{31} + \mu_{32} + \mu_{33} + \mu_{34} + \mu_{35})\]

This can be specified to contrast as

\{race\#agegrp -1 -1 -1 -1 0 0 0 0 0 1 1 1 1 1\}

The following call to contrast yields the same test results as above.

. contrast {race\#agegrp -1 -1 -1 -1 1 1 1 1 1 1}
> {race\#agegrp -1 -1 -1 -1 0 0 0 0 0 1 1 1 1 1}, noeffects

<table>
<thead>
<tr>
<th>Margins : asbalanced</th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race#agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(1) (1)</td>
<td>1</td>
<td>6.28</td>
<td>0.0150</td>
</tr>
<tr>
<td>(2) (2)</td>
<td>1</td>
<td>4.41</td>
<td>0.0399</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>3.62</td>
<td>0.0329</td>
</tr>
<tr>
<td>Denominator</td>
<td>60</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The row labeled (1) (1) is the test for

\[\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15} = \mu_{21} + \mu_{22} + \mu_{23} + \mu_{24} + \mu_{25}\]

It was the first specified contrast. The row labeled (2) (2) is the test for

\[\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15} = \mu_{31} + \mu_{32} + \mu_{33} + \mu_{34} + \mu_{35}\]

It was the second specified contrast. The row labeled Joint tests (1) (1) and (2) (2) simultaneously.
We used the *noeffects* option above to suppress the table of contrasts. We can omit the $1/5$ from the equations for $\mu_1 = \mu_2$ and $\mu_1 = \mu_3$, and still obtain the appropriate tests. However, if we want to calculate the differences in the marginal means, we must include the $1/5 = 0.2$ on each of the contrast coefficients as follows:

```plaintext
. contrast {race#agegrp -0.2 -0.2 -0.2 -0.2 -0.2
           0.2 0.2 0.2 0.2 0.2}
{race#agegrp -0.2 -0.2 -0.2 -0.2 -0.2
           0 0 0 0 0
           0.2 0.2 0.2 0.2 0.2}
```

So far, we have reproduced the reference category contrasts by specifying user-defined contrasts on the marginal means and then on the cell means. For this test, it would have been easier to use the *r.* contrast operator:

```plaintext
. contrast r.race, noeffects
```

<p>| Contrasts of marginal linear predictions |
|==========================================|</p>
<table>
<thead>
<tr>

<tr>
<td>60</td>
</tr>
</tbody>
</table>

In most cases, we can use contrast operators to perform tests. However, if we want to compare, for instance, the second and third age groups with the fourth and fifth age groups with the test

$$
\frac{1}{2}(\mu_2 + \mu_3) = \frac{1}{2}(\mu_4 + \mu_5)
$$

there is not a contrast operator that corresponds to this particular contrast. A custom contrast is necessary.

```plaintext
. contrast {agegrp 0 -0.5 -0.5 0.5 0.5}
```

Empty cells

An empty cell is a combination of the levels of factor variables that is not observed in the estimation sample. In the previous examples, we have seen data with three levels of race, five levels of agegrp, and all level combinations of race and agegrp present. Suppose there are no observations for white individuals in the second age group (ages 20–29).

```
. use http://www.stata-press.com/data/r13/cholesterol2
(Artificial cholesterol data, empty cells)
. label list
   ages:
     1  10-19
     2  20-29
     3  30-39
     4  40-59
     5  60-79
   race:
     1  black
     2  white
     3  other

. regress chol race##agegrp
   note: 2.race#2.agegrp identifies no observations in the sample

_cons        | 175.2309 | 4.235359  | 41.37 |  0.000 |  166.7464  to  183.7153     
```
Now let’s use `contrast` to test the main effects of `race`:

```
. contrast race
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race</td>
<td>5</td>
<td>0.0498</td>
<td></td>
</tr>
<tr>
<td>Denominator</td>
<td>56</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

By “not testable”, `contrast` means that it cannot form a test for the main effects of `race` based on estimable functions of the model coefficients. `agegrp` has five levels, so `contrast` constructs an estimate of the $i$th margin for `race` as

$$
\hat{\mu}_i = \frac{1}{5} \sum_{j=1}^{5} \hat{\mu}_{ij} = \hat{\mu}_0 + \hat{\alpha}_i + \frac{1}{5} \sum_{j=1}^{5} \{ \hat{\beta}_j + (\hat{\alpha}\hat{\beta})_{ij} \}
$$

but $(\hat{\alpha}\hat{\beta})_{22}$ was constrained to zero because of the empty cell, so $\hat{\mu}_2$ is not an estimable function of the model coefficients.

See `Estimable functions` in `Methods and formulas` of [R] `margins` for a technical description of estimable functions. The `emptycells(reweight)` option causes `contrast` to estimate $\hat{\mu}_2$ by

$$
\hat{\mu}_2 = \frac{\hat{\mu}_{21} + \hat{\mu}_{23} + \hat{\mu}_{24} + \hat{\mu}_{25}}{4}
$$

which is an estimable function of the model coefficients.

```
. contrast race, emptycells(reweight)
Contrasts of marginal linear predictions
Margins : asbalanced
Empty cells : reweight

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race</td>
<td>2</td>
<td>3.17</td>
<td>0.0498</td>
</tr>
<tr>
<td>Denominator</td>
<td>56</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```
We can reconstruct the effect of the emptycells(reweight) option by using custom contrasts.

```
. contrast {race#agegrp -4 -4 -4 -4 -4 5 0 5 5 5}
>   {race#agegrp -1 -1 -1 -1 -1 0 0 0 0 0 1 1 1 1 1}, noeffects
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race#agegrp(1) (1)</td>
<td>1</td>
<td>1.06</td>
<td>0.3080</td>
</tr>
<tr>
<td>race#agegrp(2) (2)</td>
<td>1</td>
<td>2.37</td>
<td>0.1291</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>3.17</td>
<td>0.0498</td>
</tr>
<tr>
<td>Denominator</td>
<td>56</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

The row labeled (1) (1) is the test for

$$\frac{1}{5}(\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15}) = \frac{1}{4}(\mu_{21} + \mu_{23} + \mu_{24} + \mu_{25})$$

It was the first specified contrast. The row labeled (2) (2) is the test for

$$\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15} = \mu_{31} + \mu_{32} + \mu_{33} + \mu_{34} + \mu_{35}$$

It was the second specified contrast. The row labeled Joint is the overall test of the main effects of race.

**Empty cells, ANOVA style**

Let’s refit the linear model from the previous example with `anova` to compare with `contrast`’s test for the main effects of `race`.

```
. anova chol race##agegrp
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>15751.6113</td>
<td>13</td>
<td>1211.66241</td>
<td>13.51</td>
<td>0.0000</td>
</tr>
<tr>
<td>race</td>
<td>305.49046</td>
<td>2</td>
<td>152.74523</td>
<td>1.70</td>
<td>0.1914</td>
</tr>
<tr>
<td>agegrp</td>
<td>14387.8559</td>
<td>4</td>
<td>3596.96397</td>
<td>40.10</td>
<td>0.0000</td>
</tr>
<tr>
<td>race#agegrp</td>
<td>795.807574</td>
<td>7</td>
<td>113.686796</td>
<td>1.27</td>
<td>0.2831</td>
</tr>
<tr>
<td>Residual</td>
<td>5022.71559</td>
<td>56</td>
<td>89.6913498</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>20774.3269</td>
<td>69</td>
<td>301.077201</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

`contrast` and `anova` handled the empty cell differently; the $F$ statistic reported by `contrast` was 3.17, but `anova` reported 1.70. To see how they differ, consider the following table of the cell means and margins for our situation.
For testing the main effects of `race`, we know that we will be testing the equality of the marginal means for rows 1 and 3, that is, $\mu_1 = \mu_3$. This translates into the following constraint:

$$\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15} = \mu_{31} + \mu_{32} + \mu_{33} + \mu_{34} + \mu_{35}$$

Because row 2 contains an empty cell in column 2, `anova` dropped column 2 and tested the equality of the marginal mean for row 2 with the average of the marginal means from rows 1 and 3, using only the remaining cell means. This translates into the following constraint:

$$2(\mu_{21} + \mu_{23} + \mu_{24} + \mu_{25}) = \mu_{11} + \mu_{13} + \mu_{14} + \mu_{15} + \mu_{31} + \mu_{33} + \mu_{34} + \mu_{35} \quad (1)$$

Now that we know the constraints that `anova` used to test for the main effects of `race`, we can use custom contrasts to reproduce the `anova` test result.

```plaintext
> . contrast \{race#agegrp -1 -1 -1 -1 -1 0 0 0 0 0 1 1 1 1 1\}
> > \{race#agegrp 1 0 1 1 1 -2 0 -2 -2 -2 1 0 1 1 1\}, noeffects

Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race#agegrp (1) (1)</td>
<td>1</td>
<td>2.37</td>
<td>0.1291</td>
</tr>
<tr>
<td></td>
<td>1</td>
<td>1.03</td>
<td>0.3138</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>1.70</td>
<td>0.1914</td>
</tr>
<tr>
<td>Denominator</td>
<td>56</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

The row labeled (1) (1) is the test for $\mu_1 = \mu_3$; it was the first specified contrast. The row labeled (2) (2) is the test for the constraint in (1); it was the second specified contrast. The row labeled Joint is an overall test for the main effects of `race`.

**Nested effects**

`contrast` has the `|` operator for computing simple effects when the levels of one factor are nested within the levels of another. Here is a fictional example where we are interested in the effect of five methods of teaching algebra on students’ scores for the math portion of the SAT. Suppose three algebra classes are randomly sampled from classes using each of the five methods so that `class` is nested in `method` as demonstrated in the following tabulation.
. use http://www.stata-press.com/data/r13/sat
(Artificial SAT data)
. tabulate class method

<table>
<thead>
<tr>
<th>class</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>Total</th>
</tr>
</thead>
<tbody>

<td>0</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>7</td>
<td>0</td>
<td>0</td>
<td>5</td>
<td>0</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>8</td>
<td>0</td>
<td>0</td>
<td>5</td>
<td>0</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>9</td>
<td>0</td>
<td>0</td>
<td>5</td>
<td>0</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>10</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>5</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>11</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>5</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>12</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>5</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>13</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>5</td>
<td>5</td>
</tr>
<tr>
<td>14</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>5</td>
<td>5</td>
</tr>
<tr>
<td>15</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>5</td>
<td>5</td>
</tr>
<tr>
<td>Total</td>
<td>15</td>
<td>15</td>
<td>15</td>
<td>15</td>
<td>15</td>
<td>75</td>
</tr>
</tbody>
</table>

We will consider method as fixed and class nested in method as random. To use class nested in method as the error term for method, we can specify the following anova model:

```
. anova score method / class|method /
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>980312</td>
<td>14</td>
<td>70022.2857</td>
<td>13.56</td>
<td>0.0000</td>
</tr>
<tr>
<td>method</td>
<td>905872</td>
<td>4</td>
<td>226468</td>
<td>30.42</td>
<td>0.0000</td>
</tr>
<tr>
<td>class</td>
<td>method</td>
<td>74440</td>
<td>10</td>
<td>7444</td>
<td>1.44</td>
</tr>
<tr>
<td>Residual</td>
<td>309760</td>
<td>60</td>
<td>5162.6667</td>
<td>1.44</td>
<td>0.1845</td>
</tr>
<tr>
<td>Total</td>
<td>1290072</td>
<td>74</td>
<td>17433.4054</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Like anova, contrast allows the | operator, which specifies that one variable is nested in the levels of another. We can use contrast to test the main effects of method and the simple effects of class within method.
Although *contrast* was able to perform the individual tests for the simple effects of *class* within *method*, empty cells in the interaction between *method* and *class* prevented *contrast* from testing for a main effect of *method*. Here we add the *emptycells(reweight)* option so that *contrast* can take the empty cells into account when computing the marginal means for *method*.

```
. contrast method class|method, emptycells(reweight)
Contrasts of marginal linear predictions
Margins : asbalanced
Empty cells : reweight

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>method</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(not testable)</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>class</td>
<td>method</td>
<td></td>
<td></td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>2.80</td>
<td>0.0687</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>0.91</td>
<td>0.4089</td>
</tr>
<tr>
<td>3</td>
<td>2</td>
<td>1.10</td>
<td>0.3390</td>
</tr>
<tr>
<td>4</td>
<td>2</td>
<td>0.22</td>
<td>0.8025</td>
</tr>
<tr>
<td>5</td>
<td>2</td>
<td>2.18</td>
<td>0.1221</td>
</tr>
<tr>
<td>Joint</td>
<td>10</td>
<td>1.44</td>
<td>0.1845</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td>60</td>
<td></td>
</tr>
</tbody>
</table>
```

Now *contrast* does report a test for the main effects of *method*. However, if we compare this with the *anova* results, we will see that the results are different. They are different because *contrast* uses the residual error term to compute the $F$ test by default. Using notation similar to *anova*, we can use the `/` operator to specify a different error term for the test. Therefore, we can reproduce the test of main effects from our *anova* command by typing

```
. anova class|method / method
```

```
. anova class|method / method
```
Multiple comparisons

We have seen that `contrast` can report the individual linear combinations that make up the requested effects. Depending upon the specified option, `contrast` will report confidence intervals, \( p \)-values, or both in the effects table. By default, the reported confidence intervals and \( p \)-values are not adjusted for multiple comparisons. Use the `mcompare()` option to adjust the confidence intervals and \( p \)-values for multiple comparisons of the individual effects.

Let’s compute the grand mean effects of `race` using the `g.` operator. We also specify the `mcompare(bonferroni)` option to compute \( p \)-values and confidence intervals using Bonferroni’s adjustment.

```
. use http://www.stata-press.com/data/r13/cholesterol
(Artificial cholesterol data)
. anova chol race##agegrp
(output omitted)
. contrast g.race, mcompare(bonferroni)
```

<table>
<thead>
<tr>
<th>race</th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>(black vs mean)</td>
<td>1</td>
<td>7.07</td>
<td>0.0100</td>
<td>0.0301</td>
</tr>
<tr>
<td>(white vs mean)</td>
<td>1</td>
<td>2.82</td>
<td>0.0982</td>
<td>0.2947</td>
</tr>
<tr>
<td>(other vs mean)</td>
<td>1</td>
<td>0.96</td>
<td>0.3312</td>
<td>0.9936</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>3.62</td>
<td>0.0329</td>
<td></td>
</tr>
<tr>
<td>Denominator</td>
<td>60</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Note: Bonferroni-adjusted \( p \)-values are reported for tests on individual contrasts only.
### Number of Comparisons

<table>
<thead>
<tr>
<th>Race</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>race</td>
<td>3</td>
</tr>
</tbody>
</table>

### Bonferroni

<table>
<thead>
<tr>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>(black vs mean)</td>
<td>4.17666</td>
<td>1.570588 0.3083743 8.044945</td>
</tr>
<tr>
<td>(white vs mean)</td>
<td>-2.638058</td>
<td>1.570588 -6.506343 1.230227</td>
</tr>
<tr>
<td>(other vs mean)</td>
<td>-1.538602</td>
<td>1.570588 -5.406887 2.329684</td>
</tr>
</tbody>
</table>

The last table reports a Bonferroni-adjusted confidence interval for each individual contrast. (Use the `effects` option to add `p`-values to the last table.) The first table includes a Bonferroni-adjusted `p`-value for each test that is not a joint test.

Joint tests are never adjusted for multiple comparisons. For example,

```stata
. contrast race@agegrp, mcompare(bonferroni)
```

Contrasts of marginal linear predictions

Margins : asbalanced

<table>
<thead>
<tr>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>

<tr>
<td>10</td>
<td>2.07</td>
<td>0.0409</td>
</tr>
</tbody>
</table>

Denominator 60

Note: Bonferroni-adjusted `p`-values are reported for tests on individual contrasts only.
Here we have five tests of simple effects with two degrees of freedom each. No Bonferroni-adjusted $p$-values are available for these tests, but the confidence intervals for the individual contrasts are adjusted.

### Unbalanced data

By default, `contrast` treats all factors as balanced when computing marginal means. By balanced, we mean that `contrast` assumes an equal number of observations in each level of each factor and an equal number of observations in each cell of each interaction. If our data are balanced, there is no issue. If, however, our data are not balanced, we might prefer that `contrast` use the actual cell frequencies from our data in computing marginal means. We instruct `contrast` to use observed frequencies by adding the `asobserved` option.

Even if our data are unbalanced, we might still want `contrast` to compute balanced marginal means. It depends on what we want to test and what our data represent. If we have data from a designed experiment that started with an equal number of males and females but the data became unbalanced because the data from a few males were unusable, we might still want our margins computed as though the data were balanced. If, however, we have a representative sample of individuals from Los Angeles with 40% of European descent, 34% African-American, 25% Hispanic, and 1% Australian, we probably want our margins computed using these representative frequencies. We do not want Australians receiving the same weight as Europeans.

The following examples will use an unbalanced version of our dataset.

```
use http://www.stata-press.com/data/r13/cholesterol3
(Artificial cholesterol data, unbalanced)
```

<table>
<thead>
<tr>
<th>race@agegrp</th>

</tbody>
</table>

The row labeled `Total` gives observed cell frequencies for age group. These can be obtained by summing frequencies from the cells in the corresponding column. In this respect, we can also refer to them as marginal frequencies. We use the terms marginal frequencies and cell frequencies interchangeably below.
We begin by fitting the two-factor model with an interaction.

```
. anova chol race##agegrp
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob &gt; F</th>

Using observed cell frequencies

Recall that the marginal means are computed from the cell means. Treating the factors as balanced yields the following marginal means for race:

\[
\eta_1 = \frac{1}{5}(\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15})
\]

\[
\eta_2 = \frac{1}{5}(\mu_{21} + \mu_{22} + \mu_{23} + \mu_{24} + \mu_{25})
\]

\[
\eta_3 = \frac{1}{5}(\mu_{31} + \mu_{32} + \mu_{33} + \mu_{34} + \mu_{35})
\]

If we have a fixed population and unbalanced cells, then the \( \eta_i \) do not represent population means. If, however, our data are representative of the population, we can use the frequencies from our estimation sample to estimate the population marginal means, denoted \( \mu_i \).

Here are the results of testing for a main effect of race, treating all the factors as balanced.

```
. contrast r.race
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(white vs black)</td>
<td>1</td>
<td>3.28</td>
<td>0.0757</td>
</tr>
<tr>
<td>(other vs black)</td>
<td>1</td>

<tr>
<td>(other vs black)</td>
<td>-3.596867</td>
<td>2.93778</td>
<td>-9.491955 2.298221</td>
</tr>
</tbody>
</table>
The row labeled (white vs black) is the test for $\eta_2 = \eta_1$. The row labeled (other vs black) is the test for $\eta_3 = \eta_1$.

If the observed marginal frequencies are representative of the distribution of the levels of agegrp, we can use them to form the marginal means of chol for each of the levels of race from the cell means.

$$
\mu_1 = \frac{1}{67}(8\mu_{11} + 17\mu_{12} + 18\mu_{13} + 13\mu_{14} + 11\mu_{15})
$$

$$
\mu_2 = \frac{1}{67}(8\mu_{21} + 17\mu_{22} + 18\mu_{23} + 13\mu_{24} + 11\mu_{25})
$$

$$
\mu_3 = \frac{1}{67}(8\mu_{31} + 17\mu_{32} + 18\mu_{33} + 13\mu_{34} + 11\mu_{35})
$$

Here are the results of testing for the main effects of race, using the observed marginal frequencies:

```
. contrast r.race, asobserved
Contras ts of marginal linear predictions
Margins : asobserved

<table>
<thead>

</tbody>
</table>
```

The row labeled (white vs black) is the test for $\mu_2 = \mu_1$. The row labeled (other vs black) is the test for $\mu_3 = \mu_1$. Both tests were insignificant when we tested the cell means resulting from balanced frequencies; however, when we tested the cell means from observed frequencies, the first test is significant beyond the 5% level (and the second test is nearly so).

Here we reproduce the results of the `asobserved` option with custom contrasts. Because we are modifying the way that the marginal means are constructed from the cell means, we will specify the contrasts on the predicted cell means. We use macro expansion, `exp`, to evaluate the fractions instead of approximating them with decimals. Macro expansion guarantees that the contrast coefficients sum to zero. For more information, see `Macro expansion operators and function in [P] macro`. 

```
. contrast r.race, asobserved exp

Weighted contrast operators

contrast provides observation-weighted versions of five of the contrast operators—gw., hw., jw., pw., and qw.. The first three of these operators perform comparisons of means across cells, and like the marginal means just discussed, these means can be computed in two ways: 1) as though the cell frequencies were equal or 2) using the observed cell frequencies from the estimation sample. The weighted operators provide versions of the standard (as balanced) operators that weight these means by their cell frequencies. The two orthogonal polynomial operators involve similar adjustments for weighting.

Let’s examine what this means by using the gw. operator. The gw. operator is a weighted version of the g. operator. The gw. operator computes the grand mean using the cell frequencies for race obtained from the model fit.

Here we test the effects of race, comparing each level with the weighted grand mean but otherwise treating the factors as balanced in the marginal mean calculations.

. contrast gw.race

Contrasts of marginal linear predictions

Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(black vs mean)</td>
<td>1</td>
<td>2.78</td>
<td>0.1014</td>
</tr>
<tr>
<td>(white vs mean)</td>
<td>1</td>
<td>2.06</td>
<td>0.1573</td>
</tr>
<tr>
<td>(other vs mean)</td>
<td>1</td>
<td>0.06</td>
<td>0.8068</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>1.64</td>
<td>0.2029</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td>52</td>
<td></td>
</tr>
</tbody>
</table>
The observed marginal frequencies of race are 18, 24, and 25. Thus the row labeled (black vs mean) tests \( \eta_1 = (18\eta_1 + 24\eta_2 + 25\eta_3) / 67 \); the row labeled (white vs mean) tests \( \eta_2 = (18\eta_1 + 24\eta_2 + 25\eta_3) / 67 \); and the row labeled (other vs mean) tests \( \eta_3 = (18\eta_1 + 24\eta_2 + 25\eta_3) / 67 \).

Now we reproduce the above results using custom contrasts. We are weighting the calculation of the grand mean from the marginal means for each of the races, but we are not weighting the calculation of the marginal means themselves. Therefore, we can specify the custom contrast on the marginal means for race instead of on the cell means.

```
. contrast {race '=49/67' -'=24/67' -'=25/67'}
{race -'=18/67' '=43/67' -'=25/67'}
{race -'=18/67' -'=24/67' '=42/67'}
```

Contrasts of marginal linear predictions

<td>4.542662</td>
<td>1.740331</td>
</tr>
<tr>
<td>(white vs mean)</td>
<td>-2.689771</td>
<td>1.39142</td>
</tr>
<tr>
<td>(other vs mean)</td>
<td>-0.6885363</td>
<td>1.341261</td>
</tr>
</tbody>
</table>

The row labeled (black vs mean) tests \( \mu_1 = (18\mu_1 + 24\mu_2 + 25\mu_3)/67 \); the row labeled (white vs mean) tests \( \mu_2 = (18\mu_1 + 24\mu_2 + 25\mu_3)/67 \); and the row labeled (other vs mean) tests \( \mu_3 = (18\mu_1 + 24\mu_2 + 25\mu_3)/67 \).

Here we use a custom contrast to reproduce the above result testing \( \mu_1 = (18\mu_1 + 24\mu_2 + 25\mu_3)/67 \). Because both the calculation of the marginal means and the calculation of the grand mean are adjusted, we specify the custom contrast on the cell means.

. contrast {race#agegrp '=49/67*8/67' '=49/67*17/67' '=49/67*18/67'}
   > '=49/67*13/67' '=49/67*11/67'
   > '=24/67*8/67' '=24/67*17/67' '=24/67*18/67'
   > '=24/67*13/67' '=24/67*11/67'

Contrasts of marginal linear predictions
Margins : asbalanced

</thead>
<tbody>
<tr>
<td>race#agegrp (1) (1)</td>
<td>4.542662</td>
<td>1.740331</td>
</tr>
</tbody>
</table>

The Helmert and reverse Helmert contrasts also involve calculating averages of the marginal means; therefore, weighted versions of these parameters are available as well. The hw. operator is a weighted version of the h. operator that computes the mean of the subsequent levels using the cell frequencies obtained from the model fit. The jw. operator is a weighted version of the j. operator that computes the mean of the previous levels using the cell frequencies obtained from the model fit.

For orthogonal polynomials, we can use the pw. and qw. operators, which are the weighted versions of the p. and q. operators. In this case, the cell frequencies from the model fit are used in the calculation of the orthogonal polynomial contrast coefficients.
## Testing factor effects on slopes

For linear models where the independent variables are all factor variables, the linear prediction at fixed levels of the factor variables turns out to be a cell mean. With these models, contrast computes and tests the effects of the factor variables on the expected mean of the dependent variable. When factor variables are interacted with continuous variables, contrast distinguishes factor effects on the intercept from factor effects on the slope.

Here we have 1980 census data including information on the birth rate (brate), the median age (medage), and the region of the country (region) for each of the 50 states. We can fit an ANCOVA model for brate using main effects of the factor variable region and the continuous variable medage.

```stata
. use http://www.stata-press.com/data/r13/census3
(1980 Census data by state)
. label list cenreg
  cenreg:
  1 NE
  2 NCentral
  3 South
  4 West
. anova brate i.region c.medage
```

For those more comfortable with linear regression, this is equivalent to the regression model

```stata
. regress brate i.region c.medage
```

You may use either.

We can use contrast to compute reference category effects for region. These contrasts compare the adjusted means of NCentral, South, and West regions with the adjusted mean of the NE region.

```stata
. contrast r.region
```

### Contrasts of marginal linear predictions

<table>
<thead>
<tr>
<th>Margins</th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>

</tr>
</tbody>
</table>

Denominator 45
Let’s add the interaction between region and medage to the model.

\[
E(brate|\text{region} = i, \text{medage}) = \alpha_0 + \alpha_i + \beta_0 \text{medage} + \beta_i \text{medage}
\]

where \(\alpha_0\) is the intercept and \(\beta_0\) is the slope of medage. We are modeling the effects of region in two different ways. The \(\alpha_i\) parameters measure the effect of region on the intercept, and the \(\beta_i\) parameters measure the effect of region on the slope of medage.

\textit{contrast} computes and tests effects on slopes separately from effects on intercepts. First, we will compute the reference category effects of region on the intercept:

\[
. \ b.s.
. contrast r.region

<td>343.0024</td>
<td>117.6547</td>
<td>105.5656   580.4393</td>
</tr>
</tbody>
</table>
Now we will compute the reference category effects of `region` on the slope of `medage`:

```
. contrast r.region#c.medage
Contrasts of marginal linear predictions
Margins : asbalanced
```

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>region#c.medage</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(NCentral vs NE)</td>
<td>1</td>
<td>0.16</td>
<td>0.6917</td>
</tr>
<tr>
<td>(South vs NE)</td>
<td>1</td>
<td>0.03</td>
<td>0.8558</td>
</tr>
<tr>
<td>(West vs NE)</td>
<td>1</td>
<td>8.18</td>
<td>0.0066</td>
</tr>
<tr>
<td>Joint</td>
<td>3</td>
<td>10.29</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td>42</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

```
Contrast Std. Err. [95% Conf. Interval]
region#c.medage
(NCentral vs NE) 2.208539 5.530981 -8.953432 13.37051
(South vs NE) .6928008 3.788735 -6.953175 8.338777
(West vs NE) -10.94649 3.827357 -18.67041 -3.22257
```

At the 5% level, the slope of `medage` for the `West` region differs from that of the `NE` region, but at that level of significance, we cannot say that the slope for the `NCentral` or the `South` region differs from that of the `NE` region.

This model is simple enough that the reference category contrasts reproduce the coefficients for `region` and for the interactions in an equivalent model fit by `regress`.

```
. regress brate region##c.medage
Source | SS      | df | MS         | Number of obs = 50

_cons   | 411.8268 | 108.2084 | 3.81  | 0.000 | 193.4533 630.2002
```

This will not be the case for models that are more complicated.
Chow tests

Now let’s suppose we are fitting a model for birth rates on median age and marriage rate. We are also interested in whether the regression coefficients differ for states in the east versus states in the west. We use census divisions to create a new variable, west, that indicates which states are in the western half of the United States.

```
. generate west = inlist(division, 4, 7, 8, 9)
```

We fit a model that includes a separate intercept for west as well as an interaction between west and each of the other variables in our model.

```
. regress brate i.west##c.medage i.west##c.mrgrate
```

```
Source | SS      | df | MS          | Number of obs = 50
       |         |    |             | F(  5,  44) = 92.09
Model  | 38516.2172 |  5 | 7703.24344 |
Residual | 3680.60281 | 44 | 83.6500639 |

       |       |           |       |     |                     
1.west | 327.8733 | 58.71793 | 5.58  | 0.000 | 209.5351 | 446.2115
medage | -7.532304 | 1.387624 | -5.43 | 0.000 | -10.32888 | -4.735731
west#c.medage | -10.11443 | 1.849103 | -5.47 | 0.000 | -13.84105 | -6.387808
1 | 828.6813 | 643.3443 | 1.29  | 0.204 | -467.8939 | 2125.257
west#c.mrgrate | -800.8036 | 645.488 | -1.24 | 0.221 | -2101.699 | 500.092
1 | 366.5325 | 47.08904 | 7.78  | 0.000 | 271.6308 | 461.4343
```

We can test the effects of west on the intercept and on the slopes of medage and mrgrate. We will specify all of these effects in a single `contrast` command and include the `overall` option to obtain a joint test of effects, that is, a test that the coefficients for eastern states and for western states are equal.

```
. contrast west west#c.medage west#c.mrgrate, overall
```

```
Contrasts of marginal linear predictions
Margins : asbalanced
```

```
          | df | F     | P>|F|
----------|----|-------|-----
west      | 1  | 31.18 | 0.0000
west#c.medage | 1  | 29.92 | 0.0000
west#c.mrgrate | 1  | 1.54  | 0.2213
Overall | 3  | 22.82 | 0.0000
Denominator | 44
```

This overall test is referred to as a Chow test in econometrics (Chow 1960).
Beyond linear models

contrast may be used after almost any estimation command, with the added benefit that contrast provides direct support for testing main and interaction effects that is not available in most estimation commands. To illustrate, we will use contrast with results from a logistic regression. Stata’s logit command fits logistic regression models, reporting the fitted regression coefficients. The logistic command fits the same models but reports odds ratios. Although contrast can report odds ratios for the computed effects, the tests are all computed from linear combinations of the model coefficients regardless of which estimation command we used.

Suppose we have data on patient satisfaction for three hospitals in a city. Let’s begin by fitting a model for satisfied, whether the patient was satisfied with his or her treatment, using the main effects of hospital:

```
. use http://www.stata-press.com/data/r13/hospital, clear
(Artificial hospital satisfaction data)
. logit satisfied i.hospital
```

```
Iteration 0: log likelihood = -393.72216
Iteration 1: log likelihood = -387.55736
Iteration 2: log likelihood = -387.47680
Iteration 3: log likelihood = -387.47679
Logistic regression
Number of obs = 802
LR chi2(2) = 12.49
Prob > chi2 = 0.0019
Log likelihood = -387.47679
Pseudo R2 = 0.0159

satisfied | Coef. Std. Err. z P>|z| [95% Conf. Interval]
--------- | ------------------ --------- -------- -------------- --------------
hospital |        
2 | .5348129 .2136021 2.50  0.012  .1161604 .9534654
3 | .7354519 .2221929 3.31  0.001  .2999618 1.170942
_cons | 1.034708 .1391469 7.44  0.000  .7619855 1.307431
```

Because there are no other independent variables in this model, the reference category effects of hospital computed by contrast will match the fitted model coefficients, assuming a common reference level.

```
. contrast r.hospital
Contrasts of marginal linear predictions
Margins : asbalanced

|          | df  | chi2   | P>|chi2|   
|----------|-----|--------|--------|
| hospital |     |        |        |
| (2 vs 1) | 1   | 6.27   | 0.0123 |
| (3 vs 1) | 1   | 10.96  | 0.0009 |
| Joint    | 2   | 12.55  | 0.0019 |
```

```
<table>
<thead>
<tr>
<th></th>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>hospital</td>
<td>(2 vs 1)</td>

<td>(3 vs 1)</td>
<td>.7354519</td>
<td>.2221929 .2999618 1.170942</td>
</tr>
</tbody>
</table>
```
We see that the reference category effects are equal to the fitted coefficients. They also have the same interpretation, the difference in log odds from the reference category. The top table also provides a joint test of these effects, a test of the main effects of hospital.

We also have information on the condition for which each patient is being treated in the variable illness. Here we fit a logistic regression using a two-way crossed model of hospital and illness.

```
. label list illness
illness:
    1 heart attack
    2 stroke
    3 pneumonia
    4 lung disease
    5 kidney failure
. logistic satisfied hospital##illness
```

Using `contrast`, we can obtain an ANOVA-style table of tests for the main effects and interaction effects of hospital and illness.

```
Using contrast, we can obtain an ANOVA-style table of tests for the main effects and interaction effects of hospital and illness.
```
Our interaction effect is significant, so we decide to evaluate the simple reference category effects of `hospital` within `illness`. We are particularly interested in patient satisfaction when being treated for a heart attack or stroke, so we will use the `i.` operator to limit our output to simple effects within the first two illnesses.

```stata
. contrast r.hospital@i(1 2).illness, nowald
```

The row labeled `(2 vs 1) heart attack` estimates simple effects on the log odds when comparing hospital 2 with hospital 1 for patients having heart attacks. These effects are differences in the cell means of the linear predictions.

We can add the `or` option to report an odds ratio for each of these simple effects:

```stata
. contrast r.hospital@i(1 2).illness, nowald or
```

These odds ratios are just the exponentiated version of the contrasts in the previous table.

For contrasts of the margins of nonlinear predictions, such as predicted probabilities, see `[R] margins, contrast`. 

Multiple equations

contrast works with models containing multiple equations. Commands such as `intreg` and `gnbreg` allow their ancillary parameters to be modeled as functions of independent variables, and contrast can compute and test effects within these equations. In addition, contrast allows a special pseudofactor for equation—called `_eqns`—when working with results from `manova`, `mvreg`, `mlogit`, and `mprobit`.

In example 4 of [MV] `manova`, we fit a two-way MANOVA model using data from Woodard (1931). Here we will fit this model using `mvreg`. The data represent patients with jaw fractures. `y1` is the patient’s age, `y2` is blood lymphocytes, and `y3` is blood polymorphonuclears. Two factor variables, `gender` and `fracture`, are used as independent variables.

```
. use http://www.stata-press.com/data/r13/jaw
   (Table 4.6 Two-Way Unbalanced Data for Fractures of the Jaw -- Rencher (1998))
. mvreg y1 y2 y3 = gender##fracture, vsquish nofvlabel
```

</tbody>
</table>

Denominator 21

Because we are investigating the results from `mvreg`, we can use the special `_eqns` factor to test for a marginal effect on the means among the dependent variables:

. contrast _eqns

Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>_eqns</td>
<td>2</td>
<td>49.19</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td>21</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Here we test whether the main effects of `gender` differ among the dependent variables:

. contrast gender#_eqns

Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>gender#_eqns</td>
<td>2</td>
<td>3.61</td>
<td>0.0448</td>
</tr>
<tr>
<td>Denominator</td>
<td>21</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
Although it is not terribly interesting in this case, we can even calculate contrasts across equations:

```
. contrast gender#_eqns
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>

<tr>
<td>Denominator</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>21</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

**Video example**

Introduction to contrasts in Stata: One-way ANOVA

**Stored results**

`contrast` stores the following in `r()`:

Scalars
- `r(df_r)` variance degrees of freedom
- `r(k_terms)` number of terms in `termlist`
- `r(level)` confidence level of confidence intervals

Macros
- `r(cmd)` contrast
- `r(cmdline)` command as typed
- `r(est_cmd)` `e(cmd)` from original estimation results
- `r(est_cmdline)` `e(cmdline)` from original estimation results
- `r(title)` title in output
- `r(overall)` overall or empty
- `r(empspec)` `empspec` from `emptcells()`
- `r(mcmethod)` `method` from `mcompare()`
- `r(mctitle)` title for `method` from `mcompare()`
- `r(mcadjustall)` adjustall or empty
- `r(margin_method)` asbalanced or asobserved

Matrices
- `r(b)` contrast estimates
- `r(V)` variance-covariance matrix of the contrast estimates
- `r(error)` contrast estimability codes;
  - 0 means estimable,
  - 8 means not estimable
- `r(L)` matrix of contrasts applied to the model coefficients
- `r(table)` matrix containing the contrasts with their standard errors, test statistics, p-values, and confidence intervals
- `r(F)` vector of F statistics; `r(df_r)` present
- `r(chi2)` vector of χ² statistics; `r(df_r)` not present
- `r(p)` vector of p-values corresponding to `r(F)` or `r(chi2)`
- `r(df)` vector of degrees of freedom corresponding to `r(p)`
- `r(df2)` vector of denominator degrees of freedom corresponding to `r(F)`
contrast with the post option stores the following in e():

Scalars
- \(e(\text{df}_r)\): variance degrees of freedom
- \(e(k\_\text{terms})\): number of terms in \text{termlist}

Macros
- \(e(\text{cmd})\): contrast
- \(e(\text{cmdline})\): command as typed
- \(e(\text{est\_cmd})\): \(e(\text{cmd})\) from original estimation results
- \(e(\text{est\_cmdline})\): \(e(\text{cmdline})\) from original estimation results
- \(e(\text{title})\): title in output
- \(e(\text{overall})\): overall or empty
- \(e(\text{emptycells})\): \text{empspec} from \text{emptycells()}
- \(e(\text{margin\_method})\): \text{abas} or \text{asob}
- \(e(\text{properties})\): \text{b V}

Matrices
- \(e(b)\): contrast estimates
- \(e(V)\): variance–covariance matrix of the contrast estimates
- \(e(\text{error})\): contrast estimability codes;
  - 0 means estimable,
  - 8 means not estimable
- \(e(L)\): matrix of contrasts applied to the model coefficients
- \(e(F)\): vector of unadjusted \(F\) statistics; \(e(\text{df}_r)\) present
- \(e(\text{chi2})\): vector of \(\chi^2\) statistics; \(e(\text{df}_r)\) not present
- \(e(p)\): vector of unadjusted \(p\)-values corresponding to \(e(F)\) or \(e(\text{chi2})\)
- \(e(df)\): vector of degrees of freedom corresponding to \(e(p)\)
- \(e(df2)\): vector of denominator degrees of freedom corresponding to \(e(F)\)

Methods and formulas

Methods and formulas are presented under the following headings:

- **Marginal linear predictions**
- **Contrast operators**
  - Reference level contrasts
  - Adjacent contrasts
  - Grand mean contrasts
  - Helmert contrasts
  - Reverse Helmert contrasts
  - Orthogonal polynomial contrasts
- **Contrasts within interactions**
- **Multiple comparisons**

**Marginal linear predictions**

\(\text{contrast}\) treats intercept effects separately from slope effects. To illustrate, consider the following parameterization for a quadratic regression of \(y\) on \(x\) that also models the effects of two factor variables \(A\) and \(B\), where the levels of \(A\) are indexed by \(i = 1, \ldots, k_a\) and the levels of \(B\) are indexed by \(j = 1, \ldots, k_b\).

\[
E(y|A = i, B = j, x) = \eta_{0ij} + \eta_{1ij}x + \eta_{2ij}x^2
\]

\[
\eta_{0ij} = \eta_0 + \alpha_{0i} + \beta_{0j} + (\alpha \beta)_{0ij}
\]
\[ \eta_{1ij} = \eta_1 + \alpha_{1i} + \beta_{1j} + (\alpha\beta)_{1ij} \]

\[ \eta_{2ij} = \eta_2 + \alpha_{2i} + \beta_{2j} + (\alpha\beta)_{2ij} \]

We have partitioned the coefficients into three groups of parameters: \( \eta_{0ij} \) is a cell prediction for the intercept, \( \eta_{1ij} \) is a cell prediction for the slope on \( x \), and \( \eta_{2ij} \) is a cell prediction for the slope on \( x^2 \). For the intercept parameters, \( \eta_0 \) is the intercept, \( \alpha_0 \) represents a main effect for factor \( A \) at its \( i \)th level, \( \beta_0 \) represents a main effect for factor \( B \) at its \( j \)th level, and \( (\alpha\beta)_0 \) represents an effect for the interaction of \( A \) and \( B \) at the \( ij \)th level. The individual coefficients in \( \eta_{1ij} \) and \( \eta_{2ij} \) have similar interpretations, but the effects are on the slopes of \( x \) and \( x^2 \), respectively.

The marginal intercepts for \( A \) are given by

\[ \eta_{0i} = \sum_{j=1}^{k_b} f_{ij} \eta_{0ij} \]

where \( f_{ij} \) is a marginal relative frequency of the \( j \)th level of \( B \) and is controlled by the \texttt{asobserved} and \texttt{emptycells(reweight)} options according to

\[
    f_{ij} = \begin{cases} 
        1/k_b, & \text{default} \\
        w_{.j}/w_{..}, & \texttt{asobserved} \\
        1/(k_b - e_i), & \texttt{emptycells(reweight)} \\
        w_{ij}/w_{i.}, & \texttt{emptycells(reweight) and asobserved}
    \end{cases}
\]

Above, \( w_{ij} \) is the number of individuals with \( A \) at its \( i \)th level and \( B \) at its \( j \)th level,

\[ w_{i.} = \sum_{j=1}^{k_b} w_{ij} \]

\[ w_{.j} = \sum_{i=1}^{k_a} w_{ij} \]

\[ w_{..} = \sum_{i=1}^{k_a} \sum_{j=1}^{k_b} w_{ij} \]

and \( e_i \) is the number of empty cells where \( A \) is at its \( i \)th level. The marginal intercepts for \( B \) and marginal slopes on \( x \) and \( x^2 \) are similarly defined.

Estimates for the cell intercepts and slopes are computed using the corresponding linear combination of the coefficients from the fitted model. For example, the estimated cell intercepts are computed using

\[ \hat{\eta}_{0ij} = \hat{\eta}_0 + \hat{\alpha}_{0i} + \hat{\beta}_{0j} + (\hat{\alpha}\hat{\beta})_{0ij} \]

and the estimated marginal intercepts for \( A \) are computed as
Contrast operators

contrast performs Wald tests using linear combinations of marginal linear predictions. For example, the following linear combination can be used to test for a specific effect of factor A on the marginal intercepts.

\[ \sum_{i=1}^{k_A} c_i \hat{\eta}_{0i} \]

If the \( c_i \) elements sum to zero, the linear combination is called a contrast. If the factor A is represented by a variable named A, then we specify this contrast using the following syntax:

\{A \ c_1 \ c_2 \ldots \ c_{k_A} \}

Similarly, the following linear combination can be used to test for a specific interaction effect of factors A and B on the marginal slope of \( x \).

\[ \sum_{i=1}^{k_A} \sum_{j=1}^{k_B} c_{ij} \eta_{1ij} \]

If the factor B is represented by a variable named B, then we specify this contrast using the following syntax:

\{A#B \ c_{11} \ c_{12} \ldots \ c_{1k_B} \ c_{21} \ldots \ c_{k_Ak_B} \}

contrast has variable operators for several commonly used contrasts. Each contrast operator specifies a matrix of linear combinations that yield the requested set of contrasts to be applied to the marginal linear predictions associated with the attached factor variable.

Reference level contrasts

The r. operator compares each level with a reference level. Let \( R \) be the corresponding contrast matrix for factor A, and then \( R \) is a \((k_A - 1) \times k_A\) matrix with elements

\[ R_{ij} = \begin{cases} -1, & \text{if } j \text{ is the reference level} \\ 1, & \text{if } i = j \text{ and } j \text{ is less than the reference level} \\ 1, & \text{if } i + 1 = j \text{ and } j \text{ is greater than the reference level} \\ 0, & \text{otherwise} \end{cases} \]
If \( k_a = 5 \) and the reference level is the third level of \( A \) (specified as \( \text{rb(#3).A} \)), then

\[
R = \begin{pmatrix}
1 & 0 & -1 & 0 & 0 \\
0 & 1 & -1 & 0 & 0 \\
0 & 0 & -1 & 1 & 0 \\
0 & 0 & -1 & 0 & 1
\end{pmatrix}
\]

**Adjacent contrasts**

The \( \text{a.} \) operator compares each level with the next level. Let \( A \) be the corresponding contrast matrix for factor \( A \), and then \( A \) is a \((k_a - 1) \times k_a\) matrix with elements

\[
A_{ij} = \begin{cases}
1, & \text{if } i = j \\
-1, & \text{if } i + 1 = j \\
0, & \text{otherwise}
\end{cases}
\]

If \( k_a = 5 \), then

\[
A = \begin{pmatrix}
1 & -1 & 0 & 0 & 0 \\
0 & 1 & -1 & 0 & 0 \\
0 & 0 & 1 & -1 & 0 \\
0 & 0 & 0 & 1 & -1
\end{pmatrix}
\]

The \( \text{ar.} \) operator compares each level with the previous level. If \( A \) is the contrast matrix for the \( \text{a.} \) operator, then \(-A\) is the corresponding contrast matrix for the \( \text{ar.} \) operator.

**Grand mean contrasts**

The \( \text{g.} \) operator compares each level with the mean of all the levels. Let \( G \) be the corresponding contrast matrix for factor \( A \), and then \( G \) is a \( k_a \times k_a \) matrix with elements

\[
G_{ij} = \begin{cases}
1 - 1/k_a, & \text{if } i = j \\
-1/k_a, & \text{if } i \neq j
\end{cases}
\]

If \( k_a = 5 \), then

\[
G = \begin{pmatrix}
4/5 & -1/5 & -1/5 & -1/5 & -1/5 \\
-1/5 & 4/5 & -1/5 & -1/5 & -1/5 \\
-1/5 & -1/5 & 4/5 & -1/5 & -1/5 \\
-1/5 & -1/5 & -1/5 & 4/5 & -1/5 \\
-1/5 & -1/5 & -1/5 & -1/5 & 4/5
\end{pmatrix}
\]

The \( \text{gw.} \) operator compares each level with the weighted mean of all the levels. The weights are taken from the observed weighted cell frequencies in the estimation sample of the fitted model. Let \( G_w \) be the corresponding contrast matrix for factor \( A \), and then \( G_w \) is a \( k_a \times k_a \) matrix with elements
where $w_i$ is a marginal weight representing the number of individuals with $A$ at its $i$th level and $w. = \sum_i w_i$.

**Helmert contrasts**

The $h.$ operator compares each level with the mean of the subsequent levels. Let $H$ be the corresponding contrast matrix for factor $A$, and then $H$ is a $(k_a - 1) \times k_a$ matrix with elements

$$
H_{ij} = \begin{cases} 
1, & \text{if } i = j \\
-1/(k_a - i), & \text{if } i < j \\
0, & \text{otherwise}
\end{cases}
$$

If $k_a = 5$, then

$$
H = \begin{pmatrix}
1 & -1/4 & -1/4 & -1/4 & -1/4 \\
0 & 1 & -1/3 & -1/3 & -1/3 \\
0 & 0 & 1 & -1/2 & -1/2 \\
0 & 0 & 0 & 1 & -1
\end{pmatrix}
$$

The $hw.$ operator compares each level with the weighted mean of the subsequent levels. Let $H_w$ be the corresponding contrast matrix for factor $A$, and then $H_w$ is a $(k_a - 1) \times k_a$ matrix with elements

$$
H_{wij} = \begin{cases} 
1, & \text{if } i = j \\
-w_j / \sum_{l=j}^{k_a} w_l, & \text{if } i < j \\
0, & \text{otherwise}
\end{cases}
$$

**Reverse Helmert contrasts**

The $j.$ operator compares each level with the mean of the previous levels. Let $J$ be the corresponding contrast matrix for factor $A$, and then $J$ is a $(k_a - 1) \times k_a$ matrix with elements

$$
J_{ij} = \begin{cases} 
1, & \text{if } i + 1 = j \\
-1/i, & \text{if } j \leq i \\
0, & \text{otherwise}
\end{cases}
$$

If $k_a = 5$, then

$$
H = \begin{pmatrix}
-1 & 1 & 0 & 0 & 0 \\
-1/2 & -1/2 & 1 & 0 & 0 \\
-1/3 & -1/3 & -1/3 & 1 & 0 \\
-1/4 & -1/4 & -1/4 & -1/4 & 1
\end{pmatrix}
$$
The \( jw. \) operator compares each level with the weighted mean of the previous levels. Let \( J_w \) be the corresponding contrast matrix for factor \( A \), and then \( J_w \) is a \( (k_a - 1) \times k_a \) matrix with elements

\[
J_{wij} = \begin{cases} 
1, & \text{if } i + 1 = j \\
-w_j / \sum_{l=1}^{i} w_l, & \text{if } i \leq j \\
0, & \text{otherwise}
\end{cases}
\]

**Orthogonal polynomial contrasts**

The \( p. \) operator applies orthogonal polynomial contrasts using the level values of the attached factor variable. The \( q. \) operator applies orthogonal polynomial contrasts using the level indices of the attached factor variable. These two operators are equivalent when the level values of the attached factor are equally spaced. The \( pw. \) and \( qw. \) operators are weighted versions of \( p. \) and \( q. \), where the weights are taken from the observed weighted cell frequencies in the estimation sample of the fitted model. \texttt{contrast} uses the Christoffel–Darboux recurrence formula for computing orthogonal polynomial contrasts (Abramowitz and Stegun 1972). The elements of the contrasts are normalized such that

\[
Q'WQ = \frac{1}{w} I
\]

where \( W \) is a diagonal matrix of the marginal cell weights \( w_1, w_2, \ldots, w_k \) of the attached factor variable (all 1 for \( p. \) and \( q. \)), and \( w \) is the sum of the weights (the number of levels \( k \) for \( p. \) and \( q. \)).

**Contrasts within interactions**

Contrast operators are allowed to be specified on factor variables participating in interactions. In such cases, \texttt{contrast} applies the proper matrix product of the contrast matrices to the cell margins of the interacted factor variables.

For example, consider the contrasts implied by specifying \( r.A#h.B \). Let \( M \) be the matrix of estimated cell margins for the levels of \( A \) and \( B \), where the rows of \( M \) are indexed by the levels of \( A \) and the columns are indexed by the levels of \( B \). \texttt{contrast} puts the estimated cell margins in the following vector form:

\[
v = \text{vec}(M') = \begin{pmatrix} M_{11} \\
M_{12} \\
\vdots \\
M_{1kb} \\
M_{21} \\
M_{22} \\
\vdots \\
M_{2kb} \\
\vdots \\
M_{ka kb} \end{pmatrix}
\]
The individual contrasts are then given by the elements of

\((R \otimes H)v\)

where \(\otimes\) denotes the Kronecker direct product.

**Multiple comparisons**

See [R] `pwcompare` for details on the methods and formulas used to adjust \(p\)-values and confidence intervals for multiple comparisons. The formulas for Bonferroni’s method and Šidák’s method are presented with \(m = k(k - 1)/2\), the number of pairwise comparisons for a factor term with \(k\) levels. For contrasts, \(m\) is instead the number of contrasts being performed on the factor term; often, \(m = k - 1\) for a term with \(k\) levels.

[U] 20 Estimation and postestimation commands
### Description

The following postestimation commands are available after `contrast, post`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>lincom</code></td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td><code>nlcom</code></td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

### Remarks and examples

In *Orthogonal polynomial contrasts* in [R] *contrast*, we used the `p.` operator to test the orthogonal polynomial effects of age group.

```
    . contrast p.agegrp, noeffects
```

We then used a second `contrast` command,

```
    . contrast p(2 3 4).agegrp, noeffects
```

selecting levels to test whether the quadratic, cubic, and quartic contrasts were jointly significant.

We can perform the same joint test by using the `test` command after specifying the `post` option with our first `contrast` command.
. use http://www.stata-press.com/data/r13/cholesterol
(Artificial cholesterol data)
. anova chol agegrp
(output omitted)
. contrast p.agegrp, noeffects post

Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>

Syntax

    copyright

Description

    copyright presents copyright notifications concerning tools, libraries, etc., used in the construction of Stata.

Remarks and examples

    The correct form for a copyright notice is
    
    Copyright dates by author/owner
    
    The word “Copyright” is spelled out. You can use the © symbol, but “(C)” has never been given legal recognition. The phrase “All Rights Reserved” was historically required but is no longer needed.

    Currently, most works are copyrighted from the moment they are written, and no copyright notice is required. Copyright concerns the protection of the expression and structure of facts and ideas, not the facts and ideas themselves. Copyright concerns the ownership of the expression and not the name given to the expression, which is covered under trademark law.

    Copyright law as it exists today began in England in 1710 with the Statute of Anne, An Act for the Encouragement of Learning, by Vesting the Copies of Printed Books in the Authors or Purchases of Such Copies, during the Times therein mentioned. In 1672, Massachusetts introduced the first copyright law in what was to become the United States. After the Revolutionary War, copyright was introduced into the U.S. Constitution in 1787 and went into effect on May 31, 1790. On June 9, 1790, the first copyright in the United States was registered for The Philadelphia Spelling Book by John Barry.

    There are significant differences in the understanding of copyright in the English- and non–English-speaking world. The Napoleonic or Civil Code, the dominant legal system in the non–English-speaking world, splits the rights into two classes: the author’s economic rights and the author’s moral rights. Moral rights are available only to “natural persons”. Legal persons (corporations) have economic rights but not moral rights.

TERMS AND CONDITIONS FOR USE, REPRODUCTION, AND DISTRIBUTION

1. Definitions.
   “License” shall mean the terms and conditions for use, reproduction, and distribution as defined by Sections 1 through 9 of this document.
   “Licensor” shall mean the copyright owner or entity authorized by the copyright owner that is granting the License.
   “Legal Entity” shall mean the union of the acting entity and all other entities that control, are controlled by, or are under common control with that entity. For the purposes of this definition, “control” means (i) the power, direct or indirect, to cause the direction or management of such entity, whether by contract or otherwise, or (ii) ownership of fifty percent (50%) or more of the outstanding shares, or (iii) beneficial ownership of such entity.
   “You” (or “Your”) shall mean an individual or Legal Entity exercising permissions granted by this License.
   “Source” form shall mean the preferred form for making modifications, including but not limited to software source code, documentation source, and configuration files.
   “Object” form shall mean any form resulting from mechanical transformation or translation of a Source form, including but not limited to compiled object code, generated documentation, and conversions to other media types.
   “Work” shall mean the work of authorship, whether in Source or Object form, made available under the License, as indicated by a copyright notice that is included in or attached to the work (an example is provided in the Appendix below).
   “Derivative Works” shall mean any work, whether in Source or Object form, that is based on (or derived from) the Work and for which the editorial revisions, annotations, elaborations, or other modifications represent, as a whole, an original work of authorship. For the purposes of this License, Derivative Works shall not include works that remain separable from, or merely link (or bind by name) to the interfaces of, the Work and Derivative Works thereof.
“Contribution” shall mean any work of authorship, including the original version of the Work and any modifications or additions to that Work or Derivative Works thereof, that is intentionally submitted to Licensor for inclusion in the Work by the copyright owner or by an individual or Legal Entity authorized to submit on behalf of the copyright owner. For the purposes of this definition, “submitted” means any form of electronic, verbal, or written communication sent to the Licensor or its representatives, including but not limited to communication on electronic mailing lists, source code control systems, and issue tracking systems that are managed by, or on behalf of, the Licensor for the purpose of discussing and improving the Work, but excluding communication that is conspicuously marked or otherwise designated in writing by the copyright owner as “Not a Contribution.”

“Contributor” shall mean Licensor and any individual or Legal Entity on behalf of whom a Contribution has been received by Licensor and subsequently incorporated within the Work.

2. Grant of Copyright License. Subject to the terms and conditions of this License, each Contributor hereby grants to You a perpetual, worldwide, non-exclusive, no-charge, royalty-free, irrevocable copyright license to reproduce, prepare Derivative Works of, publicly display, publicly perform, sublicense, and distribute the Work and such Derivative Works in Source or Object form.

3. Grant of Patent License. Subject to the terms and conditions of this License, each Contributor hereby grants to You a perpetual, worldwide, non-exclusive, no-charge, royalty-free, irrevocable (except as stated in this section) patent license to make, have made, use, offer to sell, sell, import, and otherwise transfer the Work, where such license applies only to those patent claims licensable by such Contributor that are necessarily infringed by their Contribution(s) alone or by combination of their Contribution(s) with the Work to which such Contribution(s) was submitted. If You institute patent litigation against any entity (including a cross-claim or counterclaim in a lawsuit) alleging that the Work or a Contribution incorporated within the Work constitutes direct or contributory patent infringement, then any patent licenses granted to You under this License for that Work shall terminate as of the date such litigation is filed.

4. Redistribution. You may reproduce and distribute copies of the Work or Derivative Works thereof in any medium, with or without modifications, and in Source or Object form, provided that You meet the following conditions:

   You must give any other recipients of the Work or Derivative Works a copy of this License; and

   You must cause any modified files to carry prominent notices stating that You changed the files; and

   You must retain, in the Source form of any Derivative Works that You distribute, all copyright, patent, trademark, and attribution notices from the Source form of the Work, excluding those notices that do not pertain to any part of the Derivative Works; and

   If the Work includes a “NOTICE” text file as part of its distribution, then any Derivative Works that You distribute must include a readable copy of the attribution notices contained within such NOTICE file, excluding those notices that do not pertain to any part of the Derivative Works, in at least one of the following places: within a NOTICE text file distributed as part of the Derivative Works; within the Source form or documentation, if provided along with the Derivative Works; or, within a display generated by the Derivative Works, if and wherever such third-party notices normally appear. The contents of the NOTICE file are for informational purposes only and do not modify the License. You may
add Your own attribution notices within Derivative Works that You distribute, alongside or as an addendum to the NOTICE text from the Work, provided that such additional attribution notices cannot be construed as modifying the License. You may add Your own copyright statement to Your modifications and may provide additional or different license terms and conditions for use, reproduction, or distribution of Your modifications, or for any such Derivative Works as a whole, provided Your use, reproduction, and distribution of the Work otherwise complies with the conditions stated in this License.

5. Submission of Contributions. Unless You explicitly state otherwise, any Contribution intentionally submitted for inclusion in the Work by You to the Licensor shall be under the terms and conditions of this License, without any additional terms or conditions. Notwithstanding the above, nothing herein shall supersede or modify the terms of any separate license agreement you may have executed with Licensor regarding such Contributions.

6. Trademarks. This License does not grant permission to use the trade names, trademarks, service marks, or product names of the Licensor, except as required for reasonable and customary use in describing the origin of the Work and reproducing the content of the NOTICE file.

7. Disclaimer of Warranty. Unless required by applicable law or agreed to in writing, Licensor provides the Work (and each Contributor provides its Contributions) on an “AS IS” BASIS, WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied, including, without limitation, any warranties or conditions of TITLE, NON-INFRINGEMENT, MERCHANTABILITY, or FITNESS FOR A PARTICULAR PURPOSE. You are solely responsible for determining the appropriateness of using or redistributing the Work and assume any risks associated with Your exercise of permissions under this License.

8. Limitation of Liability. In no event and under no legal theory, whether in tort (including negligence), contract, or otherwise, unless required by applicable law (such as deliberate and grossly negligent acts) or agreed to in writing, shall any Contributor be liable to You for damages, including any direct, indirect, special, incidental, or consequential damages of any character arising as a result of this License or out of the use or inability to use the Work (including but not limited to damages for loss of goodwill, work stoppage, computer failure or malfunction, or any and all other commercial damages or losses), even if such Contributor has been advised of the possibility of such damages.

9. Accepting Warranty or Additional Liability. While redistributing the Work or Derivative Works thereof, You may choose to offer, and charge a fee for, acceptance of support, warranty, indemnity, or other liability obligations and/or rights consistent with this License. However, in accepting such obligations, You may act only on Your own behalf and on Your sole responsibility, not on behalf of any other Contributor, and only if You agree to indemnify, defend, and hold each Contributor harmless for any liability incurred by, or claims asserted against, such Contributor by reason of your accepting any such warranty or additional liability.

END OF TERMS AND CONDITIONS

APPENDIX: How to apply the Apache License to your work

To apply the Apache License to your work, attach the following boilerplate notice, with the fields enclosed by brackets “[ ]” replaced with your own identifying information. (Don’t include the brackets!) The text should be enclosed in the appropriate comment syntax for the file format. We also recommend that a file or class name and description of purpose be included on the same “printed page” as the copyright notice for easier identification within third-party archives.
Copyright [yyyy] [name of copyright owner]

Description

Stata uses portions of FreeType, a library used by JagPDF, which helps create PDF files, with the express permission of the authors.

StataCorp thanks and acknowledges the authors of FreeType for producing FreeType and allowing its use in Stata and other software.

For more information about FreeType, visit http://www.freetype.org/.

The full FreeType copyright notice is

Legal Terms

0. Definitions

Throughout this license, the terms ‘package’, ‘FreeType Project’, and ‘FreeType archive’ refer to the set of files originally distributed by the authors (David Turner, Robert Wilhelm, and Werner Lemberg) as the ‘FreeType Project’, be they named as alpha, beta or final release.

‘You’ refers to the licensee, or person using the project, where ‘using’ is a generic term including compiling the project’s source code as well as linking it to form a ‘program’ or ‘executable’. This program is referred to as ‘a program using the FreeType engine’.

This license applies to all files distributed in the original FreeType Project, including all source code, binaries and documentation, unless otherwise stated in the file in its original, unmodified form as distributed in the original archive. If you are unsure whether or not a particular file is covered by this license, you must contact us to verify this.

This license applies to all files distributed in the original FreeType Project, including all source code, binaries and documentation, unless otherwise stated in the file in its original, unmodified form as distributed in the original archive. If you are unsure whether or not a particular file is covered by this license, you must contact us to verify this.

The FreeType Project is copyright © 1996–2000 by David Turner, Robert Wilhelm, and Werner Lemberg. All rights reserved except as specified below.

1. No Warranty

THE FREETYPE PROJECT IS PROVIDED ‘AS IS’ WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESS OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. IN NO EVENT WILL ANY OF THE AUTHORS OR COPYRIGHT HOLDERS BE LIABLE FOR ANY DAMAGES CAUSED BY THE USE OR THE INABILITY TO USE, OF THE FREETYPE PROJECT.
2. Redistribution

This license grants a worldwide, royalty-free, perpetual and irrevocable right and license to use, execute, perform, compile, display, copy, create derivative works of, distribute and sublicense the FreeType Project (in both source and object code forms) and derivative works thereof for any purpose; and to authorize others to exercise some or all of the rights granted herein, subject to the following conditions:

• Redistribution of source code must retain this license file (‘FTL.TXT’) unaltered; any additions, deletions or changes to the original files must be clearly indicated in accompanying documentation. The copyright notices of the unaltered, original files must be preserved in all copies of source files.

• Redistribution in binary form must provide a disclaimer that states that the software is based in part of the work of the FreeType Team, in the distribution documentation. We also encourage you to put an URL to the FreeType web page in your documentation, though this isn’t mandatory.

These conditions apply to any software derived from or based on the FreeType Project, not just the unmodified files. If you use our work, you must acknowledge us. However, no fee need be paid to us.

3. Advertising

Neither the FreeType authors and contributors nor you shall use the name of the other for commercial, advertising, or promotional purposes without specific prior written permission.

We suggest, but do not require, that you use one or more of the following phrases to refer to this software in your documentation or advertising materials: ‘FreeType Project’, ‘FreeType Engine’, ‘FreeType library’, or ‘FreeType Distribution’.

As you have not signed this license, you are not required to accept it. However, as the FreeType Project is copyrighted material, only this license, or another one contracted with the authors, grants you the right to use, distribute, and modify it. Therefore, by using, distributing, or modifying the FreeType Project, you indicate that you understand and accept all the terms of this license.

4. Contacts

There are two mailing lists related to FreeType:

• freetype@nongnu.org

  Discusses general use and applications of FreeType, as well as future and wanted additions to the library and distribution. If you are looking for support, start in this list if you haven’t found anything to help you in the documentation.

• freetype-devel@nongnu.org

  Discusses bugs, as well as engine internals, design issues, specific licenses, porting, etc.

Our home page can be found at

http://www.freetype.org

*varlist* may contain time-series operators; see [U] 11.4.4 Time-series varlists.

by is allowed with correlate and pwcorr; see [D] by.
aweights and fweights are allowed; see [U] 11.1.6 weight.
Menu

correlate
Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Correlations and covariances

pwcorr
Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Pairwise correlations

Description

The `correlate` command displays the correlation matrix or covariance matrix for a group of variables. If `varlist` is not specified, the matrix is displayed for all variables in the dataset. Also see the `estat vce` command in [R] estat vce.

`pwcorr` displays all the pairwise correlation coefficients between the variables in `varlist` or, if `varlist` is not specified, all the variables in the dataset.

Options for `correlate`

- `means` displays summary statistics (means, standard deviations, minimums, and maximums) with the matrix.
- `noformat` displays the summary statistics requested by the `means` option in g format, regardless of the display formats associated with the variables.
- `covariance` displays the covariances rather than the correlation coefficients.
- `wrap` requests that no action be taken on wide correlation matrices to make them readable. It prevents Stata from breaking wide matrices into pieces to enhance readability. You might want to specify this option if you are displaying results in a window wider than 80 characters. Then you may need to set `linesize` to however many characters you can display across a line; see [R] log.

Options for `pwcorr`

- `obs` adds a line to each row of the matrix reporting the number of observations used to calculate the correlation coefficient.
- `sig` adds a line to each row of the matrix reporting the significance level of each correlation coefficient.
- `listwise` handles missing values through listwise deletion, meaning that the entire observation is omitted from the estimation sample if any of the variables in `varlist` is missing for that observation. By default, `pwcorr` handles missing values by pairwise deletion; all available observations are used to calculate each pairwise correlation without regard to whether variables outside that pair are missing.

`correlate` uses listwise deletion. Thus `listwise` allows users of `pwcorr` to mimic `correlate`’s treatment of missing values while retaining access to `pwcorr`’s features.

`casewise` is a synonym for `listwise`. 
print(#) specifies the significance level of correlation coefficients to be printed. Correlation coefficients with larger significance levels are left blank in the matrix. Typing `pwcorr, print(.10)` would list only correlation coefficients significant at the 10% level or better.

`star(#)` specifies the significance level of correlation coefficients to be starred. Typing `pwcorr, star(.05)` would star all correlation coefficients significant at the 5% level or better.

`bonferroni` makes the Bonferroni adjustment to calculated significance levels. This option affects printed significance levels and the `print()` and `star()` options. Thus `pwcorr, print(.05) bonferroni` prints coefficients with Bonferroni-adjusted significance levels of 0.05 or less.

`sidak` makes the Šidák adjustment to calculated significance levels. This option affects printed significance levels and the `print()` and `star()` options. Thus `pwcorr, print(.05) sidak` prints coefficients with Šidák-adjusted significance levels of 0.05 or less.

Remarks and examples

Remarks are presented under the following headings:

- `correlate`
- `pwcorr`
- `Video example`

**correlate**

Typing `correlate` by itself produces a correlation matrix for all variables in the dataset. If you specify the `varlist`, a correlation matrix for just those variables is displayed.

> **Example 1**

We have state data on demographic characteristics of the population. To obtain a correlation matrix, we type

```
. use http://www.stata-press.com/data/r13/census13
(1980 Census data by state)
. correlate
(obs=50)
```

<table>
<thead>
<tr>
<th></th>
<th>state</th>
<th>brate</th>
<th>pop</th>
<th>medage</th>
<th>division</th>
<th>region</th>
<th>mrgrate</th>
</tr>
</thead>
<tbody>
<tr>
<td>state</td>
<td>1.0000</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>brate</td>
<td>0.0208</td>
<td>1.0000</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>pop</td>
<td>-0.0540</td>
<td>-0.2830</td>
<td>1.0000</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>medage</td>
<td>-0.0624</td>
<td>-0.8800</td>
<td>0.3294</td>
<td>1.0000</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>division</td>
<td>-0.1345</td>
<td>0.6356</td>
<td>-0.1081</td>
<td>-0.5207</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>region</td>
<td>-0.1339</td>
<td>0.6086</td>
<td>-0.1515</td>
<td>-0.5292</td>
<td>0.9688</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td>mrgrate</td>
<td>0.0509</td>
<td>0.0677</td>
<td>-0.1502</td>
<td>-0.0177</td>
<td>0.2280</td>
<td>0.2490</td>
<td>1.0000</td>
</tr>
<tr>
<td>dvcrate</td>
<td>-0.0655</td>
<td>0.3508</td>
<td>-0.2064</td>
<td>-0.2229</td>
<td>0.5522</td>
<td>0.5682</td>
<td>0.7700</td>
</tr>
<tr>
<td>medagesq</td>
<td>-0.0621</td>
<td>-0.8609</td>
<td>0.3324</td>
<td>0.9984</td>
<td>-0.5162</td>
<td>-0.5239</td>
<td>-0.0202</td>
</tr>
<tr>
<td>dvcrate</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>medagesq</td>
<td>-0.2192</td>
<td>1.0000</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Because we did not specify the `wrap` option, Stata did its best to make the result readable by breaking the table into two parts.
To obtain the correlations between `mrgrate`, `dvcrate`, and `medage`, we type

```
correlate mrgrate dvcrate medage
(obs=50)
```

<table>
<thead>
<tr>
<th></th>
<th>mrgrate</th>
<th>dvcrate</th>
<th>medage</th>
</tr>
</thead>
<tbody>
<tr>
<td>mrgrate</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>dvcrate</td>
<td>0.7700</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td>medage</td>
<td>-0.0177</td>
<td>-0.2229</td>
<td>1.0000</td>
</tr>
</tbody>
</table>

**Example 2**

The `pop` variable in example 1 represents the total population of the state. Thus, to obtain population-weighted correlations among `mrgrate`, `dvcrate`, and `medage`, we type

```
correlate mrgrate dvcrate medage [w=pop]
```

You will see output similar to the above but with population weights applied.

**Example 3**

To obtain the matrix of covariances between `mrgrate`, `dvcrate`, and `medage`, we type `correlate mrgrate dvcrate medage, covariance`:

```
correlate mrgrate dvcrate medage, covariance
(obs=50)
```

<table>
<thead>
<tr>
<th></th>
<th>mrgrate</th>
<th>dvcrate</th>
<th>medage</th>
</tr>
</thead>
<tbody>
<tr>
<td>mrgrate</td>
<td>.000662</td>
<td></td>
<td></td>
</tr>
<tr>
<td>dvcrate</td>
<td>.000063</td>
<td>1.0e-05</td>
<td></td>
</tr>
<tr>
<td>medage</td>
<td>-.000769</td>
<td>-.001191</td>
<td>2.86775</td>
</tr>
</tbody>
</table>

We could have obtained the `pop`-weighted covariance matrix by typing `correlate mrgrate dvcrate medage [w=pop], covariance`. 
**pwcorr**

`correlate` calculates correlation coefficients by using casewise deletion; when you request correlations of variables $x_1, x_2, \ldots, x_k$, any observation for which any of $x_1, x_2, \ldots, x_k$ is missing is not used. Thus if $x_3$ and $x_4$ have no missing values, but $x_2$ is missing for half the data, the correlation between $x_3$ and $x_4$ is calculated using only the half of the data for which $x_2$ is not missing. Of course, you can obtain the correlation between $x_3$ and $x_4$ by using all the data by typing `correlate x_3 x_4`.

`pwcorr` makes obtaining such pairwise correlation coefficients easier.

---

**Example 4**

Using `auto.dta`, we investigate the correlation between several of the variables.

```
use http://www.stata-press.com/data/r13/auto1
(Automobile Models)
.pwcorr mpg price rep78 foreign, obs sig
```

```
<table>
<thead>
<tr>

---

Technical note

The `correlate` command will report the correlation matrix of the data, but there are occasions when you need the matrix stored as a Stata matrix so that you can further manipulate it. You can obtain the matrix by typing

```
. matrix accum R = varlist, noconstant deviations
. matrix R = corr(R)
```

The first line places the cross-product matrix of the data in matrix R. The second line converts that to a correlation matrix. Also see `[P] matrix define` and `[P] matrix accum`.

Video example

Pearson’s correlation coefficient in Stata

Stored results

`correlate` stores the following in `r()`:

Scalars
- `r(N)` number of observations
- `r(rho)` $\rho$ (first and second variables)
- `r(cov_12)` covariance (covariance only)
- `r(Var_1)` variance of first variable (covariance only)
- `r(Var_2)` variance of second variable (covariance only)

Matrices
- `r(C)` correlation or covariance matrix

`pwcorr` will leave in its wake only the results of the last call that it makes internally to `correlate` for the correlation between the last variable and itself. Only rarely is this feature useful.

Methods and formulas

For a discussion of correlation, see, for instance, Snedecor and Cochran (1989, 177–195); for an introductory explanation using Stata examples, see Acock (2014, 200–206).

According to Snedecor and Cochran (1989, 180), the term “co-relation” was first proposed by Galton (1888). The product-moment correlation coefficient is often called the Pearson product-moment correlation coefficient because Pearson (1896) and Pearson and Filon (1898) were partially responsible for popularizing its use. See Stigler (1986) for information on the history of correlation.

The estimate of the product-moment correlation coefficient, $\rho$, is

$$
\hat{\rho} = \frac{\sum_{i=1}^{n} w_i (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n} w_i (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^{n} w_i (y_i - \bar{y})^2}}
$$

where $w_i$ are the weights, if specified, or $w_i = 1$ if weights are not specified. $\bar{x} = (\sum w_i x_i) / (\sum w_i)$ is the mean of $x$, and $\bar{y}$ is similarly defined.

The unadjusted significance level is calculated by `pwcorr` as

$$
p = 2 \times \text{ttail}(n - 2, |\hat{\rho}| \sqrt{n - 2 / \sqrt{1 - \hat{\rho}^2}})
$$
Let \( v \) be the number of variables specified so that \( k = v(v-1)/2 \) correlation coefficients are to be estimated. If \texttt{bonferroni} is specified, the adjusted significance level is \( p' = \min(1, kp) \). If \texttt{sidak} is specified, \( p' = \min \{ 1, 1 - (1 - p)^k \} \). In both cases, see Methods and formulas in \([R]\) \texttt{oneway} for a more complete description of the logic behind these adjustments.

---

Carlo Emilio Bonferroni (1892–1960) studied in Turin and taught there and in Bari and Florence. He published on actuarial mathematics, probability, statistics, analysis, geometry, and mechanics. His work on probability inequalities has been applied to simultaneous statistical inference, although the method known as Bonferroni adjustment usually relies only on an inequality established earlier by Boole.

Florence Nightingale David (1909–1993) was born in Ivington, England, to parents who were friends with Florence Nightingale, David’s namesake. She began her studies in statistics under the direction of Karl Pearson at University College London and continued her studies under the direction of Jerzy Neyman. After receiving her doctorate in statistics in 1938, David became a senior statistician for various departments within the British military. She developed statistical models to forecast the toll on life and infrastructure that would occur if a large city were bombed. In 1938, she also published her book \textit{Tables of the Correlation Coefficient}, dealing with the distributions of correlation coefficients. After the war, she returned to University College London, serving as a lecturer until her promotion to professor in 1962. In 1967, David joined the University of California–Riverside, eventually becoming chair of the Department of Statistics. One of her most well-known works is the book \textit{Games, Gods and Gambling: The Origins and History of Probability and Statistical Ideas from the Earliest Times to the Newtonian Era}, a history of statistics. David published over 100 papers on topics including combinatorics, symmetric functions, the history of statistics, and applications of statistics, including ecological diversity. She published under the name F. N. David to avoid revealing her gender in a male-dominated profession.

Karl Pearson (1857–1936) studied mathematics at Cambridge. He was professor of applied mathematics (1884–1911) and eugenics (1911–1933) at University College London. His publications include literary, historical, philosophical, and religious topics. Statistics became his main interest in the early 1890s after he learned about its application to biological problems. His work centered on distribution theory, the method of moments, correlation, and regression. Pearson introduced the chi-squared test and the terms coefficient of variation, contingency table, heteroskedastic, histogram, homoskedastic, kurtosis, mode, random sampling, random walk, skewness, standard deviation, and truncation. Despite many strong qualities, he also fell into prolonged disagreements with others, most notably, William Bateson and R. A. Fisher.

Zbyněk Šidák (1933–1999) was a notable Czech statistician and probabilist. He worked on Markov chains, rank tests, multivariate distribution theory and multiple-comparison methods, and he served as the chief editor of \textit{Applications of Mathematics}.

Title

cumul — Cumulative distribution

Syntax

```
cumul varname [if] [in] [weight], generate(newvar) [options]
```

Options

<table>
<thead>
<tr>
<th>Description</th>
<th>Syntax</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Options</td>
</tr>
<tr>
<td></td>
<td>Main</td>
</tr>
<tr>
<td></td>
<td>freq</td>
</tr>
<tr>
<td></td>
<td>equal</td>
</tr>
</tbody>
</table>

Remarks and examples

* `generate(newvar)` is required.
  
  `by` is allowed; see [D] by.
  
  `fweight` and `aweights` are allowed; see [U] 11.1.6 weight.

Menu

Statistics > Summaries, tables, and tests > Distributional plots and tests > Generate cumulative distribution

Description

`cumul` creates `newvar`, defined as the empirical cumulative distribution function of `varname`.

Options

`generate(newvar)` is required. It specifies the name of the new variable to be created.

`freq` specifies that the cumulative be in frequency units; otherwise, it is normalized so that `newvar` is 1 for the largest value of `varname`.

`equal` requests that observations with equal values in `varname` get the same cumulative value in `newvar`. 
Remarks and examples

Example 1

cumul is most often used with graph to graph the empirical cumulative distribution. For instance, we have data on the median family income of 957 U.S. cities:

```
. use http://www.stata-press.com/data/r13/hsng
(1980 Census housing data)
. cumul faminc, gen(cum)
. sort cum
. line cum faminc, ylab(, grid) ytitle("") xlab(, grid)
> title("Cumulative of median family income")
> subtitle("1980 Census, 957 U.S. Cities")
```

![Cumulative of median family income](image)

It would have been enough to type `line cum faminc`, but we wanted to make the graph look better; see [G-2] `graph twoway line`.

If we had wanted a weighted cumulative, we would have typed `cumul faminc [w=pop]` at the first step.

Example 2

To graph two (or more) cumulatives on the same graph, use `cumul` and `stack`; see [D] `stack`. For instance, we have data on the average January and July temperatures of 956 U.S. cities:
As before, it would have been enough to type `line cjan cjuly temp, sort`. See `[D] stack` for an explanation of how the `stack` command works.

Technical note

According to Beniger and Robyn (1978), Fourier (1821) published the first graph of a cumulative frequency distribution, which was later given the name “ogive” by Galton (1875).

---

Jean Baptiste Joseph Fourier (1768–1830) was born in Auxerre in France. As a young man, Fourier became entangled in the complications of the French Revolution. As a result, he was arrested and put into prison, where he feared he might meet his end at the guillotine. When he was not in prison, he was studying, researching, and teaching mathematics. Later, he served Napoleon’s army in Egypt as a scientific adviser. Upon his return to France in 1801, he was appointed Prefect of the Department of Isère. While prefect, Fourier worked on the mathematical basis of the theory of heat, which is based on what are now called Fourier series. This work was published in 1822, despite the skepticism of Lagrange, Laplace, Legendre, and others—who found the work lacking in generality and even rigor—and disagreements of both priority and substance with Biot and Poisson.
Acknowledgment

The equal option was added by Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal*.

**Menu**

Statistics > Other > Quality control > Cusum plots and tests for binary variables

**Description**

cusum graphs the cumulative sum (cusum) of a binary (0/1) variable, `yvar`, against a (usually) continuous variable, `xvar`.

**Options**

- `generate(newvar)` saves the cusum in `newvar`.
- `yfit(fitvar)` calculates a cusum against `fitvar`, that is, the running sums of the “residuals” `fitvar` minus `yvar`. Typically, `fitvar` is the predicted probability of a positive outcome obtained from a logistic regression analysis.
- `nograph` suppresses the plot.
- `nocalc` suppresses calculation of the cusum test statistics.
Cusum plots and tests for binary variables

Cusum plots and tests for binary variables

connect_options affect the rendition of the plotted line; see [G-3] connect_options.

Add plots

addplot(plot) provides a way to add other plots to the generated graph. See [G-3] addplot_option.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples

The cusum is the running sum of the proportion of ones in the sample, a constant number, minus yvar,

\[ c_j = \sum_{k=1}^{j} f - yvar(k), \quad 1 \leq j \leq N \]

where \( f = (\sum yvar)/N \) and \( yvar(k) \) refers to the corresponding value of yvar when xvar is placed in ascending order: \( xvar_{(k+1)} \geq xvar_{(k)} \). Tied values of xvar are broken at random. If you want them broken the same way in two runs, you must set the random-number seed to the same value before giving the cusum command; see [R] set seed.

A U-shaped or inverted U-shaped cusum indicates, respectively, a negative or a positive trend of yvar with xvar. A sinusoidal shape is evidence of a nonmonotonic (for example, quadratic) trend. cusum displays the maximum absolute cusum for monotonic and nonmonotonic trends of yvar on xvar. These are nonparametric tests of departure from randomness of yvar with respect to xvar. Approximate values for the tests are given.

Example 1

For the automobile dataset, auto.dta, we wish to investigate the relationship between foreign (0 = domestic, 1 = foreign) and car weight as follows:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. cusum foreign weight
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Pr(1)</th>
<th>CusumL</th>
<th>zL</th>
<th>Pr&gt;zL</th>
<th>CusumQ</th>
<th>zQ</th>
<th>Pr&gt;zQ</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>74</td>
<td>0.2973</td>
<td>10.30</td>
<td>3.963</td>
<td>0.000</td>
<td>3.32</td>
<td>0.469</td>
<td>0.320</td>
</tr>
</tbody>
</table>
The resulting plot, which is U-shaped, suggests a negative monotonic relationship. The trend is confirmed by a highly significant linear cusum statistic, labeled \texttt{CusumL} in the output above.

Some 29.73\% of the cars are foreign (coded 1). The proportion of foreign cars diminishes with increasing weight. The domestic cars are crudely heavier than the foreign ones. We could have discovered that by typing \texttt{table foreign, stats(mean weight)}, but such an approach does not give the full picture of the relationship. The quadratic cusum (\texttt{CusumQ}) is not significant, so we do not suspect any tendency for the very heavy cars to be foreign rather than domestic. A slightly enhanced version of the plot shows the preponderance of domestic (coded 0) cars at the heavy end of the weight axis:

```
. label values foreign
. cusum foreign weight, s(none) recast(scatter) mlabel(foreign) mlabp(0)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Pr(1)</th>
<th>CusumL</th>
<th>zL</th>
<th>Pr&gt;zL</th>
<th>CusumQ</th>
<th>zQ</th>
<th>Pr&gt;zQ</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>74</td>
<td>0.2973</td>
<td>10.30</td>
<td>3.963</td>
<td>0.000</td>
<td>2.92</td>
<td>0.064</td>
<td>0.475</td>
</tr>
</tbody>
</table>
The example is, of course, artificial, because we would not really try to model the probability of a car being foreign given its weight.

## Stored results

`cusum` stores the following in `r()`:

Scalars

- `r(N)`: number of observations
- `r(prop1)`: proportion of positive outcomes
- `r(cusum1)`: cusum
- `r(z1)`: test (linear)
- `r(P_zl)`: p-value for test (linear)
- `r(cusumq)`: quadratic cusum
- `r(zq)`: test (quadratic)
- `r(P_zq)`: p-value for test (quadratic)

## Acknowledgment

`cusum` was written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model*.

Title

| db — Launch dialog |

Syntax   | Description | Options | Remarks and examples | Also see |

Syntax

**Syntax for db**

```
   db commandname
```

*For programmers*

```
   db commandname [ , message(string) debug dryrun ]
```

**Set system parameter**

```
   set maxdb # [ , permanently ]
```

where # must be between 5 and 1,000.

Description

```
   db is the command-line way to launch a dialog for a Stata command.
   The second syntax (which is the same but includes options) is for use by programmers.
   If you wish to allow the launching of dialogs from a help file, see [P] smcl for information on the dialog SMCL directive.
```

```
   set maxdb sets the maximum number of dialog boxes whose contents are remembered from one invocation to the next during a session. The default value of maxdb is 50.
```

Options

```
   message(string) specifies that string be passed to the dialog box, where it can be referred to from the __MESSAGE STRING property.
   debug specifies that the underlying dialog box be loaded with debug messaging turned on.
   dryrun specifies that, rather than launching the dialog, db show the commands it would issue to launch the dialog.
   permanently specifies that, in addition to making the change right now, the maxdb setting be remembered and become the default setting when you invoke Stata.
```

Remarks and examples

```
   The usual way to launch a dialog is to open the Data, Graphics, or Statistics menu and to make your selection from there. When you know the name of the command that you want to run, however, db provides a way to invoke the dialog from the command line.
```
db follows the same abbreviation rules that Stata’s command-line interface follows. So, to launch the dialog for `regress`, you can type
```
.db regress
```

or
```
.db reg
```

Say that you use the dialog box for `regress`, either by selecting

`Statistics > Linear models and related > Linear regression`

or by typing
```
.db regress
```
You fit a regression.

Much later during the session, you return to the `regress` dialog box. It will have the contents as you left them if 1) you have not typed `clear all` between the first and second invocations; 2) you have not typed `discard` between the two invocations; and 3) you have not used more than 50 different dialog boxes—regardless of how many times you have used each—between the first and second invocations of `regress`. If you use 51 or more, the contents of the `regress` dialog box will be forgotten.

`set maxdb` determines how many different dialog boxes are remembered. A dialog box takes, on average, about 20 KB of memory, so the 50 default corresponds to allowing dialog boxes to consume about 1 MB of memory.

Description

**symplot** graphs a symmetry plot of *varname*.

**quantile** plots the ordered values of *varname* against the quantiles of a uniform distribution.

**qqplot** plots the quantiles of *varname*₁ against the quantiles of *varname*₂ (Q–Q plot).

**qnorm** plots the quantiles of *varname* against the quantiles of the normal distribution (Q–Q plot).

**pnorm** graphs a standardized normal probability plot (P–P plot).

**qchi** plots the quantiles of *varname* against the quantiles of a $\chi^2$ distribution (Q–Q plot).

**pchi** graphs a $\chi^2$ probability plot (P–P plot).

See [R] regress postestimation diagnostic plots for regression diagnostic plots and [R] logistic postestimation for logistic regression diagnostic plots.

Options for symplot, quantile, and qqplot

---

**Plot**

*marker_options* affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] *marker_options*.

*marker_label_options* specify if and how the markers are to be labeled; see [G-3] *marker_label_options*.

---

**Reference line**

*rlopts(cline_options)* affect the rendition of the reference line; see [G-3] *cline_options*. 
Add plots

`addplot(plot)` provides a way to add other plots to the generated graph; see [G-3] `addplot_option`.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] `twoway_options`, excluding `by()`. These include options for titling the graph (see [G-3] `title_options`) and for saving the graph to disk (see [G-3] `saving_option`).

Options for `qnorm` and `pnorm`

Main

grid adds grid lines at the 0.05, 0.10, 0.25, 0.50, 0.75, 0.90, and 0.95 quantiles when specified with `qnorm`. With `pnorm`, grid is equivalent to `yline(.25,.5,.75) xline(.25,.5,.75)`.

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] `marker_options`.

marker_label_options specify if and how the markers are to be labeled; see [G-3] `marker_label_options`.

Reference line

rlopts(cline_options) affect the rendition of the reference line; see [G-3] `cline_options`.

Add plots

`addplot(plot)` provides a way to add other plots to the generated graph; see [G-3] `addplot_option`.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] `twoway_options`, excluding `by()`. These include options for titling the graph (see [G-3] `title_options`) and for saving the graph to disk (see [G-3] `saving_option`).

Options for `qchi` and `pchi`

Main

grid adds grid lines at the 0.05, 0.10, 0.25, 0.50, 0.75, 0.90, and .95 quantiles when specified with `qchi`. With `pchi`, grid is equivalent to `yline(.25,.5,.75) xline(.25,.5,.75)`.

def(#) specifies the degrees of freedom of the $\chi^2$ distribution. The default is `df(1)`.

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] `marker_options`.

marker_label_options specify if and how the markers are to be labeled; see [G-3] `marker_label_options`. 
Reference line
rlopts(cline_options) affect the rendition of the reference line; see [G-3] cline_options.

Add plots
addplot(plot) provides a way to add other plots to the generated graph; see [G-3] addplot_option.

Y axis, X axis, Titles, Legend, Overall
twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples

Remarks are presented under the following headings:
symplot
quantile
qgplot
qnorm
pnorm
qchi
pchi

> Example 1

We have data on 74 automobiles. To make a symmetry plot of the variable price, we type

    . use http://www.stata-press.com/data/r13/auto
    (1978 Automobile Data)
    . symplot price

![Symmetry plot of price](image-url)
All points would lie along the reference line (defined as $y = x$) if car prices were symmetrically distributed. The points in this plot lie above the reference line, indicating that the distribution of car prices is skewed to the right—the most expensive cars are far more expensive than the least expensive cars are inexpensive.

The logic works as follows: a variable, $z$, is distributed symmetrically if

$$\text{median} - z(i) = z(N+1-i) - \text{median}$$

where $z(i)$ indicates the $i$th-order statistic of $z$. symplot graphs $y_i = \text{median} - z(i)$ versus $x_i = z(N+1-i) - \text{median}$.

For instance, consider the largest and smallest values of price in the example above. The most expensive car costs $15,906 and the least expensive, $3,291. Let’s compare these two cars with the typical car in the data and see how much more it costs to buy the most expensive car, and compare that with how much less it costs to buy the least expensive car. If the automobile price distribution is symmetric, the price differences would be the same.

Before we can make this comparison, we must agree on a definition for the word “typical”. Let’s agree that “typical” means median. The price of the median car is $5,006.50, so the most expensive car costs $10,899.50 more than the median car, and the least expensive car costs $1,715.50 less than the median car. We now have one piece of evidence that the car price distribution is not symmetric.

We can repeat the experiment for the second-most-expensive car and the second-least-expensive car. We find that the second-most-expensive car costs $9,494.50 more than the median car, and the second-least-expensive car costs $1,707.50 less than the median car. We now have more evidence.

We can continue doing this with the third most expensive and the third least expensive, and so on.

Once we have all of these numbers, we want to compare each pair and ask how similar, on average, they are. The easiest way to do that is to plot all the pairs.
We have data on the prices of 74 automobiles. To make a quantile plot of price, we type

```
. use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)
. quantile price, rlopts(clpattern(dash))
```

We changed the pattern of the reference line by specifying `rlopts(clpattern(dash))`.

In a quantile plot, each value of the variable is plotted against the fraction of the data that have values less than that fraction. The diagonal line is a reference line. If automobile prices were rectangularly distributed, all the data would be plotted along the line. Because all the points are below the reference line, we know that the price distribution is skewed right.

We have data on the weight and country of manufacture of 74 automobiles. We wish to compare the distributions of weights for domestic and foreign automobiles:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. generate weightd=weight if !foreign
   (22 missing values generated)
. generate weightf=weight if foreign
   (52 missing values generated)
. qqplot weightd weightf
```
Example 4

Continuing with our price data on 74 automobiles, we now wish to compare the distribution of price with the normal distribution:

```stata
. qnorm price, grid ylabel(, angle(horizontal) axis(1))
> ylabel(, angle(horizontal) axis(2))
```

The result shows that the distributions are different.
Technical note

The idea behind `qnorm` is recommended strongly by Miller (1997): he calls it probit plotting. His recommendations from much practical experience should interest many users. “My recommendation for detecting nonnormality is probit plotting” (Miller 1997, 10). “If a deviation from normality cannot be spotted by eye on probit paper, it is not worth worrying about. I never use the Kolmogorov–Smirnov test (or one of its cousins) or the $\chi^2$ test as a preliminary test of normality. They do not tell you how the sample is differing from normality, and I have a feeling they are more likely to detect irregularities in the middle of the distribution than in the tails” (Miller 1997, 13–14).

`pnorm`

Example 5

Quantile–normal plots emphasize the tails of the distribution. Normal probability plots put the focus on the center of the distribution:

```
.pnorn price, grid
```

`qchi`

Example 6

 Suppose that we want to examine the distribution of the sum of squares of `price` and `mpg`, standardized for their variances.

```
. egen c1 = std(price)
. egen c2 = std(mpg)
. generate ch = c1^2 + c2^2
. qchi ch, df(2) grid ylabel(, alt axis(2)) xlabel(, alt axis(2))
```
The quadratic form is clearly not $\chi^2$ with 2 degrees of freedom.

Example 7

We can focus on the center of the distribution by doing a probability plot:

```
   . pchi ch, df(2) grid
```
Methods and formulas

Let \( x(1), x(2), \ldots, x(N) \) be the data sorted in ascending order.

If a continuous variable, \( x \), has a cumulative distribution function \( F(x) = P(X \leq x) = p \), the quantiles \( x_{p_i} \) are such that \( F(x_{p_i}) = p_i \). For example, if \( p_i = 0.5 \), then \( x_{0.5} \) is the median. When we plot data, the probabilities, \( p_i \), are often referred to as plotting positions. There are many different conventions for choice of plotting positions, given \( x(1) \leq \cdots \leq x(N) \). Most belong to the family \( (i - a)/(N - 2a + 1) \). \( a = 0.5 \) (suggested by Hazen) and \( a = 0 \) (suggested by Weibull) are popular choices.

For a wider discussion of the calculation of plotting positions, see Cox (2002).

- `symplot` plots median \(- x(i) \) versus \( x(N+1-i) - \) median.
- `quantile` plots \( x(i) \) versus \((i - 0.5)/N\) (the Hazen position).
- `qnorm` plots \( x(i) \) against \( q_i = \Phi^{-1}(p_i) \), \( \Phi \) is the cumulative normal distribution, and \( p_i = i/(N+1) \) (the Weibull position).
- `pnorm` plots \( \Phi\left\{ (x_i - \hat{\mu})/\hat{\sigma}\right\} \) versus \( p_i = i/(N+1) \), where \( \hat{\mu} \) is the mean of the data and \( \hat{\sigma} \) is the standard deviation.
- `qchi` and `pchi` are similar to `qnorm` and `pnorm`; the cumulative \( \chi^2 \) distribution is used in place of the cumulative normal distribution.
- `qqplot` is just a two-way scatterplot of one variable against the other after both variables have been sorted into ascending order, and both variables have the same number of nonmissing observations. If the variables have unequal numbers of nonmissing observations, interpolated values of the variable with more data are plotted against the variable with fewer data.

Ramanathan Gnanadesikan (1932– ) was born in Madras. He obtained degrees from the Universities of Madras and North Carolina. He worked in industry at Procter & Gamble, Bell Labs, and Bellcore, as well as in universities, retiring from Rutgers in 1998. Among many contributions to statistics he is especially well known for work on probability plotting, robustness, outlier detection, clustering, classification, and pattern recognition.

Martin Bradbury Wilk (1922–2013) was born in Montreal. He obtained degrees in chemical engineering and statistics from McGill and Iowa State Universities. After holding several statistics-related posts in industry and at universities (including periods at Princeton, Bell Labs, and Rutgers), Wilk was appointed Chief Statistician at Statistics Canada (1980–1986). He is especially well known for his work with Gnanadesikan on probability plotting and with Shapiro on tests for normality.

Acknowledgments

We thank Peter A. Lachenbruch of the Department of Public Health at Oregon State University for writing the original versions of `qchi` and `pchi`. Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model also published a similar command in the Stata Technical Bulletin (Royston 1996).

display — Substitute for a hand calculator

Syntax

```
display exp
```

Description

display displays strings and values of scalar expressions.

display really has many more features and a more complex syntax diagram, but the diagram shown above is adequate for interactive use. For a full discussion of display’s capabilities, see [P] display.

Remarks and examples

display can be used as a substitute for a hand calculator.

Example 1

display 2+2 produces the output 4. Stata variables may also appear in the expression, such as in display myvar/2. Because display works only with scalars, the resulting calculation is performed only for the first observation. You could type display myvar[10]/2 to display the calculation for the 10th observation. Here are more examples:

```
. display sqrt(2)/2
 .70710678
 . display normal(-1.1)
  .13566606
 . display (57.2-3)/(12-2)
   5.42
 . display myvar/10
    7
 . display myvar[10]/2
   3.5
```

<td></td>
</tr>
</tbody>
</table>

**Syntax**

\[
\{ \text{do} | \text{run} \}\ \text{filename} \ [\ arguments] \ [\ , \text{nostop}]
\]

**Menu**

File > Do...

**Description**

`do` and `run` cause Stata to execute the commands stored in `filename` just as if they were entered from the keyboard. `do` echoes the commands as it executes them, whereas `run` is silent. If `filename` is specified without an extension, `.do` is assumed.

**Option**

`nostop` allows the do-file to continue executing even if an error occurs. Normally, Stata stops executing the do-file when it detects an error (nonzero return code).

**Remarks and examples**

You can create `filename` (called a *do-file*) using Stata’s Do-file Editor; see [R] `doedit`. This file will be a standard ASCII (text) file. A complete discussion of do-files can be found in [U] 16 Do-files.

You can also create `filename` by using a non-Stata text editor; see [D] `shell` for a way to invoke your favorite editor from inside Stata. Make sure that you save the file in ASCII format.

If the path or `filename` contains spaces, it should be enclosed in double quotes.

[U] 15 Saving and printing output—log files

[U] 16 Do-files
doedit — Edit do-files and other text files

Syntax

doedit [ filename ]

Menu

Window >> Do-file Editor

Description

doedit opens a text editor that lets you edit do-files and other text files. The Do-file Editor lets you submit several commands to Stata at once.

Remarks and examples

Clicking on the Do-file Editor button is equivalent to typing doedit.

doedit, typed by itself, invokes the Editor with an empty document. If you specify filename, that file is displayed in the Editor.

You may have more than one Do-file Editor open at once. Each time you submit the doedit command, a new window will be opened.

A tutorial discussion of doedit can be found in the Getting Started with Stata manual. Read [U] 16 Do-files for an explanation of do-files, and then read [GSW] 13 Using the Do-file Editor— automating Stata to learn how to use the Do-file Editor to create and execute do-files.

**Menu**

- Graphics > Distributional graphs > Distribution dotplot

**Description**

A dotplot is a scatterplot with values grouped together vertically (“binning”, as in a histogram) and with plotted points separated horizontally. The aim is to display all the data for several variables or groups in one compact graphic.
In the first syntax, `dotplot` produces a columnar dotplot of `varname`, with one column per value of `groupvar`. In the second syntax, `dotplot` produces a columnar dotplot for each variable in `varlist`, with one column per variable; `over(groupvar)` is not allowed. In each case, the “dots” are plotted as small circles to increase readability.

Options

- `over(groupvar)` identifies the variable for which `dotplot` will display one columnar dotplot for each value of `groupvar`.

- `nx(#)` sets the horizontal dot density. A larger value of # will increase the dot density, reducing the horizontal separation between dots. This option will increase the separation between columns if two or more groups or variables are used.

- `ny(#)` sets the vertical dot density (number of “bins” on the y axis). A larger value of # will result in more bins and a plot that is less spread out horizontally. # should be determined in conjunction with `nx()` to give the most pleasing appearance.

- `incr(#)` specifies how the x axis is to be labeled. `incr(1)`, the default, labels all groups. `incr(2)` labels every second group.

- `[mean|median]` plots a horizontal line of pluses at the mean or median of each group.

- `bounded` forces the minimum and maximum of the variable to be used as boundaries of the smallest and largest bins. It should be used with one variable whose support is not the whole of the real line and whose density does not tend to zero at the ends of its support, for example, a uniform random variable or an exponential random variable.

- `bar` plots horizontal dashed lines at the “shoulders” of each group. The shoulders are taken to be the upper and lower quartiles unless `mean` has been specified; here they will be the mean plus or minus the standard deviation.

- `nogroup` uses the actual values of `yvar` rather than grouping them (the default). This option may be useful if `yvar` takes on only a few values.

- `center` centers the dots for each column on a hidden vertical line.

Plot marker options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] `marker_options`.

`marker_label_options` specify if and how the markers are to be labeled; see [G-3] `marker_label_options`.

`twoway_options` are any of the options documented in [G-3] `twoway_options`, excluding `by()`. These include options for titling the graph (see [G-3] `title_options`) and for saving the graph to disk (see [G-3] `saving_option`).
Remarks and examples

dotplot produces a figure that has elements of a boxplot, a histogram, and a scatterplot. Like a boxplot, it is most useful for comparing the distributions of several variables or the distribution of 1 variable in several groups. Like a histogram, the figure provides a crude estimate of the density, and, as with a scatterplot, each symbol (dot) represents 1 observation.

Example 1

dotplot may be used as an alternative to Stata’s histogram graph for displaying the distribution of one variable.

```
. set seed 123456789
. set obs 1000
. generate norm = rnormal()
. dotplot norm, title("Normal distribution, sample size 1000")
```

![Normal distribution, sample size 1000](image)

Example 2

The over() option lets us use dotplot to compare the distribution of one variable within different levels of a grouping variable. The center, median, and bar options create a graph that may be compared with Stata’s boxplot; see [G-2] graph box. The next graph illustrates this option with Stata’s automobile dataset.
Example 3

The second version of `dotplot` lets us compare the distribution of several variables. In the next graph, all 10 variables contain measurements on tumor volume.

```stata
. use http://www.stata-press.com/data/r13/dotgr
. dotplot girl1-girl10, ytitle("Tumor volume, cu mm")
```
Example 4

When using the first form with the `over()` option, we can encode a third dimension in a dotplot by using a different plotting symbol for different groups. The third dimension cannot be encoded with a varlist. The example is of a hypothetical matched case–control study. The next graph shows the exposure of each individual in each matched stratum. Cases are marked by the letter ‘x’, and controls are marked by the letter ‘o’.

```
. use http://www.stata-press.com/data/r13/dotdose
. label define symbol 0 "o" 1 "x"
. label values case symbol
. dotplot dose, over(strata) m(none) mlabel(case) mlabp(0) center
```

Example 5

dotplot can also be used with two virtually continuous variables as an alternative to jittering the data to distinguish ties. We must use the `xlabel()` option, because otherwise `dotplot` will attempt to label too many points on the x axis. It is often useful in such instances to use a value of `nx` that is smaller than the default. That was not necessary in this example, partly because of our choice of symbols.

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. generate byte hi_price = (price>10000) if price < .
. label define symbol 0 "|" 1 "o"
. label values hi_price symbol
```
Example 6

The following figure is included mostly for aesthetic reasons. It also demonstrates dotplot’s ability to cope with even very large datasets. The sample size for each variable is 10,000, so it may take a long time to print.

```
. clear all
. set seed 123456789
. set obs 10000
. gen norm0 = rnormal()
. gen norm1 = rnormal() + 1
. gen norm2 = rnormal() + 2
. label variable norm0 "N(0,1)"
. label variable norm1 "N(1,1)"
. label variable norm2 "N(2,1)"
. dotplot norm0 norm1 norm2
```
Stored results

dotplot stores the following in r():

Scalars
   r(nx)    horizontal dot density
   r(ny)    vertical dot density

Acknowledgments

dotplot was written by Peter Sasieni of the Wolfson Institute of Preventive Medicine, London, and Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book

*Either popvars(casevar_p popvar_p) or rate(ratevar_p {# | crudevar_p}) must be specified.*
**Description**

`dstdize` produces standardized rates for `charvar`, which are defined as a weighted average of the stratum-specific rates. These rates can be used to compare the characteristic `charvar` across different populations identified by `groupvars`. Weights used in the standardization are given by `popvar`; the strata across which the weights are to be averaged are defined by `stratavars`.

`istdize` produces indirectly standardized rates for a study population based on a standard population. This standardization method is appropriate when the stratum-specific rates for the population being studied are either unavailable or based on small samples and thus are unreliable. The standardization uses the stratum-specific rates of a standard population to calculate the expected number of cases in the study population(s), sums them, and then compares them with the actual number of cases observed. The standard population is in another Stata data file specified by `using filename`, and it must contain `popvar` and `stratavars`.

In addition to calculating rates, the indirect standardization command produces point estimates and exact confidence intervals of the study population’s standardized mortality ratio (SMR), if death is the event of interest, or the standardized incidence ratio (SIR) for studies of incidence. Here we refer to both ratios as SMR.

`casevars` is the variable name for the study population’s number of cases (usually deaths). It must contain integers, and for each group, defined by `groupvar`, each subpopulation identified by `stratavars` must have the same values or missing.

`popvars` identifies the number of subjects represented by each observation in the study population. `stratavars` define the strata.

**Options for dstdize**

`by(groupvars)` is required for the `dstdize` command; it specifies the variables identifying the study populations. If `base()` is also specified, there must be only one variable in the `by()` group. If you do not have a variable for this option, you can generate one by using something like `gen newvar=1` and then use `newvar` as the argument to this option.

`using(filename)` or `base(# | string)` may be used to specify the standard population. You may not specify both options. `using(filename)` supplies the name of a `.dta` file containing the standard population. The standard population must contain the `popvar` and the `stratavars`. If `using()` is not specified, the standard population distribution will be obtained from the data. `base(# | string)` lets you specify one of the values of `groupvar`—either a numeric value or a string—to be used as the standard population. If neither `base()` nor `using()` is specified, the entire dataset is used to determine an estimate of the standard population.
level(#) specifies the confidence level, as a percentage, for a confidence interval of the adjusted rate. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

Options

saving(filename) saves the computed standard population distribution as a Stata dataset that can be used in further analyses.

format(%) specifies the format in which to display the final summary table. The default is %10.0g.

print includes a table summary of the standard population before displaying the study population results.

nores suppresses storing results in r(). This option is seldom specified. Some results are stored in matrices. If there are more groups than matsize, dstdize will report “matsize too small”. Then you can either increase matsize or specify nores. The nores option does not change how results are calculated but specifies that results need not be left behind for use by other programs.

Options for istdize

Main

popvars(casevar, popvar) or rate(ratevar, # | ratevar, crudevar) must be specified with istdize. Only one of these two options is allowed. These options are used to describe the standard population’s data.

With popvars(casevar, popvar), casevar records the number of cases (deaths) for each stratum in the standard population, and popvar records the total number of individuals in each stratum (individuals at risk).

With rate(ratevar {# | crudevar}), ratevar contains the stratum-specific rates. # | crudevar specifies the crude case rate either by a variable name or by the crude case rate value. If a crude rate variable is used, it must be the same for all observations, although it could be missing for some.

level(#) specifies the confidence level, as a percentage, for a confidence interval of the adjusted rate. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

Options

by(groupvars) specifies variables identifying study populations when more than one exists in the data. If this option is not specified, the entire study population is treated as one group.

format(%) specifies the format in which to display the final summary table. The default is %10.0g.

print outputs a table summary of the standard population before displaying the study population results.
Remarks and examples

Remarks are presented under the following headings:

Direct standardization
Indirect standardization

In epidemiology and other fields, you will often need to compare rates for some characteristic across different populations. These populations often differ on factors associated with the characteristic under study; thus directly comparing overall rates may be misleading.

Direct standardization

The direct method of adjusting for differences among populations involves computing the overall rates that would result if, instead of having different distributions, all populations had the same standard distribution. The standardized rate is defined as a weighted average of the stratum-specific rates, with the weights taken from the standard distribution. Direct standardization may be applied only when the specific rates for a given population are available.

dstdize generates adjusted summary measures of occurrence, which can be used to compare prevalence, incidence, or mortality rates between populations that may differ on certain characteristics (for example, age, gender, race). These underlying differences may affect the crude prevalence, mortality, or incidence rates.

Example 1

We have data (Rothman 1986, 42) on mortality rates for Sweden and Panama for 1962, and we wish to compare mortality in these two countries:

```
. use http://www.stata-press.com/data/r13/mortality
(1962 Mortality, Sweden & Panama)
. describe
obs: 6 1962 Mortality, Sweden & Panama
vars: 4 14 Apr 2013 16:18
size: 90

storage  display value
variable name   type    format   label
nation          str6     %9s     Nation
age_category   byte     %9.0g   age_lbl Age Category
population     float    %10.0gc Population in Age Category
deaths        float     %9.0gc  Deaths in Age Category
```

Sorted by:
We divide the total number of cases in the population by the population to obtain the *crude rate*:

```
. collapse (sum) pop deaths, by(nation)
. list, abbrev(10) divider
```

We divide the total number of cases in the population by the population to obtain the *crude rate*:

```
. collapse (sum) pop deaths, by(nation)
. list, abbrev(10) divider
```

If we examine the total number of deaths in the two nations, the total crude mortality rate in Sweden is higher than that in Panama. From the original data, we see one possible explanation: Swedes are older than Panamanians, making direct comparison of the mortality rates difficult.

Direct standardization lets us remove the distortion caused by the different age distributions. The adjusted rate is defined as the weighted sum of the crude rates, where the weights are given by the standard distribution. Suppose that we wish to standardize these mortality rates to the following age distribution:

```
(Standard Population Distribution)
. list, abbrev(12) divider
```

If we multiply the above weights for the age strata by the crude rate for the corresponding age category, the sum gives us the standardized rate.

</table>

The summary table above lets us make a quick inspection of the results within the study populations, and the detail tables give the behavior among the strata within the study populations.

---

**Example 2**

We have individual-level data on persons in four cities over several years. Included in the data is a variable indicating whether the person has high blood pressure, together with information on the person’s age, sex, and race. We wish to obtain standardized high blood pressure rates for each city for 1990 and 1992, using, as the standard, the age, sex, and race distribution of the four cities and two years combined.
Our dataset contains

```
. use http://www.stata-press.com/data/r13/hbp
. describe
Contains data from http://www.stata-press.com/data/r13/hbp.dta
  obs: 1,130                             21 Feb 2013 06:42
  vars: 7                               19,210

     variable name   storage   display value variable label
id          str10    %10s
city        byte    %8.0g
year        int     %8.0g
sex         byte    %8.0g

race        byte    %8.0g
hbp         byte    %8.0g
```

Sorted by:

The `dstdize` command is designed to work with aggregate data but will work with individual-level data only if we create a variable recording the population represented by each observation. For individual-level data, this is one:

```
. generate pop = 1
```

On the next page, we specify `print` to obtain a listing of the standard population and `level(90)` to request 90% rather than 95% confidence intervals. Typing `if year==1990 | year==1992` restricts the data to the two years for both summary tables and the standard population.
```
. dstdize hbp pop age race sex if year==1990 | year==1992, by(city year) print
> level(90)

Indirect standardization

Standardization of rates can be performed via the indirect method whenever the stratum-specific rates are either unknown or unreliable. If the stratum-specific rates are known, the direct standardization method is preferred.

To apply the indirect method, you must have the following information:

- The observed number of cases in each population to be standardized, \( O \). For example, if death rates in two states are being standardized using the U.S. death rate for the same period, you must know the total number of deaths in each state.
- The distribution across the various strata for the population being studied, \( n_1, \ldots, n_k \). If you are standardizing the death rate in the two states, adjusting for age, you must know the number of individuals in each of the \( k \) age groups.
- The stratum-specific rates for the standard population, \( p_1, \ldots, p_k \). For example, you must have the U.S. death rate for each stratum (age group).
- The crude rate of the standard population, \( C \). For example, you must have the U.S. mortality rate for the year.

The indirect adjusted rate is then

\[
R_{\text{indirect}} = \frac{C O}{E}
\]

where \( E \) is the expected number of cases (deaths) in each population. See Methods and formulas for a more detailed description of calculations.

Example 3

This example is borrowed from Kahn and Sempos (1989, 95–105). We want to compare 1970 mortality rates in California and Maine, adjusting for age. Although we have age-specific population counts for the two states, we lack age-specific death rates. Direct standardization is not feasible here. We can use the U.S. population census data for the same year to produce indirectly standardized rates for these two states.

From the U.S. census, the standard population for this example was entered into Stata and saved in popkahn.dta.

```
. use http://www.stata-press.com/data/r13/popkahn, clear
. list age pop deaths rate, sep(4)
```

```
<table>
<thead>
<tr>
<th>age</th>
<th>population</th>
<th>deaths</th>

</tr>
<tr>
<td>8.</td>
<td>75+</td>
<td>7,630,000</td>
<td>736,758</td>
</tr>
</tbody>
</table>
```
The standard population contains for each age stratum the total number of individuals \((\text{pop})\) and both the age-specific mortality rate \((\text{rate})\) and the number of deaths. The standard population need not contain all three. If we have only the age-specific mortality rate, we can use the \(\text{rate}(\text{ratevar}_p)\) or \(\text{rate}(\text{ratevar}_p, \text{#})\) option, where \(\text{crudevar}_p\) refers to the variable containing the total population’s crude death rate or \(#\) is the total population’s crude death rate.

Now let’s look at the states’ data (study population):

```
. use http://www.stata-press.com/data/r13/kahn

</tr>
</tbody>
</table>
```

For each state, the number of individuals in each stratum (age group) is contained in the \(\text{pop}\) variable. The \(\text{death}\) variable is the total number of deaths observed in the state during the year. It must have the same value for all observations in the group, as for California, or it could be missing in all but one observation per group, as for Maine.

To match these two datasets, the strata variables must have the same name in both datasets and ideally the same levels. If a level is missing from either dataset, that level will not be included in the standardization.

With \textit{kahn.dta} in memory, we now execute the command. We will use the \texttt{print} option to obtain the standard population’s summary table, and because we have both the standard population’s age-specific count and deaths, we will specify the \texttt{popvars(casevar}_p, \texttt{popvar}_p) option. Or, we could specify the \texttt{rate(rate 0.00945)} option because we know that 0.00945 is the U.S. crude death rate for 1970.
.  istdize death pop age using http://www.stata-press.com/data/r13/popkahn,
> by(state) pop(deaths pop) print

Stored results

dstdize stores the following in \( r() \):

Scalars
- \( r(k) \) number of populations

Macros
- \( r(by) \) variable names specified in \( by() \)
- \( r(c#) \) values of \( r(by) \) for \( # \)th group

Matrices
- \( r(se) \) \( 1 \times k \) vector of standard errors of adjusted rates
- \( r(ub) \) \( 1 \times k \) vector of upper bounds of confidence intervals for adjusted rates
- \( r(lb) \) \( 1 \times k \) vector of lower bounds of confidence intervals for adjusted rates
- \( r(Nobs) \) \( 1 \times k \) vector of number of observations
- \( r(crude) \) \( 1 \times k \) vector of crude rates (*)
- \( r(adj) \) \( 1 \times k \) vector of adjusted rates (*)

(*) If, in a group, the number of observations is 0, then 9 is stored for the corresponding crude and adjusted rates.

Methods and formulas

The directly standardized rate, $S_R$, is defined by

$$S_R = \frac{\sum_{i=1}^{k} w_i R_i}{\sum_{i=1}^{k} w_i},$$

(Rothman 1986, 44), where $R_i$ is the stratum-specific rate in stratum $i$ and $w_i$ is the weight for stratum $i$ derived from the standard population.

If $n_i$ is the population of stratum $i$, the standard error, $se(S_R)$, in stratified sampling for proportions (ignoring the finite population correction) is

$$se(S_R) = \frac{1}{\sum w_i} \sqrt{\frac{\sum_{i=1}^{k} w_i^2 R_i (1 - R_i)}{n_i}},$$

(Cochran 1977, 108), from which the confidence intervals are calculated.

For indirect standardization, define $O$ as the observed number of cases in each population to be standardized; $n_1, \ldots, n_k$ as the distribution across the various strata for the population being studied; $R_1, \ldots, R_k$ as the stratum-specific rates for the standard population; and $C$ as the crude rate of the standard population. The expected number of cases (deaths), $E$, in each population is obtained by applying the standard population stratum-specific rates, $R_1, \ldots, R_k$, to the study populations:

$$E = \sum_{i=1}^{k} n_i R_i$$

The indirectly adjusted rate is then

$$R_{\text{indirect}} = C \frac{O}{E}$$

and $O/E$ is the study population’s SMR if death is the event of interest or the SIR for studies of disease (or other) incidence.

The exact confidence interval is calculated for each estimated SMR by assuming a Poisson process as described in Breslow and Day (1987, 69–71). These intervals are obtained by first calculating the upper and lower bounds for the confidence interval of the Poisson-distributed observed events, $O$—say, $L$ and $U$, respectively—and then computing $\text{SMR}_L = L/E$ and $\text{SMR}_U = U/E$.

**Menu**

*dydx*

Data > Create or change data > Other variable-creation commands > Calculate numerical derivatives

*integ*

Data > Create or change data > Other variable-creation commands > Calculate numeric integrals
Description

dydx and integ calculate derivatives and integrals of numeric “functions”.

Options

- **generate(newvar)** specifies the name of the new variable to be created. It must be specified with dydx.
- **trapezoid** requests that the trapezoidal rule \[ \text{the sum of } (x_i - x_{i-1})(y_i + y_{i-1})/2 \] be used to compute integrals. The default is cubic splines, which give superior results for most smooth functions; for irregular functions, trapezoid may give better results.
- **initial(#)** specifies the initial condition for calculating definite integrals; see Methods and formulas below. The default is initial(0).
- **replace** specifies that if an existing variable is specified for generate(), it should be overwritten.

Remarks and examples

**dydx** and **integ** lets you extend Stata’s graphics capabilities beyond data analysis and into mathematics. (See Gould [1993] for another command that draws functions.)

**Example 1**

We graph \( y = e^{-x/6}\sin(x) \) over the interval \([0, 12.56]\):

```
. range x 0 12.56 100
obs was 0, now 100
. generate y = exp(-x/6)*sin(x)
. label variable y "exp(-x/6)*sin(x)"
. twoway connected y x, connect(i) yline(0)
```
We estimate the derivative by using `dydx` and compute the relative difference between this estimate and the true derivative.

```
. dydx y x, gen(dy)
. generate dytrue = exp(-x/6)*(cos(x) - sin(x)/6)
. generate error = abs(dy - dytrue)/dytrue
```

The error is greatest at the endpoints, as we would expect. The error is approximately 0.5% at each endpoint, but the error quickly falls to less than 0.01%.

```
. label variable error "Error in derivative estimate"
. twoway line error x, ylabel(0(.002).006)
```

We now estimate the integral by using `integ`:

```
. integ y x, gen(iy)
  number of points = 100
  integral = .85316396
. generate iytrue = (36/37)*(1 - exp(-x/6)*(cos(x) + sin(x)/6))
. display iytrue[_N]
  .85315901
. display abs(r(integral) - iytrue[_N])/iytrue[_N]
  5.799e-06
. generate diff = iy - iytrue
```

The relative difference between the estimate [stored in `r(integral)`] and the true value of the integral is about $6 \times 10^{-6}$. A graph of the absolute difference (`diff`) is shown below. Here error is cumulative. Again most of the error is due to a relatively poorer fit near the endpoints.

```
. label variable diff "Error in integral estimate"
. twoway line diff x, ylabel(0(5.00e-06).0001)
```
dydx — Calculate numeric derivatives and integrals

Stored results

\texttt{dydx} stores the following in \texttt{r()}:  

Macros  
\texttt{r(y)} \hspace{1cm} \text{name of \texttt{yvar}}  

\texttt{integ} stores the following in \texttt{r()}:  

Scalars  
\texttt{r(N\_points)} \hspace{1cm} \text{number of unique \texttt{x} points}  
\texttt{r(integral)} \hspace{1cm} \text{estimate of the integral}  

Methods and formulas

Consider a set of data points, \((x_1, y_1), \ldots, (x_n, y_n)\), generated by a function \(y = f(x)\). \texttt{dydx} and \texttt{integ} first fit these points with a cubic spline, which is then analytically differentiated (integrated) to give an approximation for the derivative (integral) of \(f\).

The cubic spline (see, for example, Press et al. [2007]) consists of \(n - 1\) cubic polynomials \(P_i(x)\), with the \(i\)th one defined on the interval \([x_i, x_{i+1}]\),  

\[
P_i(x) = y_i a_i(x) + y_{i+1} b_i(x) + y''_i c_i(x) + y''_{i+1} d_i(x)
\]

where  
\[
a_i(x) = \frac{x_{i+1} - x}{x_{i+1} - x_i} \quad \quad \quad \quad \quad \quad \quad b_i(x) = \frac{x - x_i}{x_{i+1} - x_i}
\]
\[
c_i(x) = \frac{1}{6} (x_{i+1} - x_i)^2 a_i(x) \{[a_i(x)]^2 - 1\} \quad \quad d_i(x) = \frac{1}{6} (x_{i+1} - x_i)^2 b_i(x) \{[b_i(x)]^2 - 1\}
\]

and \(y''_i\) and \(y''_{i+1}\) are constants whose values will be determined as described below. The notation for these constants is justified because \(P''_i(x_i) = y''_i\) and \(P''_i(x_{i+1}) = y''_{i+1}\).
Because \( a_i(x_i) = 1 \), \( a_i(x_{i+1}) = 0 \), \( b_i(x_i) = 0 \), and \( b_i(x_{i+1}) = 1 \). Therefore, \( P_i(x_i) = y_i \), and \( P_i(x_{i+1}) = y_{i+1} \). Thus the \( P_i \) jointly define a function that is continuous at the interval boundaries. The first derivative should be continuous at the interval boundaries; that is,

\[ P_i'(x_{i+1}) = P_{i+1}'(x_{i+1}) \]

The above \( n - 2 \) equations (one equation for each point except the two endpoints) and the values of the first derivative at the endpoints, \( P_i'(x_1) \) and \( P_{n-1}'(x_n) \), determine the \( n \) constants \( y_i'' \).

The value of the first derivative at an endpoint is set to the value of the derivative obtained by fitting a quadratic to the endpoint and the two adjacent points; namely, we use

\[ P_1'(x_1) = \frac{y_1 - y_2}{x_1 - x_2} + \frac{y_1 - y_3}{x_1 - x_3} - \frac{y_2 - y_3}{x_2 - x_3} \]

and a similar formula for the upper endpoint.

\( \text{dydx} \) approximates \( f'(x_i) \) by using \( P_i'(x_i) \).

\( \text{integ} \) approximates \( F(x_i) = F(x_1) + \int_{x_1}^{x_i} f(x) \, dx \) by using

\[ I_0 + \sum_{k=1}^{i-1} \int_{x_k}^{x_{k+1}} P_k(x) \, dx \]

where \( I_0 \) (an estimate of \( F(x_1) \)) is the value specified by the \text{initial}(#) option. If the \text{trapezoid} option is specified, \( \text{integ} \) approximates the integral by using the trapezoidal rule:

\[ I_0 + \sum_{k=1}^{i-1} \frac{1}{2} (x_{k+1} - x_k) (y_{k+1} + y_k) \]

If there are ties among the \( x_i \), the mean of \( y_i \) is computed at each set of ties and the cubic spline is fit to these values.

Acknowledgment

The present versions of \text{dydx} and \text{integ} were inspired by the \text{dydx2} command written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book \textit{Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model}.

**Description**

An eform_option causes the coefficient table to be displayed in exponentiated form: for each coefficient, $e^b$ rather than $b$ is displayed. Standard errors and confidence intervals (CIs) are also transformed.

An eform_option is one of the following:

<table>
<thead>
<tr>
<th>eform_option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>eform(string)</td>
<td>use string for the column title</td>
</tr>
<tr>
<td>eform</td>
<td>exponentiated coefficient, string is $\exp(b)$</td>
</tr>
<tr>
<td>hr</td>
<td>hazard ratio, string is Haz. Ratio</td>
</tr>
<tr>
<td>shr</td>
<td>subhazard ratio, string is SHR</td>
</tr>
<tr>
<td>irr</td>
<td>incidence-rate ratio, string is IRR</td>
</tr>
<tr>
<td>or</td>
<td>odds ratio, string is Odds Ratio</td>
</tr>
<tr>
<td>rrr</td>
<td>relative-risk ratio, string is RRR</td>
</tr>
</tbody>
</table>

**Remarks and examples**

Example 1

Here is a simple example of the or option with svy: logit. The CI for the odds ratio is computed by transforming (by exponentiating) the endpoints of the CI for the corresponding coefficient.

```
. use http://www.stata-press.com/data/r13/nhanes2d
. svy, or: logit highbp female black
(running logit on estimation sample)
(output omitted)
```

```
| highbp | Odds Ratio | Std. Err. | t  | P>|t| | [95% Conf. Interval] |
|--------|------------|-----------|----|-----|---------------------|
| female | .6107011   | .0326159  | -9.23 | 0.000 | .5476753 .6809798   |
| black  | 1.384865 | .1336054  | 3.37 | 0.002 | 1.137507 1.686011   |
| _cons  | .7249332 | .0551062  | -4.23 | 0.000 | .6208222 .8465035   |
```

We also could have specified the following command and received the same results as above:

```
. svy: logit highbp female black, or
```

*eivreg* — Errors-in-variables regression

### Syntax

```plaintext
eivreg depvar [ indepvars ] [ if ] [ in ] [ weight ] [ , options ]
```

#### options
- **Model**
  - `reliab(indepvar # [ indepvar # [ ... ] ] )`
    - specify measurement reliability for each *indepvar* measured with error
- **Reporting**
  - `level(#)`
    - set confidence level; default is `level(95)`
  - `display_options`
    - control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
  - `coeflegend`
    - display legend instead of statistics

*indepvars* may contain factor variables; see [U] 11.4.3 Factor variables.

`bootstrap`, `by`, `jackknife`, `rolling`, and `statsby` are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap.

`aweights` are not allowed with the `jackknife` prefix; see [R] jackknife.

`aweights` and `fweights` are allowed; see [U] 11.1.6 weight.

`coeflegend` does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

### Menu

Statistics > Linear models and related > Errors-in-variables regression

### Description

eivreg fits errors-in-variables regression models.

### Options

#### Model

```
reliab(indepvar # [ indepvar # [ ... ] ] )
```

specifies the measurement reliability for each independent variable measured with error. Reliabilities are specified as pairs consisting of an independent variable name (a name that appears in *indepvars*) and the corresponding reliability \( r \), \( 0 < r \leq 1 \). Independent variables for which no reliability is specified are assumed to have reliability 1. If the option is not specified, all variables are assumed to have reliability 1, and the result is thus the same as that produced by `regress` (the ordinary least-squares results).
Errors-in-variables regression

Reporting level(#); see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

The following option is available with eivreg but is not shown in the dialog box: coeflegend; see [R] estimation options.

Remarks and examples

Errors-in-variables regression models are useful when one or more of the independent variables are measured with additive noise. Standard regression (as performed by regress) would underestimate the effect of the variable, and the other coefficients in the model can be biased to the extent that they are correlated with the poorly measured variable. You can adjust for the biases if you know the reliability:

\[
    r = 1 - \frac{\text{noise variance}}{\text{total variance}}
\]

That is, given the model \( y = X\beta + u \), for some variable \( x_i \) in \( X \), the \( x_i \) is observed with error, \( x_i = x_i^* + e \), and the noise variance is the variance of \( e \). The total variance is the variance of \( x_i \).

Example 1

Say that in our automobile data, the weight of cars was measured with error, and the reliability of our measured weight is 0.85. The result of this would be to underestimate the effect of weight in a regression of, say, price on weight and foreign, and it would also bias the estimate of the coefficient on foreign (because being of foreign manufacture is correlated with the weight of cars). We would ignore all of this if we fit the model with regress:

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. regress price weight foreign
```

<table>
<thead>
<tr>

</tbody>
</table>

| price | Coef.        | Std. Err. | t    | P>|t|   | [95% Conf. Interval] |
|-------|--------------|-----------|------|-------|---------------------|
| weight| 3.320737     | .3958784  | 8.39 | 0.000 | 2.531378 4.110096  |
| foreign| 3637.001     | 668.583   | 5.44 | 0.000 | 2303.885 4970.118  |
| _cons | -4942.844    | 1345.591  | -3.67| 0.000 | -7625.876-2259.812 |
With `eivreg`, we can account for our measurement error:

```
. eivreg price weight foreign, r(weight .85)
```

<table>
<thead>
<tr>
<th>variable</th>
<th>assumed reliability</th>
<th>Errors-in-variables regression</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>0.8500</td>
<td></td>
</tr>
<tr>
<td></td>
<td>1.0000</td>
<td></td>
</tr>
</tbody>
</table>

Number of obs = 74  
F( 2, 71) = 50.37  
Prob > F = 0.0000  
R-squared = 0.6483  
Root MSE = 1773.54

| price  | Coef.    | Std. Err. | t    | P>|t|   | [95% Conf. Interval] |
|--------|----------|-----------|------|-------|----------------------|
| weight | 4.31985  | 0.431431  | 10.01| 0.000 | 3.459601 5.180099    |
| foreign| 4637.32  | 624.5362  | 7.43 | 0.000 | 3392.03 5882.609    |
| _cons  | -8257.017| 1452.086  | -5.69| 0.000 | -11152.39 -5361.639|

The effect of weight is increased—as we knew it would be—and here the effect of foreign manufacture is also increased. A priori, we knew only that the estimate of `foreign` might be biased; we did not know the direction.

**Technical note**

Swept under the rug in our example is how we would determine the reliability, r. We can easily see that a variable is measured with error, but we may not know the reliability because the ingredients for calculating r depend on the unobserved noise.

For our example, we made up a value for r, and in fact we do not believe that weight is measured with error at all, so the reported `eivreg` results have no validity. The `regress` results were the statistically correct results here.

But let’s say that we do suspect that weight is measured with error and that we do not know r. We could then experiment with various values of r to describe the sensitivity of our estimates to possible error levels. We may not know r, but r does have a simple interpretation, and we could probably produce a sensible range for r by thinking about how the data were collected.

If the reliability, r, is less than the $R^2$ from a regression of the poorly measured variable on all the other variables, including the dependent variable, the information might as well have not been collected; no adjustment to the final results is possible. For our automobile data, running a regression of `weight` on `foreign` and `price` would result in an $R^2$ of 0.6743. Thus the reliability must be at least 0.6743 here. If we specify a reliability that is too small, `eivreg` will inform us and refuse to fit the model:

```
. eivreg price weight foreign, r(weight .6742)
reliability r() too small
     r(399);
```

Returning to our problem of how to estimate r, too small or not, if the measurements are summaries of scaled items, the reliability may be estimated using the `alpha` command; see [MV] `alpha`. If the score is computed from factor analysis and the data are scored using `predict`’s default options (see [MV] `factor postestimation`), the square of the standard deviation of the score is an estimate of the reliability.
Consider a model with more than one variable measured with error. For instance, say that our model is that price is a function of weight, foreign, and mpg and that both weight and mpg are measured with error.

```
eivreg price weight foreign mpg, r(weight .85 mpg .9)
```

Stored results

`eivreg` stores the following in `e()`:

Scalars
- e(N): number of observations
- e(df_m): model degrees of freedom
- e(df_r): residual degrees of freedom
- e(r2): $R^2$
- e(F): $F$ statistic
- e(rmse): root mean squared error
- e(rank): rank of e(V)

Macros
- e(cmd): `eivreg`
- e(cmdline): command as typed
- e(depvar): name of dependent variable
- e(rellist): `indepvars` and associated reliabilities
- e(type): weight type
- e(wtype): weight type
- e(wexp): weight expression
- e(properties): `b V`
- e(predict): program used to implement predict
- e(asbalanced): factor variables `fvset` as `asbalanced`
- e(asobserved): factor variables `fvset` as `asobserved`

Matrices
- e(b): coefficient vector
- e(Cns): constraints matrix
- e(V): variance–covariance matrix of the estimators

Functions
- e(sample): marks estimation sample
Methods and formulas

Let the model to be fit be

\[ y = X^* \beta + e \]
\[ X = X^* + U \]

where \( X^* \) are the true values and \( X \) are the observed values. Let \( W \) be the user-specified weights. If no weights are specified, \( W = I \). If weights are specified, let \( v \) be the specified weights. If \( fweight \) frequency weights are specified, then \( W = \text{diag}(v) \). If \( aweight \) analytic weights are specified, then \( W = \text{diag}\{v/(1'v)(1'/1)\} \), meaning that the weights are normalized to sum to the number of observations.

The estimates \( b \) of \( \beta \) are obtained as \( A^{-1}X'Wy \), where \( A = X'WX - S \). \( S \) is a diagonal matrix with elements \( N(1 - r_i)s_i^2 \). \( N \) is the number of observations, \( r_i \) is the user-specified reliability coefficient for the \( i \)th explanatory variable or 1 if not specified, and \( s_i^2 \) is the (appropriately weighted) variance of the variable.

The variance–covariance matrix of the estimators is obtained as \( s^2A^{-1}X'WXA^{-1} \), where the root mean squared error \( s^2 = (y'Wy - bAb')/(N - p) \), where \( p \) is the number of estimated parameters.

residuals  | residuals
stdp       | standard error of the prediction
stdf       | standard error of the forecast
`pr(a,b)`   | `Pr(a < y_j < b)`
`e(a,b)`    | `E(y_j | a < y_j < b)`
`ystar(a,b)`| `E(y^*_j), y^*_j = max{a, min(y_j,b)}`

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.
where \( a \) and \( b \) may be numbers or variables; \( a \) missing \((a \geq .)\) means \(-\infty\), and \( b \) missing \((b \geq .)\) means \(+\infty\); see [U] 12.2.1 Missing values.

**Menu for predict**

Statistics > Postestimation > Predictions, residuals, etc.

**Options for predict**

- \( xb \), the default, calculates the linear prediction.
- \( residuals \) calculates the residuals, that is, \( y_j - x_j b \).
- \( stdp \) calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.
- \( stdf \) calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation and is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by \( stdf \) are always larger than those produced by \( stdp \); see Methods and formulas in [R] regress postestimation.
- \( pr(a,b) \) calculates \( \Pr(a < x_j b + u_j < b) \), the probability that \( y_j | x_j \) would be observed in the interval \((a, b)\).
  - \( a \) and \( b \) may be specified as numbers or variable names; \( lb \) and \( ub \) are variable names; \( pr(20,30) \) calculates \( \Pr(20 < x_j b + u_j < 30) \); \( pr(lb,ub) \) calculates \( \Pr(lb < x_j b + u_j < ub) \); and \( pr(20,ub) \) calculates \( \Pr(20 < x_j b + u_j < ub) \).
  - \( a \) missing \((a \geq .)\) means \(-\infty\); \( pr(.,30) \) calculates \( \Pr(-\infty < x_j b + u_j < 30) \); \( pr(lb,30) \) calculates \( \Pr(-\infty < x_j b + u_j < 30) \) in observations for which \( lb \geq . \) and calculates \( \Pr(lb < x_j b + u_j < 30) \) elsewhere.
  - \( b \) missing \((b \geq .)\) means \(+\infty\); \( pr(20,.) \) calculates \( \Pr(+\infty > x_j b + u_j > 20) \); \( pr(20,ub) \) calculates \( \Pr(+\infty > x_j b + u_j > 20) \) in observations for which \( ub \geq . \) and calculates \( \Pr(20 < x_j b + u_j < ub) \) elsewhere.
- \( e(a,b) \) calculates \( E(x_j b + u_j | a < x_j b + u_j < b) \), the expected value of \( y_j | x_j \) being in the interval \((a, b)\), meaning that \( y_j | x_j \) is truncated. \( a \) and \( b \) are specified as they are for \( pr() \).
- \( ystar(a,b) \) calculates \( E(y_j^*) \), where \( y_j^* = a \) if \( x_j b + u_j \leq a \), \( y_j^* = b \) if \( x_j b + u_j \geq b \), and \( y_j^* = x_j b + u_j \) otherwise, meaning that \( y_j^* \) is censored. \( a \) and \( b \) are specified as they are for \( pr() \).

[R] eivreg — Errors-in-variables regression  
[U] 20 Estimation and postestimation commands
Whenever Stata detects that something is wrong— that what you typed is uninterpretable, that you are trying to do something you should not be trying to do, or that you requested the impossible— Stata responds by typing a message describing the problem, together with a return code. For instance,

```
. lsit  
unrecognized command: lsit  
r(199);
. list myvar  
variable myvar not found  
r(111);
. test a=b  
last estimates not found  
r(301);
```

In each case, the message is probably sufficient to guide you to a solution. When we typed `lsit`, Stata responded with “unrecognized command”. We meant to type `list`. When we typed `list myvar`, Stata responded with “variable myvar not found”. There is no variable named `myvar` in our data. When we typed `test a=b`, Stata responded with “last estimates not found”. `test` tests hypotheses about previously fit models, and we have not yet fit a model.

The numbers in parentheses in the `r(199)`, `r(111)`, and `r(301)` messages are called the return codes. To find out more about these messages, type `search rc #`, where `#` is the number returned in the parentheses.

**Example 1**

```
. search rc 301
[P] error messages ................. Return code 301
last estimates not found;
You typed an estimation command such as `regress` without arguments or attempted to perform a `test` or typed `predict`, but there were no previous estimation results.
```

Programmers should see [P] error for details on programming error messages.

### Syntax

**Effect sizes for two independent samples using groups**

```
esize twosample varname [if] [in], by(groupvar) [options]
```

**Effect sizes for two independent samples using variables**

```
esize unpaired varname1 == varname2 [if] [in], [options]
```

**Immediate form of effect sizes for two independent samples**

```
esizei #obs1 #mean1 #sd1 #obs2 #mean2 #sd2 [ , options]
```

**Immediate form of effect sizes for F tests after an ANOVA**

```
esizei #df1 #df2 #F [ , level(#)]
```

#### options Description

**Main**

- **cohen**d
  report Cohen’s $d$ (1988)
- **hedgesg**
  report Hedges’s $g$ (1981)
- **glassdelta**
  report Glass’s $\Delta$ (Smith and Glass 1977) using each group’s standard deviation
- **pbcorr**
  report the point-biserial correlation coefficient (Pearson 1909)
- **all**
  report all estimates of effect size
- **unequal**
  use unequal variances
- **welch**
  use Welch’s (1947) approximation
- **level(#)**
  set confidence level; default is level(95)

by is allowed with `esize`; see [D] by.

### Menu

**esize**

Statistics > Summaries, tables, and tests > Classical tests of hypotheses > Effect size based on mean comparison

**esizei**

Statistics > Summaries, tables, and tests > Classical tests of hypotheses > Effect-size calculator

479
Description

esize calculates effect sizes for comparing the difference between the means of a continuous variable for two groups. In the first form, esize calculates effect sizes for the difference between the mean of varname for two groups defined by groupvar. In the second form, esize calculates effect sizes for the difference between varname1 and varname2, assuming unpaired data.

esizei is the immediate form of esize; see [U] 19 Immediate commands. In the first form, esizei calculates the effect size for comparing the difference between the means of two groups. In the second form, esizei calculates the effect size for an \(F\) test after an ANOVA.

Options

by(groupvar) specifies the groupvar that defines the two groups that esize will use to estimate the effect sizes. Do not confuse the by() option with the by prefix; you can specify both.

cohensd specifies that Cohen’s \(d\) (1988) be reported.

hedgesg specifies that Hedges’s \(g\) (1981) be reported.

glassdelta specifies that Glass’s \(\Delta\) (Smith and Glass 1977) be reported.

pbcorr specifies that the point-biserial correlation coefficient (Pearson 1909) be reported.

all specifies that all estimates of effect size be reported. The default is Cohen’s \(d\) and Hedges’s \(g\).

unequal specifies that the data not be assumed to have equal variances.

welch specifies that the approximate degrees of freedom for the test be obtained from Welch’s formula (1947) rather than from Satterthwaite’s approximation formula (1946), which is the default when unequal is specified. Specifying welch implies unequal.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

Remarks and examples

Whereas \(p\)-values are used to assess the statistical significance of a result, measures of effect size are used to assess the practical significance of a result. Effect sizes can be broadly categorized as “measures of group differences” (the \(d\) family) and “measures of association” (the \(r\) family); see Ellis (2010, table 1.1). The \(d\) family includes estimators such as Cohen’s \(d\), Hedges’s \(g\), and Glass’s \(\Delta\). The \(r\) family includes estimators such as the point-biserial correlation coefficient, \(\omega^2\) and \(\eta^2\) (also see estat esize in [R] regress postestimation). For an introduction to the concepts and calculation of effect sizes, see Kline (2013) and Thompson (2006). For a more detailed discussion, see Kirk (1996), Ellis (2010), Cumming (2012), Grissom and Kim (2012), and Kelley and Preacher (2012).

It should be noted that there is much variation in the definitions of measures of effect size (Kline 2013). As Ellis (2010, 27) cautions, “However, beware the inconsistent terminology. What is labeled here as \(g\) was labeled by Hedges and Olkin as \(d\) and vice versa. For these authors writing in the early 1980s, \(g\) was the mainstream effect-size index developed by Cohen and refined by Glass (hence \(g\) for Glass). However, since then \(g\) has become synonymous with Hedges’s equation (not Glass’s) and the reason it is called Hedges’s \(g\) and not Hedges’s \(h\) is because it was originally named after Glass—even though it was developed by Larry Hedges. Confused?”
To avoid confusion, `esize` and `esizei` closely follow the notation of Hedges (1981), Smithson (2001), Kline (2013), and Ellis (2010).

## Example 1: Effect size for two independent samples using by()

Suppose we are interested in question 1 from the fictitious `depression.dta`: “My statistical software makes me feel sad”. We might have conducted a $t$ test to test the null hypothesis that there is no difference in response by sex. We could then compute various measures of effect size to describe the magnitude of the effect of sex.

```
. use http://www.stata-press.com/data/r13/depression
(Fictitious Depression Inventory data based on the Beck Depression Inventory)
. esize twosample qu1, by(sex) all
```

<table>
<thead>
<tr>

</tr>
<tr>
<td>Point-Biserial r</td>
<td>-0.0232208</td>
<td>-0.0849629 -0.0387996</td>
</tr>
</tbody>
</table>

Cohen’s $d$, Hedges’s $g$, and both estimates of Glass’s $\Delta$ indicate that the score for females is 0.05 standard deviations lower than the score for males. The point-biserial correlation coefficient indicates that there is a small, negative correlation between the scores for females and males.

### Technical note

Glass’s $\Delta$ has traditionally been estimated for experimental studies using the control group standard deviation rather than the pooled standard deviation. Kline (2013) notes that the choice of group becomes arbitrary for data arising from observational studies and recommends the reporting of Glass’s $\Delta$ using each group standard deviation.

## Example 2: Effect size for two independent samples by a third variable

If we are interested in the same effect sizes from example 1 stratified by race, we could use the by prefix with the sort option to accomplish this task.
. by race, sort: esize twosample qui, by(sex)

-> race = Hispanic
Effect size based on mean comparison

<table>

Example 3: Bootstrap confidence intervals for effect sizes

Simulation studies have shown that bootstrap confidence intervals may be preferable to confidence intervals based on the noncentral $t$ distribution when the variable of interest does not have a normal distribution (Kelley 2005; Algina, Keselman, and Penfield 2006). Bootstrap confidence intervals can be easily estimated for effect sizes using the bootstrap prefix.
. use http://www.stata-press.com/data/r13/depression
(Fictitious Depression Inventory data based on the Beck Depression Inventory)
. set seed 12345
. bootstrap r(d) r(g), reps(1000) nodots nowarn: esize twosample qu1, by(sex)
 Bootstrap results
 Number of obs = 1000
 Replications = 1000
 command: esize twosample qu1, by(sex)
 _bs_1: r(d)
 _bs_2: r(g)

<table>
<thead>
<tr>
<th></th>
<th>Observed</th>
<th>Bootstrap</th>
<th>Normal-based</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Coef.</td>
<td>Std. Err.</td>
<td>z</td>

<td>-.0512417</td>
<td>.07169</td>
<td>-0.71</td>
</tr>
<tr>
<td>_bs_2</td>
<td>-.0512032</td>
<td>.0716361</td>
<td>-0.71</td>
</tr>
</tbody>
</table>

Example 4: Effect sizes for two independent samples using variables

Sometimes, the data of interest are stored in two separate variables. We can calculate effect sizes for the two groups by using the unpaired version of esize.

. use http://www.stata-press.com/data/r13/fuel
. esize unpaired mpg1==mpg2

Effect size based on mean comparison

<table>
<thead>
<tr>
<th>Effect Size</th>
<th>Estimate</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cohen's d</td>
<td>-.5829654</td>
<td>-1.394934 .2416105</td>
</tr>
<tr>
<td>Hedges's g</td>
<td>-.5628243</td>
<td>-1.34674 .2332631</td>
</tr>
</tbody>
</table>

Example 5: Immediate form for effect sizes for two means

Often we do not have access to raw data, but we are given summary statistics in a report or manuscript. To calculate the effect sizes from summary statistics, we can use the immediate command esizei. For example, Kline (2013) in table 4.2 shows summary statistics for a hypothetical sample where mean1 = 13, sd1 = 2.74, mean2 = 11, and sd2 = 2.24; there are 30 people in each group. We can estimate the effect sizes from these summary data using esizei:

. esizei 30 13 2.74 30 11 2.24

Effect size based on mean comparison

<table>
<thead>
<tr>
<th>Effect Size</th>
<th>Estimate</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cohen's d</td>
<td>.7991948</td>
<td>.2695509 1.322465</td>
</tr>
<tr>
<td>Hedges's g</td>
<td>.7888081</td>
<td>.2660477 1.305277</td>
</tr>
</tbody>
</table>
Example 6: Immediate form for effect sizes for F tests after an ANOVA

`esizei` can also be used to compute $\eta^2$ and $\omega^2$ for $F$ tests after an ANOVA. The following example from Smithson (2001, 623) illustrates the use of `esizei` for $df_{\text{num}} = 4$, $df_{\text{den}} = 50$, and $F^* = 4.2317$.

```
esizei 4 50 4.2317, level(90)
```

**Effect sizes for linear models**

<table>
<thead>
<tr>
<th>Effect Size</th>
<th>Estimate</th>
<th>[90% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Eta-Squared</td>
<td>.2529151</td>
<td>.0521585 .3603621</td>
</tr>
<tr>
<td>Omega-Squared</td>
<td>.1931483</td>
<td>0 .309191</td>
</tr>
</tbody>
</table>

**Stored results**

`esize` and `esizei` for comparing two means store the following in `r()`:

Scalars:
- `r(d)`: Cohen’s $d$
- `r(lb_d)`: lower confidence bound for Cohen’s $d$
- `r(ub_d)`: upper confidence bound for Cohen’s $d$
- `r(g)`: Hedges’ $g$
- `r(lb_g)`: lower confidence bound for Hedges’ $g$
- `r(ub_g)`: upper confidence bound for Hedges’ $g$
- `r(delta1)`: Glass’s $\Delta$ for group 1
- `r(lb_delta1)`: lower confidence bound for Glass’s $\Delta$ for group 1
- `r(ub_delta1)`: upper confidence bound for Glass’s $\Delta$ for group 1
- `r(delta2)`: Glass’s $\Delta$ for group 2
- `r(lb_delta2)`: lower confidence bound for Glass’s $\Delta$ for group 2
- `r(ub_delta2)`: upper confidence bound for Glass’s $\Delta$ for group 2
- `r(r_pb)`: point-biserial correlation coefficient
- `r(lb_r_pb)`: lower confidence bound for the point-biserial correlation coefficient
- `r(ub_r_pb)`: upper confidence bound for the point-biserial correlation coefficient
- `r(N_1)`: sample size $n_1$
- `r(N_2)`: sample size $n_2$
- `r(df_t)`: degrees of freedom
- `r(level)`: confidence level

`esizei` for $F$ tests after ANOVA stores the following in `r()`:

Scalars:
- `r(eta2)`: $\eta^2$
- `r(lb_eta2)`: lower confidence bound for $\eta^2$
- `r(ub_eta2)`: upper confidence bound for $\eta^2$
- `r(omega2)`: $\omega^2$
- `r(lb_omega2)`: lower confidence bound for $\omega^2$
- `r(ub_omega2)`: upper confidence bound for $\omega^2$
- `r(level)`: confidence level

**Methods and formulas**

For the $d$ family, the effect-size parameter of interest is the scaled difference between the means given by

$$
\delta = \frac{(\mu_1 - \mu_2)}{\sigma}
$$
One of the most popular estimators of effect size is Cohen’s $d$, given by

$$
Cohen’s\ d = \frac{(\bar{x}_1 - \bar{x}_2)}{s^*}
$$

where

$$
s^* = \sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}}
$$

Hedges (1981) showed that Cohen’s $d$ is biased and proposed the unbiased estimator

$$
Hedges’s\ g = Cohen’s\ d \times c(m)
$$

where $m = n_1 + n_2 - 2$ and

$$
c(m) = \frac{\Gamma\left(\frac{m}{2}\right)}{\sqrt{\frac{m}{2}\Gamma\left(\frac{m-1}{2}\right)}}
$$

Glass (Smith and Glass 1977) proposed an estimator for $\delta$ in the context of designed experiments,

$$
Glass’s\ \Delta = \frac{(\bar{x}_{treated} - \bar{x}_{control})}{s_{control}}
$$

where $s_{control}$ is the standard deviation for the control group.

As noted above, esize and esizei report two estimates of Glass’s $\Delta$: one using the standard deviation for group 1 and the other using the standard deviation for group 2:

$$
Glass’s\ \Delta_1 = \frac{(\bar{x}_1 - \bar{x}_2)}{s_1}
$$

and

$$
Glass’s\ \Delta_2 = \frac{(\bar{x}_1 - \bar{x}_2)}{s_2}
$$

For the $r$ family, the effect-size parameter of interest is the ratio of the variance attributable to an effect and the total variance:

$$
\eta^2 = \frac{\sigma^2_{effect}}{\sigma^2_{total}}
$$

A popular estimator of $\eta$ when there are two groups is the point-biserial correlation coefficient,

$$
r_{PB} = \frac{t}{\sqrt{t^2 + df}}
$$

where $t$ is the $t$ statistic for the difference between the means of the two groups, and $df$ is the corresponding degrees of freedom. Satterthwaite’s or Welch’s adjustment (see [R] ttest for details) to the degrees of freedom can be used to calculate $r_{PB}$ by specifying the unequal or welch option, respectively.
When more than two means are being compared, as in the case of an ANOVA with \( p \) groups, a popular estimator of effect size is the correlation ratio denoted \( \eta^2 \) (Fisher 1925; Kerlinger 1964). \( \eta^2 \) can be computed directly as the ratio of the \( SS_{\text{effect}} \) and the \( SS_{\text{total}} \) or as a function of the \( F \) statistic with numerator degrees of freedom equal to \( df_{\text{num}} \) and denominator degrees of freedom equal to \( df_{\text{den}} \).

\[
\hat{\eta}^2 = \frac{(F \times df_{\text{num}})}{(F \times df_{\text{num}}) + df_{\text{den}}}
\]

Like its equivalent estimator \( R^2 \), \( \eta^2 \) has an upward bias. The less biased (though not unbiased) estimator \( \omega^2 \) (Hays 1963) is equivalent to the adjusted \( R^2 \) and can be estimated directly from the sums of squares, the \( F \) statistic, or as a function of \( \eta^2 \); that is,

\[
\hat{\omega}^2 = \frac{SS_{\text{between}} - (p - 1)MS_{\text{within}}}{SS_{\text{total}} + MS_{\text{within}}}
\]
or

\[
\hat{\omega}^2 = \frac{(p - 1)(F - 1)}{(p - 1)(F - 1) + (p)(n)}
\]
or

\[
\hat{\omega}^2 = \eta^2 - \left(\frac{df_{\text{num}}}{df_{\text{den}}}\right) \times (1 - \eta^2)
\]

To calculate \( \hat{\eta}^2 \) and \( \hat{\omega}^2 \) directly after \texttt{anova} or \texttt{regress}, see \texttt{estat esize} in [R] \texttt{regress postestimation}.

Cohen’s \( d \), Hedges’s \( g \), and Glass’s \( \Delta \) have been shown to have a noncentral \( t \) distribution (Hedges 1981) with noncentrality parameter equal to

\[
\lambda = \delta \sqrt{\frac{n_1 n_2}{n_1 + n_2}}
\]

Confidence intervals are calculated by finding the noncentrality parameters \( \lambda_{\text{lower}} \) and \( \lambda_{\text{upper}} \) that correspond to

\[
\Pr(df, \delta, \lambda_{\text{lower}}) = 1 - \frac{\alpha}{2}
\]
and

\[
\Pr(df, \delta, \lambda_{\text{upper}}) = \frac{\alpha}{2}
\]
using the function \texttt{npnt(df, t, p)}. The noncentrality parameters are then transformed back to the effect-size scale:

\[
\delta_{\text{lower}} = \lambda_{\text{lower}} \sqrt{\frac{n_1 + n_2}{n_1 n_2}}
\]
and

\[
\delta_{\text{upper}} = \lambda_{\text{upper}} \sqrt{\frac{n_1 + n_2}{n_1 n_2}}
\]

(see Venables [1975]; Steiger and Fouladi [1997]; Cumming and Finch [2001]; Smithson [2001]).
Confidence intervals for the point-biserial correlation coefficient are calculated similarly and transformed back to the effect-size scale as

\[ r_{\text{lower}} = \frac{\lambda_{\text{lower}}}{\sqrt{\lambda_{\text{lower}}^2 + \text{df}}} \]

and

\[ r_{\text{upper}} = \frac{\lambda_{\text{upper}}}{\sqrt{\lambda_{\text{upper}}^2 + \text{df}}} \]

Following Smithson’s (2001) notation, the \( F \) statistic is written as

\[ F_{\text{df}_{\text{num}}, \text{df}_{\text{den}}} = f^2(\text{df}_{\text{num}}/\text{df}_{\text{den}}) \]

This equation has a noncentral \( F \) distribution with noncentrality parameter:

\[ \lambda = f^2(\text{df}_{\text{num}} + \text{df}_{\text{den}} + 1) \]

where \( f^2 = R^2/(1 - R^2) \).

Confidence intervals for \( \hat{\eta}^2 \) and \( \hat{\omega}^2 \) are calculated by finding the noncentrality parameters \( \lambda_{\text{lower}} \) and \( \lambda_{\text{upper}} \) for a noncentral \( F \) distribution that correspond to

\[ \text{Pr}(\text{df}_{\text{num}}, \text{df}_{\text{den}}, F, \lambda_{\text{lower}}) = 1 - \frac{\alpha}{2} \]

and

\[ \text{Pr}(\text{df}_{\text{num}}, \text{df}_{\text{den}}, F, \lambda_{\text{upper}}) = \frac{\alpha}{2} \]

using the function \( \text{npnF}(df_1, df_2, f, p) \). The noncentrality parameters are transformed back to the \( \hat{\eta}^2 \) scale as

\[ \hat{\eta}^2_{\text{lower}} = \max \left( 0, \frac{\lambda_{\text{lower}}}{\lambda_{\text{lower}} + \text{df}_{\text{num}} + \text{df}_{\text{den}} + 1} \right) \]

and

\[ \hat{\eta}^2_{\text{upper}} = \min \left( 1, \frac{\lambda_{\text{upper}}}{\lambda_{\text{upper}} + \text{df}_{\text{num}} + \text{df}_{\text{den}} + 1} \right) \]

The confidence limits for \( \hat{\omega}^2 \) are then calculated as a function of \( \hat{\eta}^2 \):

\[ \hat{\omega}^2_{\text{lower}} = \hat{\eta}^2_{\text{lower}} - \left( \frac{\text{df}_{\text{num}}}{\text{df}_{\text{den}}} \right) \times (1 - \hat{\eta}^2_{\text{lower}}) \]

and

\[ \hat{\omega}^2_{\text{upper}} = \hat{\eta}^2_{\text{upper}} - \left( \frac{\text{df}_{\text{num}}}{\text{df}_{\text{den}}} \right) \times (1 - \hat{\eta}^2_{\text{upper}}) \]

See Smithson (2001) for further details.
Fred Nichols Kerlinger (1910–1991) was born in New York City. He studied music at New York University and graduated magna cum laude with a degree in education and philosophy. After graduation, he joined the U.S. Army and served as a counterintelligence officer in Japan in 1946. Kerlinger earned an MA and a PhD in educational psychology from the University of Michigan and held faculty appointments at several universities, including New York University. He was president of the American Educational Research Association and is best known for his popular and influential book *Foundations of Behavioral Research* (1964), which introduced Fisher’s (1925) $\eta^2$ statistic to behavioral researchers.

William Lee Hays (1926–1995) was born in Clarksville, Texas. He studied mathematics and psychology at Paris Junior College in Paris, Texas, and at East Texas State College. He earned BS and MS degrees from North Texas State University. Upon completion of his PhD in psychology at the University of Michigan, he joined the faculty, where he eventually became associate vice president for academic affairs. In 1977, Hays accepted an appointment as vice president for academic affairs at the University of Texas at Austin, where he remained until his death in 1995. Hays is best known for his book *Statistics for Psychologists* (1963), which introduced the $\omega^2$ statistic.

</table>

**Description**

`estat` displays scalar- and matrix-valued statistics after estimation; it complements `predict`, which calculates variables after estimation. Exactly what statistics `estat` can calculate depends on the previous estimation command.

Three sets of statistics are so commonly used that they are available after all estimation commands that store the model log likelihood. `estat ic` displays Akaike’s and Schwarz’s Bayesian information criteria. `estat summarize` summarizes the variables used by the command and automatically restricts the sample to `e(sample)`; it also summarizes the weight variable and cluster structure, if specified. `estat vce` displays the covariance or correlation matrix of the parameter estimates of the previous model.
Syntax

```plaintext
estat classification [if] [in] [weight] [ , options ]
```

fweights are allowed; see [U] 11.1.6 weight.
estat classification is not appropriate after the svy prefix.

Menu for estat

Statistics > Postestimation > Reports and statistics

Description

estat classification reports various summary statistics, including the classification table.
estat classification requires that the current estimation results be from logistic, logit, probit, or ivprobit; see [R] logistic, [R] logit, [R] probit, or [R] ivprobit.

Options

all requests that the statistic be computed for all observations in the data, ignoring any if or in restrictions specified by the estimation command.
cutoff(#) specifies the value for determining whether an observation has a predicted positive outcome. An observation is classified as positive if its predicted probability is $\geq$ #. The default is 0.5.

Remarks and examples

estat classification presents the classification statistics and classification table after logistic, logit, probit, or ivprobit.

Statistics are produced either for the estimation sample (the default) or for any set of observations. When weights, if, or in is used with the estimation command, it is not necessary to repeat the qualifier when you want statistics computed for the estimation sample. Specify if, in, or the all option only when you want statistics computed for a set of observations other than the estimation sample. Specify weights only when you want to use a different set of weights.
We illustrate `estat classification` after `logistic`; see `[R] logistic`.

<td>189</td>
</tr>
</tbody>
</table>
```

Classified + if predicted Pr(D) >= .5
True D defined as low != 0

```
Sensitivity             Pr( +| D)  35.59%
Specificity            Pr( -|~D)  90.77%
Positive predictive value Pr( D| +)  63.64%
Negative predictive value Pr( ~D| -)  75.64%

False + rate for true ~D Pr( +|~D)  9.23%
False - rate for true D  Pr( -| D)  64.41%
False + rate for classified + Pr(~D| +) 36.36%
False - rate for classified - Pr( D| -) 24.36%
```

Correctly classified 73.54%

The overall rate of correct classification is estimated to be 73.54, with 90.77% of the normal weight group correctly classified (specificity) and only 35.59% of the low weight group correctly classified (sensitivity). Classification is sensitive to the relative sizes of each component group, and always favors classification into the larger group. This phenomenon is evident here.

By default, `estat classification` uses a cutoff of 0.5, although you can vary this with the `cutoff()` option. You can use the `lsens` command to review the potential cutoffs; see `[R] lsens`.

### Stored results

`estat classification` stores the following in `r()`:

- Scalars
  - `r(P_corr)`  percent correctly classified
  - `r(P_p1)`    sensitivity
  - `r(P_n0)`    specificity
  - `r(P_p0)`    false-positive rate given true negative
  - `r(P_n1)`    false-negative rate given true positive
  - `r(P_lp)`    positive predictive value
  - `r(P_on)`    negative predictive value
  - `r(P_op)`    false-positive rate given classified positive
  - `r(P_ln)`    false-negative rate given classified negative
Methods and formulas

Let \( j \) index observations. Define \( c \) as the `cut-off()` specified by the user or, if not specified, as 0.5. Let \( p_j \) be the predicted probability of a positive outcome and \( y_j \) be the actual outcome, which we will treat as 0 or 1, although Stata treats it as 0 and non-0, excluding missing observations.

A prediction is classified as positive if \( p_j \geq c \) and otherwise is classified as negative. The classification is correct if it is positive and \( y_j = 1 \) or if it is negative and \( y_j = 0 \).

Sensitivity is the fraction of \( y_j = 1 \) observations that are correctly classified. Specificity is the percentage of \( y_j = 0 \) observations that are correctly classified.

Syntax

.estat gof [ if ] [ in ] [ weight ] [ , options ]

.options Description

Main

.group(#) perform Hosmer–Lemeshow goodness-of-fit test using # quantiles
.all execute test for all observations in the data
.outsample adjust degrees of freedom for samples outside estimation sample
.table display table of groups used for test

fweights are allowed; see [U] 11.1.6 weight.
For information on using estat gof with survey data, see [SVY] estat.

Menu for estat

Statistics > Postestimation > Reports and statistics

Description

.estat gof reports the Pearson goodness-of-fit test or the Hosmer–Lemeshow goodness-of-fit test.
estat gof requires that the current estimation results be from logistic, logit, or probit; see [R] logistic, [R] logit, or [R] probit. For estat gof after poisson, see [R] poisson postestimation. For estat gof after sem, see [SEM] estat gof.

Options

Main

.group(#) specifies the number of quantiles to be used to group the data for the Hosmer–Lemeshow goodness-of-fit test. group(10) is typically specified. If this option is not given, the Pearson goodness-of-fit test is computed using the covariate patterns in the data as groups.

.all requests that the statistic be computed for all observations in the data, ignoring any if or in restrictions specified by the estimation command.

.outsample adjusts the degrees of freedom for the Pearson and Hosmer–Lemeshow goodness-of-fit tests for samples outside the estimation sample. See Samples other than the estimation sample later in this entry.
Table displays a table of the groups used for the Hosmer–Lemeshow or Pearson goodness-of-fit test with predicted probabilities, observed and expected counts for both outcomes, and totals for each group.

Remarks and examples

Remarks are presented under the following headings:

Introduction

Sampling other than the estimation sample

Example 1

`estat gof`, typed without options, presents the Pearson $\chi^2$ goodness-of-fit test for the fitted model. The Pearson $\chi^2$ goodness-of-fit test is a test of the observed against expected number of responses using cells defined by the covariate patterns; see `predict with the number option` in [R] logistic postestimation for the definition of covariate patterns.

```
use http://www.stata-press.com/data/r13/lbw
(logistic & Lemeshow data)
logistic low age lwt i.race smoke ptl ht ui
(output omitted)
estat gof
```

**Logistic model for low, goodness-of-fit test**

- number of observations = 189
- number of covariate patterns = 182
  - Pearson chi2(173) = 179.24
  - Prob > chi2 = 0.3567

Our model fits reasonably well. However, the number of covariate patterns is close to the number of observations, making the applicability of the Pearson $\chi^2$ test questionable but not necessarily inappropriate. Hosmer, Lemeshow, and Sturdivant (2013, 157–160) suggest regrouping the data by ordering on the predicted probabilities and then forming, say, 10 nearly equal-sized groups. `estat gof` with the `group()` option does this:

```
estat gof, group(10)
```

**Logistic model for low, goodness-of-fit test**

(Table collapsed on quantiles of estimated probabilities)

- number of observations = 189
- number of groups = 10
  - Hosmer–Lemeshow chi2(8) = 9.65
  - Prob > chi2 = 0.2904

Again we cannot reject our model. If we specify the `table` option, `estat gof` displays the groups along with the expected and observed number of positive responses (low-birthweight babies):
. estat gof, group(10) table

number of observations = 189
number of groups = 10
Hosmer-Lemeshow chi2(8) = 9.65
Prob > chi2 = 0.2904

### Technical note

`estat gof` with the `group()` option puts all observations with the same predicted probabilities into the same group. If, as in the previous example, we request 10 groups, the groups that `estat gof` makes are \([p_0, p_{10}], (p_{10}, p_{20}], (p_{20}, p_{30}], \ldots, (p_{90}, p_{100}],\) where \(p_k\) is the \(k\)th percentile of the predicted probabilities, with \(p_0\) the minimum and \(p_{100}\) the maximum.

If there are many ties at the quantile boundaries, as will often happen if all independent variables are categorical and there are only a few of them, the sizes of the groups will be uneven. If the totals in some of the groups are small, the \(\chi^2\) statistic for the Hosmer–Lemeshow test may be unreliable. In this case, fewer groups should be specified, or the Pearson goodness-of-fit test may be a better choice.

### Example 2

The `table` option can be used without the `group()` option. We would not want to specify this for our current model because there were 182 covariate patterns in the data, caused by including the two continuous variables, `age` and `lwt`, in the model. As an aside, we fit a simpler model and specify `table` with `estat gof`:
. logistic low i.race smoke ui
Logistic regression                 Number of obs = 189
LR chi2(4) = 18.80
Prob > chi2 = 0.0009

number of observations = 189
number of covariate patterns = 11
Pearson chi2(6) = 5.71
Prob > chi2 = 0.4569
Technical note

logistic, logit, or probit and estat gof keep track of the estimation sample. If you type, for instance, logistic ... if x==1, then when you type estat gof, the statistics will be calculated on the x==1 subsample of the data automatically.

You should specify if or in with estat gof only when you wish to calculate statistics for a set of observations other than the estimation sample. See Samples other than the estimation sample later in this entry.

If the logistic model was fit with fweights, estat gof properly accounts for the weights in its calculations. (estat gof only allows fweights.) You do not have to specify the weights when you run estat gof. Weights should be specified with estat gof only when you wish to use a different set of weights.

Samples other than the estimation sample

estat gof can be used with samples other than the estimation sample. By default, estat gof remembers the estimation sample used with the last logistic, logit, or probit command. To override this, simply use an if or in restriction to select another set of observations, or specify the all option to force the command to use all the observations in the dataset.

If you use estat gof with a sample that is completely different from the estimation sample (that is, no overlap), you should also specify the outsample option so that the $\chi^2$ statistic properly adjusts the degrees of freedom upward. For an overlapping sample, the conservative thing to do is to leave the degrees of freedom the same as they are for the estimation sample.

Example 3

We want to develop a model for predicting low-birthweight babies. One approach would be to divide our data into two groups, a developmental sample and a validation sample. See Lemeshow and Gall (1994) and Tilford, Roberson, and Fiser (1995) for more information on developing prediction models and severity-scoring systems.

We will do this with the low-birthweight data that we considered previously. First, we randomly divide the data into two samples.

```
. use http://www.stata-press.com/data/r13/lbw, clear
   (Hosmer & Lemeshow data)
. set seed 1
. generate r = runiform()
. sort r
. generate group = 1 if _n <= _N/2
     (95 missing values generated)
. replace group = 2 if group==.
     (95 real changes made)
```

Then we fit a model using the first sample (group = 1), which is our developmental sample.
To test calibration in the developmental sample, we calculate the Hosmer–Lemeshow goodness-of-fit test by using `estat gof`.

```
estat gof, group(10)
```

**Logistic model for low, goodness-of-fit test**

(Table collapsed on quantiles of estimated probabilities)

|   | Odds Ratio | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|---|------------|-----------|------|-----|---------------------|
| age | .91542     | .0553937  | -1.46| 0.144 | .8130414           | 1.03069       |

| race |           |           |      |      |                     |              |
| black | 5.063678   | 3.78442   | 2.17 | 0.030 | 1.170327           | 21.90913     |
| other | 2.606209   | 1.657608  | 1.51 | 0.132 | .7492483           | 9.065522     |
| smoke | .909912    | .5252898  | -0.16| 0.870 | .2934966           | 2.820953     |
| ptl  | 3.033543   | 1.507048  | 2.23 | 0.025 | 1.145718           | 8.03198      |
| ht   | 21.07565   | 22.64788  | 2.84 | 0.005 | 2.565304           | 173.1652     |
| ui   | .988479    | .6699458  | -0.02| 0.986 | .2618557           | 3.731409     |
| _cons | 30.73641   | 56.82168  | 1.85 | 0.064 | .8204589           | 1151.462     |

We did not specify an `if` statement with `estat gof` because we wanted to use the estimation sample. Because the test is not significant, we are satisfied with the fit of our model.

Running `lroc` (see [R] `lroc`) gives a measure of the discrimination:

```
lroc, nograph
```

Logistic model for low

| number of observations = | 94 |
| area under ROC curve =   | 0.8156 |

Now we test the calibration of our model by performing a goodness-of-fit test on the validation sample. We specify the `outsample` option so that the number of degrees of freedom is 10 rather than 8.

number of observations = 95  
number of groups = 10  
Hosmer-Lemeshow chi2(10) = 28.03  
Prob > chi2 = 0.0018

We must acknowledge that our model does not fit well on the validation sample. The model’s discrimination in the validation sample is appreciably lower, as well.

. lroc if group==2, nograph

Logistic model for low  
number of observations = 95  
area under ROC curve = 0.5839

---

**Stored results**

estat gof stores the following in r():

Scalars

r(N) number of observations  
r(m) number of covariate patterns or groups  
r(df) degrees of freedom  
r(chi2) \( \chi^2 \)

**Methods and formulas**

Let \( M \) be the total number of covariate patterns among the \( N \) observations. View the data as collapsed on covariate patterns \( j = 1, 2, \ldots, M \), and define \( m_j \) as the total number of observations having covariate pattern \( j \) and \( y_j \) as the total number of positive responses among observations with covariate pattern \( j \). Define \( p_j \) as the predicted probability of a positive outcome in covariate pattern \( j \).

The Pearson \( \chi^2 \) goodness-of-fit statistic is

\[
\chi^2 = \sum_{j=1}^{M} \frac{(y_j - m_j p_j)^2}{m_j p_j (1 - p_j)}
\]
This $\chi^2$ statistic has approximately $M - k$ degrees of freedom for the estimation sample, where $k$ is the number of independent variables, including the constant. For a sample outside the estimation sample, the statistic has $M$ degrees of freedom.

The Hosmer–Lemeshow goodness-of-fit $\chi^2$ (Hosmer and Lemeshow 1980; Lemeshow and Hosmer 1982; Hosmer, Lemeshow, and Klar 1988) is calculated similarly, except that rather than using the $M$ covariate patterns as the group definition, the quantiles of the predicted probabilities are used to form groups. Let $G = \#$ be the number of quantiles requested with \texttt{group(#)}. The smallest index $1 \leq q(i) \leq M$, such that

$$W_{q(i)} = \sum_{j=1}^{q(i)} m_j \geq \frac{N}{G}$$

gives $p_{q(i)}$ as the upper boundary of the $i$th quantile for $i = 1, 2, \ldots, G$. Let $q(0) = 1$ denote the first index.

The groups are then

$$[p_{q(0)}, p_{q(1)}], (p_{q(1)}, p_{q(2)}], \ldots, (p_{q(G-1)}, p_{q(G)}]$$

If the \texttt{table} option is given, the upper boundaries $p_{q(1)}, \ldots, p_{q(G)}$ of the groups appear next to the group number on the output.

The resulting $\chi^2$ statistic has approximately $G - 2$ degrees of freedom for the estimation sample. For a sample outside the estimation sample, the statistic has $G$ degrees of freedom.

estat ic — Display information criteria

Syntax

    estat ic [, n(#) ]

Menu for estat

Statistics > Postestimation > Reports and statistics

Description

    estat ic displays Akaike’s and Schwarz’s Bayesian information criteria.

Option

    n(#) specifies the \( N \) to be used in calculating \( \text{BIC} \); see [R] BIC note.

Remarks and examples

    estat ic calculates two information criteria used to compare models. Unlike likelihood-ratio, Wald, and similar testing procedures, the models need not be nested to compare the information criteria. Because they are based on the log-likelihood function, information criteria are available only after commands that report the log likelihood.

    In general, “smaller is better”: given two models, the one with the smaller AIC fits the data better than the one with the larger AIC. As with the AIC, a smaller BIC indicates a better-fitting model. For AIC and BIC formulas, see Methods and formulas.

Example 1

    In [R] mlogit, we fit a model explaining the type of insurance a person has on the basis of age, gender, race, and site of study. Here we refit the model with and without the site dummies and compare the models.
. use http://www.stata-press.com/data/r13/sysdsn1
(Health insurance data)
. mlogit insure age male nonwhite
(output omitted)
. estat ic

</tr>
</thead>
<tbody>
<tr>
<td>.</td>
<td>615</td>
<td>-555.8545</td>
<td>-534.3616</td>
<td>12</td>
<td>1092.723</td>
<td>1145.783</td>
</tr>
</tbody>
</table>

Note: N=Obs used in calculating BIC; see [R] BIC note

The AIC indicates that the model including the site dummies fits the data better, whereas the BIC indicates the opposite. As is often the case, different model-selection criteria have led to conflicting conclusions.

Technical note

`glm` and `binreg`, `m1` report a slightly different version of AIC and BIC; see [R] `glm` for the formulas used. That version is commonly used within the GLM literature; see, for example, Hardin and Hilbe (2012). The literature on information criteria is vast; see, among others, Akaike (1973), Sawa (1978), and Raftery (1995). Judge et al. (1985) contains a discussion of using information criteria in econometrics. Royston and Sauerbrei (2008, chap. 2) examine the use of information criteria as an alternative to stepwise procedures for selecting model variables.

Stored results

`estat ic` stores the following in `r()`:

Matrices
r(S) 1 × 6 matrix of results:
1. sample size
2. log likelihood of null model
3. log likelihood of full model
4. degrees of freedom
5. AIC
6. BIC
Methods and formulas

Akaike’s (1974) information criterion is defined as

\[ AIC = -2 \ln L + 2k \]

where \( \ln L \) is the maximized log-likelihood of the model and \( k \) is the number of parameters estimated. Some authors define the \( AIC \) as the expression above divided by the sample size.

Schwarz’s (1978) Bayesian information criterion is another measure of fit defined as

\[ BIC = -2 \ln L + k \ln N \]

where \( N \) is the sample size. See [r] BIC note for additional information on calculating and interpreting BIC.

Hirotugu Akaike (1927–2009) was born in Fujinomiya City, Shizuoka Prefecture, Japan. He was the son of a silkworm farmer. He gained BA and DSc degrees from the University of Tokyo. Akaike’s career from 1952 at the Institute of Statistical Mathematics in Japan culminated in service as Director General; after 1994, he was Professor Emeritus. His best known work in a prolific career is on what is now known as the Akaike information criterion (AIC), which was formulated to help selection of the most appropriate model from a number of candidates.

Gideon E. Schwarz (1933–2007) was a professor of Statistics at the Hebrew University, Jerusalem. He was born in Salzburg, Austria, and obtained an MSc in 1956 from the Hebrew University and a PhD in 1961 from Columbia University. His interests included stochastic processes, sequential analysis, probability, and geometry. He is best known for the Bayesian information criterion (BIC).

[R] estat — Postestimation statistics
[R] estat summarize — Summarize estimation sample
[R] estat vce — Display covariance matrix estimates
**estat summarize** — Summarize estimation sample

### Syntax

```
estat summarize [eqlist] [ , estat_summ_options ]
```

### estat_summ_options

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>equation</strong></td>
<td>display summary by equation</td>
</tr>
<tr>
<td><strong>group</strong></td>
<td>display summary by group; only after <code>sem</code></td>
</tr>
<tr>
<td><strong>labels</strong></td>
<td>display variable labels</td>
</tr>
<tr>
<td><strong>noheader</strong></td>
<td>suppress the header</td>
</tr>
<tr>
<td><strong>noweights</strong></td>
<td>ignore weights</td>
</tr>
<tr>
<td><strong>display_options</strong></td>
<td>control row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling</td>
</tr>
</tbody>
</table>

`eqlist` is rarely used and specifies the variables, with optional equation name, to be summarized. `eqlist` may be `varlist` or `(eqname1; varlist) (eqname2; varlist) ... varlist` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

### Menu for estat

Statistics > Postestimation > Reports and statistics

### Description

`estat summarize` summarizes the variables used by the command and automatically restricts the sample to `e(sample)`; it also summarizes the weight variable and cluster structure, if specified.

### Options

- **equation** requests that the dependent variables and the independent variables in the equations be displayed in the equation-style format of estimation commands, repeating the summary information about variables entered in more than one equation.
- **group** displays summary information separately for each group. `group` is only allowed after `sem` with a `group()` variable specified.
- **labels** displays variable labels.
- **noheader** suppresses the header.
- **noweights** ignores the weights, if any, from the previous estimation command. The default when weights are present is to perform a weighted `summarize` on all variables except the weight variable itself. An unweighted `summarize` is performed on the weight variable.
display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels,nofvlabel, fvwrap(#), and fvwraption(style); see [R] estimation options.

Remarks and examples

Often when fitting a model, you will also be interested in obtaining summary statistics, such as the sample means and standard deviations of the variables in the model. estat summarize makes this process simple. The output displayed is similar to that obtained by typing

```
. summarize varlist if e(sample)
```

without the need to type the `varlist` containing the dependent and independent variables.

Example 1

Continuing with the example in [R] estat ic, here we summarize the variables by using estat summarize.

```
. use http://www.stata-press.com/data/r13/sysdsn1
   (Health insurance data)
. mlogit insure age male nonwhite i.site
   (output omitted)
. estat summarize, noomitted
```

```
Estimation sample mlogit        Number of obs =  615

                      Variable   |      Mean    Std. Dev.     Min    Max
---------------------|-------------|------------------------|--------|--------
          insure      |  1.596748   |   .6225846             |  1     |  3
           age        |  44.46832   |   14.18523             | 18.1109|  86.0725
        male         | 0.2504065   |   .4335998             | 0      |  1
      nonwhite      | 0.196748    |   .3978638             | 0      |  1
        site        |             |                        |        |        
          2          | 0.3707317   |   0.4833939            | 0      |  1
          3          | 0.3138211   |   0.4644224            | 0      |  1
```

The output in the previous example contains all the variables in one table, though mlogit presents its results in a multiple-equation format. For models in which the same variables appear in all equations, that is fine; but for other multiple-equation models, we may prefer to have the variables separated by the equation in which they appear. The equation option makes this possible.

Example 2

Systems of simultaneous equations typically have different variables in each equation, and the equation option of estat summarize is helpful in such situations. In example 2 of [R] reg3, we have a model of supply and demand. We first refit the model and then call estat summarize.
. use http://www.stata-press.com/data/r13/supDem
. reg3 (Demand:quantity price pcompete income) (Supply:quantity price praw),
> endog(price)
> (output omitted)
. estat summarize, equation

Estimation sample reg3      Number of obs =  49

<table>
<thead>

<tr>
<td>praw</td>
<td>4.740891</td>
<td>2.962565</td>
<td>.151028</td>
<td>9.79881</td>
</tr>
</tbody>
</table>

The first block of the table contains statistics on the dependent (or, more accurately, left-hand-side) variables, and because we specified quantity as the left-hand-side variable in both equations, it is listed twice. The second block refers to the variables in the first equation we specified, which we labeled “Demand” in our call to reg3; and the final block refers to the supply equation.

Stored results

estat summarize stores the following in r():

Scalars
r(N_groups)  number of groups (group only)

Matrices
r(stats)     k × 4 matrix of means, standard deviations, minimums, and maximums
r(stats[_,#]) k × 4 matrix of means, standard deviations, minimums, and maximums for group # (group only)

Also see
[R] estat — Postestimation statistics
[R] estat ic — Display information criteria

**Title**

`estat vce` — Display covariance matrix estimates

---

**Syntax**

`estat vce [ , estat_vce_options ]`

**estat_vce_options**

- **covariance**
  - display as covariance matrix; the default
- **correlation**
  - display as correlation matrix
- **equation(spec)**
  - display only specified equations
- **block**
  - display submatrices by equation
- **diag**
  - display submatrices by equation; diagonal blocks only
- **format(%fmt)**
  - display format for covariances and correlations
- **nolines**
  - suppress lines between equations
- **display_options**
  - control display of omitted variables and base and empty cells

---

**Menu for estat**

Statistics > Postestimation > Reports and statistics

**Description**

`estat vce` displays the covariance or correlation matrix of the parameter estimates of the previous model.

**Options**

- **covariance**
  - displays the matrix as a variance–covariance matrix; this is the default.
- **correlation**
  - displays the matrix as a correlation matrix rather than a variance–covariance matrix.
  - `rho` is a synonym.
- **equation(spec)**
  - selects part of the VCE to be displayed. If `spec` is `eqlist`, the VCE for the listed equations is displayed. If `spec` is `eqlist1 \ eqlist2`, the part of the VCE associated with the equations in `eqlist1` (rowwise) and `eqlist2` (columnwise) is displayed. If `spec` is `*`, all equations are displayed.
  - `equation()` implies `block` if `diag` is not specified.
- **block**
  - displays the submatrices pertaining to distinct equations separately.
- **diag**
  - displays the diagonal submatrices pertaining to distinct equations separately.
- **format(%fmt)**
  - specifies the number format for displaying the elements of the matrix. The default is `format(%10.0g)` for covariances and `format(%8.4f)` for correlations. See [U] 12.5 Formats: Controlling how data are displayed for more information.
nolines suppresses lines between equations.
display_options: noomitted, noemptycells, baselevels, allbaselevels; see [R] estimation options.

Remarks and examples

estat vce allows you to display the VCE of the parameters of the previously fit model, as either a covariance matrix or a correlation matrix.

> Example 1

Returning to the example in [R] estat ic, here we display the covariance matrix of the parameters of the mlogit model by using estat vce.

```
use http://www.stata-press.com/data/r13/sysdsn1
(Health insurance data)
. mlogit insure age male nonwhite
   (output omitted)
. estat vce, block

nonwhite | 0 0 0
_cons | 0 0 0 0
covariances of equation Prepaid
   | age  male nonwhite _cons
---|----------------------
age | .00003711
male | -.00015303 .0402091
nonwhite | -.00008948 .00470608 .04795135
_cons | -.00159095 -.00398961 -.00628886 .08000462
covariances of equation Uninsure (row) by equation Indemnity (column)
   | o.   o.   o.   o.   
   | age  male nonwhite _cons
---|----------------------
age | 0
male | 0 0
nonwhite | 0 0 0
_cons | 0 0 0 0
```
The block option is particularly useful for multiple-equation estimators. The first block of output here corresponds to the VCE of the estimated parameters for the first equation—the square roots of the diagonal elements of this matrix are equal to the standard errors of the first equation’s parameters. Similarly, the final block corresponds to the VCE of the parameters for the second equation. The middle block shows the covariances between the estimated parameters of the first and second equations.

Description

estimates allows you to store and manipulate estimation results:

- You can save estimation results in a file for use in later sessions.
- You can store estimation results in memory so that you can
  a. switch among separate estimation results and
  b. form tables combining separate estimation results.

Remarks and examples

estimates is for use after you have fit a model, be it with regress, logistic, etc. You can use estimates after any estimation command, whether it be an official estimation command of Stata or a user-written one.

estimates has three separate but related capabilities:

1. You can save estimation results in a file on disk so that you can use them later, even in a different Stata session.
2. You can store up to 300 estimation results in memory so that they are at your fingertips.
3. You can make tables comparing any results you have stored in memory.

Remarks are presented under the following headings:

Saving and using estimation results
Storing and restoring estimation results
Comparing estimation results
Jargon

Saving and using estimation results

After you have fit a model, say, with regress, type

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. regress mpg weight displ foreign
   (output omitted)
```

You can save the results in a file:

```
. estimates save basemodel
   (file basemodel.ster saved)
```

Later, say, in a different session, you can reload those results:

```
. estimates use basemodel
```

The situation is now nearly identical to what it was immediately after you fit the model. You can replay estimation results:

```
. regress
   (output omitted)
```

You can perform tests:

```
. test foreign==0
   (output omitted)
```
And you can use any postestimation command or postestimation capability of Stata. The only difference is that Stata no longer knows what the estimation sample, `e(sample)` in Stata jargon, was. When you reload the estimation results, you might not even have the original data in memory. That is okay. Stata will know to refuse to calculate anything that can be calculated only on the original estimation sample.

If it is important that you use a postestimation command that can be used only on the original estimation sample, there is a way you can do that. You use the original data and then use `estimates esample:` to tell Stata what the original sample was.

See [R] _estimates save_ for details.

### Storing and restoring estimation results

Storing and restoring estimation results in memory is much like saving them to disk. You type

```
. estimates store base
```

to save the current estimation results under the name `base`, and you type

```
. estimates restore base
```

to get them back later. You can find out what you have stored by typing

```
. estimates dir
```

Saving estimation results to disk is more permanent than storing them in memory, so why would you want merely to store them? The answer is that, once they are stored, you can use other `estimates` commands to produce tables and reports from them.

See [R] _estimates store_ for details about the `estimates store` and `restore` commands.

### Comparing estimation results

Let’s say that you have done the following:

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. regress mpg weight displ
   (output omitted)
. estimates store base
. regress mpg weight displ foreign
   (output omitted)
. estimates store alt
```

You can now get a table comparing the coefficients:

```
. estimates table base alt
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>base</th>
<th>alt</th>
</tr>
</thead>
<tbody>
<tr>

<tr>
<td>foreign</td>
<td>-1.6006312</td>
<td></td>
</tr>
<tr>
<td>_cons</td>
<td>40.084522</td>
<td>41.847949</td>
</tr>
</tbody>
</table>
```

`estimates table` can do much more; see [R] _estimates table_. Also see [R] _estimates stats_. `estimates stats` works similarly to `estimates table` but produces model comparisons in terms of BIC and AIC.
Jargon

You know that if you fit a model, say, by typing

```
    . regress mpg weight displacement
```

then you can later replay the results by typing

```
    . regress
```

and you can do tests and calculate other postestimation statistics by typing

```
    . test displacement==0
    . estat vif
    . predict mpghat
```

As a result, we often refer to the estimation results or the current estimation results or the most recent estimation results or the last estimation results or the estimation results in memory.

With estimates store and estimates restore, you can have many estimation results in memory. One set of those, the set most recently estimated, or the set most recently restored, are the current or active estimation results, which you can replay, which you can test, or from which you can calculate postestimation statistics.

Current and active are the two words we will use interchangeably from now on.

Also see

[P] _estimates — Manage estimation results
estimates describe — Describe estimation results

Syntax

\[
\begin{align*}
\text{estimates describe} \\
\text{estimates describe name} \\
\text{estimates describe using filename} [, \text{number(#)}]
\end{align*}
\]

Menu

Statistics > Postestimation > Manage estimation results > Describe results

Description

estimates describe describes the current (active) estimates. Reported are the command line that produced the estimates, any title that was set by estimates title (see [R] estimates title), and any notes that were added by estimates notes (see [R] estimates notes).

    estimates describe name does the same but reports results for estimates stored by estimates store (see [R] estimates store).

    estimates describe using filename does the same but reports results for estimates saved by estimates save (see [R] estimates save). If filename contains multiple sets of estimates (saved in it by estimates save, append), the number of sets of estimates is also reported. If filename is specified without an extension, .ster is assumed.

Option

number(#) specifies that the #th set of estimation results from filename be described. This assumes that multiple sets of estimation results have been saved in filename by estimates save, append. The default is number(1).

Remarks and examples

estimates describe can be used to describe the estimation results currently in memory, 

    . estimates describe

    Estimation results produced by

    . regress mpg weight displ if foreign
or to describe results saved by `estimates save` in a `.ster` file:

```stata
.estimates describe using final
```

Estimation results "Final results" saved on 12apr2013 14:20, produced by

```stata
.logistic myopic age sex drug1 drug2 if complete==1
```

Notes:
1. Used file `patient.dta`
2. "datasignature myopic age sex drug1 drug2 if complete==1"
   reports 148:5(58763):2252897466:3722318443
3. must be reviewed by rgg

Example 1

```stata
.use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
.regress mpg weight displ if foreign
(output omitted)
.estimates notes: file 'c(filename)'
.datasignature
74:12(71728):3831085005:1395876116
.estimates notes: datasignature report 'r(datasignature)'
.estimates save foreign
file foreign.ster saved
.regress mpg weight displ if !foreign
(output omitted)
.estimates describe using foreign
Estimation results saved on 02may2013 10:33, produced by
.regress mpg weight displ if foreign
Notes:
1. file `http://www.stata-press.com/data/r13/auto.dta`
2. datasignature report 74:12(71728):3831085005:1395876116
```

Stored results

`estimates describe` and `estimates describe name` store the following in `r()`:

**Macros**

- `r(title)`: title
- `r(cmdline)`: original command line

`estimates describe using filename` stores the above and the following in `r()`:

**Scalars**

- `r(datetime)` : %tc value of date/time file saved
- `r(nestresults)` : number of sets of estimation results in file

Also see

[R] `estimates` — Save and manipulate estimation results
estimates for — Repeat postestimation command across models

Syntax

estimates for namelist [, options] : postestimation_command

where namelist is a name, a list of names, _all, or *. A name may be ., meaning the current (active) estimates. _all and * mean the same thing.

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>noheader</td>
<td>do not display title</td>
</tr>
<tr>
<td>nostop</td>
<td>do not stop if command fails</td>
</tr>
</tbody>
</table>

Description

estimates for performs postestimation_command on each estimation result specified.

Options

noheader suppresses the display of the header as postestimation_command is executed each time.
nostop specifies that execution of postestimation_command is to be performed on the remaining models even if it fails on some.

Remarks and examples

In the example that follows, we fit a model two different ways, store the results, and then use estimates for to perform the same test on both of them:

Example 1

. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. generate gpm = 1/mpg
. regress gpm i.foreign i.foreign#c.weight displ
   (output omitted)
. estimates store reg
. qreg gpm i.foreign i.foreign#c.weight displ
   (output omitted)
. estimates store qreg
estimates for reg qreg: test 0.foreign#c.weight==1.foreign#c.weight

Model reg

( 1) 0b.foreign#c.weight - 1.foreign#c.weight = 0
    F( 1, 69) =   4.87
    Prob > F =   0.0307

Model qreg

( 1) 0b.foreign#c.weight - 1.foreign#c.weight = 0
    F( 1, 69) =   0.03
    Prob > F =   0.8554

Also see

[R] estimates — Save and manipulate estimation results
estimates notes — Add notes to estimation results

Syntax

```
estimates notes: text

estimates notes

estimates notes list [ in noterange ]

estimates notes drop in noterange
```

where noterange is # or #/# and where # may be a number, the letter f (meaning first), or the letter l (meaning last).

Description

```
estimates notes: text adds a note to the current (active) estimation results.
estimates notes and estimates notes list list the current notes.
estimates notes drop in noterange eliminates the specified notes.
```

Remarks and examples

After adding or removing notes, if estimates have been stored, do not forget to store them again. If estimates have been saved, do not forget to save them again.

Notes are most useful when you intend to save estimation results in a file; see [R] estimates save. For instance, after fitting a model, you might type

```
. estimates note: I think these are final
. estimates save lock2
```

and then, later when going through your files, you could type

```
. estimates use lock2
. estimates notes
  1. I think these are final
```

Up to 9,999 notes can be attached to estimation results. If estimation results are important, we recommend that you add a note identifying the .dta dataset you used. The best way to do that is to type

```
. estimates notes: file ‘c(filename)’
```
because ‘c(filename)’ will expand to include not just the name of the file but also its full path; see [P] creturn.

If estimation results took a long time to estimate—say, they were produced by `asmprobit` or `gllamm` (see [R] `asmprobit` and http://www.gllamm.org)—it is also a good idea to add a data signature. A data signature takes less time to compute than reestimation when you need proof that you really have the right dataset. The easy way to do that is to type

```
    . datasignature
    74:12(71728):3831085005:1395876116
    . estimates notes: datasignature reports 'r(datasignature)'
```

Now when you ask to see the notes, you will see

```
    . estimates notes
    1. I think these are final
    2. file C:\project\one\pat4.dta
    3. datasignature reports 74:12(71728):3831085005:1395876116
```

See [D] `datasignature`.

Notes need not be positive. You might set a note to be, “I need to check that age is defined correctly.”

Example 1

```
    . use http://www.stata-press.com/data/r13/auto
    (1978 Automobile Data)
    . regress mpg weight displ if foreign
       (output omitted)
    . estimates notes: file 'c(filename)'
    . datasignature
    74:12(71728):3831085005:1395876116
    . estimates notes: datasignature report 'r(datasignature)'
    . estimates save foreign
       file foreign.ster saved
    . estimates notes list in 1/2
       1. file http://www.stata-press.com/data/r13/auto.dta
       2. datasignature report 74:12(71728):3831085005:1395876116
    . estimates notes drop in 2
       (1 note dropped)
    . estimates notes
       1. file http://www.stata-press.com/data/r13/auto.dta
```

Also see

[R] `estimates` — Save and manipulate estimation results
Title

`estimates replay — Redisplay estimation results`

Syntax

```
estimates replay

estimates replay namelist
```

where `namelist` is a name, a list of names, `_all`, or `*`. A name may be `.`, meaning the current (active) estimates. `_all` and `*` mean the same thing.

Menu

```
Statistics > Postestimation > Manage estimation results > Redisplay estimation output
```

Description

`estimates replay` redisplays the current (active) estimation results, just as typing the name of the estimation command would do.

`estimates replay namelist` redisplays each specified estimation result. The active estimation results are left unchanged.

Remarks and examples

In the example that follows, we fit a model two different ways, store the results, use `estimates for` to perform the same test on both of them, and then replay the results:

> Example 1

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. generate gpm = 1/mpg
. regress gpm i.foreign i.foreign#c.weight displ
(output omitted)
. estimates store reg
. qreg gpm i.foreign i.foreign#c.weight displ
(output omitted)
. estimates store qreg
```
estimates replay — Redisplay estimation results

Model reg

( 1) 0b.foreign#c.weight - 1.foreign#c.weight = 0
F( 1, 69) = 4.87
Prob > F = 0.0307

Model qreg

( 1) 0b.foreign#c.weight - 1.foreign#c.weight = 0
F( 1, 69) = 0.03
Prob > F = 0.8554

estimates replay

Also see

[R] estimates — Save and manipulate estimation results

estimates save — Save and use estimation results

Syntax

estimates save filename [, append replace]
estimates use filename [, number(#)]
estimates esample: [varlist] [if] [in] [weight]
[ , replace stringvars(varlist) zeroweight]
estimates esample

Menu

estimates save
Statistics > Postestimation > Manage estimation results > Save to disk

estimates use
Statistics > Postestimation > Manage estimation results > Load from disk

Description

estimates save filename saves the current (active) estimation results in filename.
estimates use filename loads the results saved in filename into the current (active) estimation results.

In both cases, if filename is specified without an extension, .ster is assumed.
estimates esample: (note the colon) resets e(sample). After estimates use filename, e(sample) is set to contain 0, meaning that none of the observations currently in memory was used in obtaining the estimates.
estimates esample (without a colon) displays how e(sample) is currently set.

Options

append, used with estimates save, specifies that results be appended to an existing file. If the file does not already exist, a new file is created.
replace, used with estimates save, specifies that filename can be replaced if it already exists.
number(#), used with estimates use, specifies that the #th set of estimation results from filename be loaded. This assumes that multiple sets of estimation results have been saved in filename by estimates save, append. The default is number(1).

replace, used with estimates esample:, specifies that e(sample) can be replaced even if it is already set.

stringvars(varlist), used with estimates esample:, specifies string variables. Observations containing variables that contain "" will be omitted from e(sample).

zeroweight, used with estimates esample:, specifies that observations with zero weights are to be included in e(sample).

Remarks and examples

See [R] estimates for an overview of the estimates commands.

For a description of estimates save and estimates use, see Saving and using estimation results in [R] estimates.

The rest of this entry concerns e(sample).

Remarks are presented under the following headings:

- Setting e(sample)
- Resetting e(sample)
- Determining who set e(sample)

Setting e(sample)

After estimates use filename, the situation is nearly identical to what it was immediately after you fit the model. The one difference is that e(sample) is set to 0.

e(sample) is Stata’s function to mark which observations among those currently in memory were used in producing the estimates. For instance, you might type

```
use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
regress mpg weight displ if foreign
(output omitted)
summarize mpg if e(sample)
(output omitted)
```

and summarize would report the summary statistics for the observations regress in fact used, which would exclude not only observations for which foreign = 0 but also any observations for which mpg, weight, or displ was missing.

If you saved the above estimation results and then reloaded them, however, summarize mpg if e(sample) would produce

```
summarize mpg if e(sample)

Variable | Obs  | Mean  | Std. Dev. | Min  | Max
---------|------|-------|-----------|------|------
  mpg     | 0    |       |           |      |      
```

Stata thinks that none of these observations was used in producing the estimates currently loaded.
What else could Stata think? When you `estimates use filename`, you do not have to have the original data in memory. Even if you do have data in memory that look like the original data, they might not be. Setting `e(sample)` to 0 is the safe thing to do. There are some postestimation statistics, for instance, that are appropriate only when calculated on the estimation sample. Setting `e(sample)` to 0 ensures that if you ask for one of them, you will get back a null result.

We recommend that you leave `e(sample)` set to 0. But what if you really need to calculate that postestimation statistic? Well, you can get it, but you are going to be responsible for setting `e(sample)` correctly. Here we just happen to know that all the observations with `foreign = 1` were used, so we can type

```
.estimates esample: if foreign
```

If all the observations had been used, we could simply type

```
.estimates esample:
```

The safe thing to do, however, is to look at the estimation command—`estimates describe` will show it to you—and then type

```
.estimates esample: mpg weight displ if foreign
```

We include all observations with `foreign = 1`, excluding any with missing values in the `mpg`, `weight`, or `displ` variable, that are to be treated as the estimation sample.

**Resetting e(sample)**

`estimates esample:` will allow you to not only set but also reset `e(sample)`. If `e(sample)` has already been set (say that you just fit the model) and you try to set it, you will see

```
.estimates esample: mpg weight displ if foreign
no; e(sample) already set
r(322);
```

Here you can specify the `replace` option:

```
.estimates esample: mpg weight displ if foreign, replace
```

We do not recommend resetting `e(sample)`, but the situation can arise where you need to. Imagine that you `estimates use filename`, you set `e(sample)`, and then you realize that you set it wrong. Here you would want to reset it.

**Determining who set e(sample)**

`estimates esample` without a colon will report whether and how `e(sample)` was set. You might see

```
.estimates esample
  e(sample) set by estimation command
```

or

```
.estimates esample
  e(sample) set by user
```

or

```
.estimates esample
  e(sample) not set (0 assumed)
```
Stored results

estimates esample without the colon saves macro r(who), which will contain cmd, user, or zero’d.

Also see

[R] estimates — Save and manipulate estimation results
estimates stats — Model-selection statistics

Syntax

estimates stats [namelist] [ , n(#) ]

where namelist is a name, a list of names, _all, or *. A name may be ., meaning the current (active) estimates. _all and * mean the same thing.

Menu

Statistics > Postestimation > Manage estimation results > Table of fit statistics

Description

estimates stats reports model-selection statistics, including the Akaike information criterion (AIC) and the Bayesian information criterion (BIC). These measures are appropriate for maximum likelihood models.

If estimates stats is used for a non–likelihood-based model, such as qreg, missing values are reported.

Option

n(#) specifies the \( N \) to be used in calculating BIC; see [R] BIC note.

Remarks and examples

If you type estimates stats without arguments, a table for the most recent estimation results will be shown:

. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. logistic foreign mpg weight displ
(output omitted)
. estimates stats

Akaike’s information criterion and Bayesian information criterion

<table>
<thead>
<tr>
<th>Model</th>
<th>Obs</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>.</td>
<td>74</td>
<td>-45.03321</td>
<td>-20.59083</td>
<td>4</td>
<td>49.18167</td>
<td>58.39793</td>
</tr>
</tbody>
</table>

Note: \( N=\text{Obs used in calculating BIC}; \) see [R] BIC note
Regarding the note at the bottom of the table, \( N \) is an ingredient in the calculation of BIC; see [R] BIC note. The note changes if you specify the \( n() \) option, which tells estimates stats what \( N \) to use. \( N = \text{Obs} \) is the default.

Regarding the table itself, \( \text{ll(null)} \) is the log likelihood for the constant-only model, \( \text{ll(model)} \) is the log likelihood for the model, \( \text{df} \) is the number of degrees of freedom, and AIC and BIC are the Akaike and Bayesian information criteria.

Models with smaller values of an information criterion are considered preferable.

estimates stats can compare estimation results:

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. logistic foreign mpg weight displ
   (output omitted)
. estimates store full
. logistic foreign mpg weight
   (output omitted)
. estimates store sub
. estimates store full sub
. estimates stats full sub
```

<table>
<thead>
<tr>
<th>Model</th>
<th>Obs</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>full</td>
<td>74</td>
<td>-45.03321</td>
<td>-20.59083</td>
<td>4</td>
<td>49.18167</td>
<td>58.39793</td>
</tr>
<tr>
<td>sub</td>
<td>74</td>
<td>-45.03321</td>
<td>-27.17516</td>
<td>3</td>
<td>60.35031</td>
<td>67.26251</td>
</tr>
</tbody>
</table>

Note: \( N = \text{Obs} \) used in calculating BIC; see [R] BIC note

Stored results

estimates stats stores the following in \( r() \):

Matrices

\( r(S) \) matrix with 6 columns (\( N \), \( \text{ll0} \), \( \text{ll} \), \( \text{df} \), AIC, and BIC) and rows corresponding to models in table

Methods and formulas

See [R] BIC note.

Also see

[R] estimates — Save and manipulate estimation results
estimates store — Store and restore estimation results

Syntax

estimates store name [, nocopy]
estimates restore name
estimates query
estimates dir [namelist]
estimates drop namelist
estimates clear

where namelist is a name, a list of names, _all, or *. _all and * mean the same thing.

Menu

estimates store
Statistics > Postestimation > Manage estimation results > Store in memory

estimates restore
Statistics > Postestimation > Manage estimation results > Restore from memory

estimates dir
Statistics > Postestimation > Manage estimation results > List results stored in memory

estimates drop
Statistics > Postestimation > Manage estimation results > Drop from memory

Description

estimates store name stores the current (active) estimation results under the name name.
estimates restore name loads the results stored under name into the current (active) estimation results.
estimates query tells you whether the current (active) estimates have been stored and, if so, the name.
estimates dir displays a list of the stored estimates.
estimates drop namelist drops the specified stored estimation results.
estimates clear drops all stored estimation results.

estimates clear, estimates drop _all, and estimates drop * do the same thing. estimates drop and estimates clear do not eliminate the current (active) estimation results.

Option

nocopy, used with estimates store, specifies that the current (active) estimation results are to be moved into name rather than copied. Typing

```
. estimates store hold, nocopy
```

is the same as typing

```
. estimates store hold
. ereturn clear
```

except that the former is faster. The nocopy option is sometimes used by programmers.

Remarks and examples

estimates store stores estimation results in memory so that you can access them later.

```
. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. regress mpg weight displ
   (output omitted)
. estimates store myreg
. . . . you do other things, including fitting other models . . .
. estimates restore myreg
. regress
   (same output shown again)
```

After estimates restore myreg, things are once again just as they were, estimationwise, just after you typed regress mpg weight displ.

estimates store stores results in memory. When you exit Stata, those stored results vanish. If you wish to make a permanent copy of your estimation results, see [R] estimates save.

The purpose of making copies in memory is 1) so that you can quickly switch between them and 2) so that you can make tables comparing estimation results. Concerning the latter, see [R] estimates table and [R] estimates stats.

Stored results

estimates dir stores the following in r():

Macros

- r(names) names of stored results

estimates table — Compare estimation results

Reporting
display_options control row spacing, line width, and display of omitted variables and base and empty cells
title(string) title for table
title() does not appear in the dialog box.

where

- A scalarlist is a list of any or all of the names of scalars stored in e(), plus aic, bic, and rank.
- #1 #2 #3 are three numbers such as .05 .01 .001.
- A coefflist is a list of coefficient names, each name of which may be simple (for example, price), an equation name followed by a colon (for example, mean:), or a full name (for example, mean:price). Names are separated by blanks.
- A matchlist specifies how equations from different estimation results are to be matched. If you need to specify a matchlist, the solution is usually 1, as in equations(1). The full syntax is

\[ \text{matchlist} := \text{term} [, \text{term} \ldots] \]
\[ \text{term} := [\text{eqname} =] \#:\#\ldots\# \]
\[ [\text{eqname} =] \# \]

See equations() under Options below.

Menu
Statistics > Postestimation > Manage estimation results > Table of estimation results

Description

estimates table displays a table of coefficients and statistics for one or more sets of estimation results.

Options

\[ \text{stats(scalarlist)} \] specifies one or more scalar statistics to be displayed in the table. scalarlist may contain

- aic Akaike’s information criterion
- bic Schwarz’s Bayesian information criterion
- rank rank of e(V) (# of free parameters in model)

along with the names of any scalars stored in e(). The specified statistics do not have to be available for all estimation results being displayed.
For example, `stats(N ll chi2 aic)` specifies that `e(N)`, `e(ll)`, `e(chi2)`, and AIC be included. In Stata, `e(N)` records the number of observations; `e(ll)`, the log likelihood; and `e(chi2)`, the chi-squared test that all coefficients in the first equation of the model are equal to zero.

`star` and `star(#1 #2 #3)` specify that stars (asterisks) are to be used to mark significance. The second syntax specifies the significance levels for one, two, and three stars. If you specify simply `star`, that is equivalent to specifying `star(.05 .01 .001)`, which means one star (*) if $p < 0.05$, two stars (**) if $p < 0.01$, and three stars (***) if $p < 0.001$.

The `star` and `star()` options may not be combined with `se`, `t`, or `p` option.

---

**Options**

`keep(coeflist)` and `drop(coeflist)` are alternatives; they specify coefficients to be included or omitted from the table. The default is to display all coefficients.

If `keep()` is specified, it specifies not only the coefficients to be included but also the order in which they appear.

A `coeflist` is a list of coefficient names, each name of which may be simple (for example, `price`), an equation name followed by a colon (for example, `mean:`), or a full name (for example, `mean:price`). Names are separated from each other by blanks.

When full names are not specified, all coefficients that match the partial specification are included. For instance, `drop(_cons)` would omit `_cons` for all equations.

`equations(matchlist)` specifies how the equations of the models in `namelist` are to be matched. The default is to match equations by name. Matching by name usually works well when all results were fit by the same estimation command. When you are comparing results from different estimation commands, however, specifying `equations()` may be necessary.

The most common usage is `equations(1)`, which indicates that all first equations are to be matched into one equation named #1.

`matchlist` has the syntax

```
  term [, term ... ]
```

where `term` is

```
  [ eqname = ] #:#...#: (syntax 1)
  [ eqname = ] # (syntax 2)
```

In syntax 1, each # is a number or a period (.). If a number, it specifies the position of the equation in the corresponding model; `1:3:1` would indicate that equation 1 in the first model matches equation 3 in the second, which matches equation 1 in the third. A period indicates that there is no corresponding equation in the model; `1:.:1` indicates that equation 1 in the first matches equation 1 in the third.

In syntax 2, you specify just one number, say, 1 or 2, and that is shorthand for `1:1...:1` or `2:2...:2`, meaning that equation 1 matches across all models specified or that equation 2 matches across all models specified.

Now that you can specify a `term`, you can put that together into a `matchlist` by separating one term from the other by commas. In what follows, we will assume that three names were specified,

```
  . estimates table alpha beta gamma, ...
```

`equations(1)` is equivalent to `equations(1:1:1)`; we would be saying that the first equations match across the board.
equations(1:.:1) would specify that equation 1 matches in models alpha and gamma but that there is nothing corresponding in model beta.

equations(1,2) is equivalent to equations(1:1:1, 2:2:2). We would be saying that the first equations match across the board and so do the second equations.

equations(1, 2:.:2) would specify that the first equations match across the board, that the second equations match for models alpha and gamma, and that there is nothing equivalent to equation 2 in model beta.

If equations() is specified, equations not matched by position are matched by name.

**Numerical formats**

- b(\%fmt) specifies how the coefficients are to be displayed. You might specify b(\%9.2f) to make decimal points line up. There is also a b option, which specifies that coefficients are to be displayed, but that is just included for consistency with the se, t, and p options. Coefficients are always displayed.

- se, t, and p specify that standard errors, t or z statistics, and significance levels are to be displayed. The default is not to display them. se(\%fmt), t(\%fmt), and p(\%fmt) specify that each is to be displayed and specifies the display format to be used to format them.

- stfmt(\%fmt) specifies the format for displaying the scalar statistics included by the stats() option.

**General format**

- varwidth(#) specifies the number of character positions used to display the names of the variables and statistics. The default is 12.

- modelwidth(#) specifies the number of character positions used to display the names of the models. The default is 12.

- eform displays coefficients in exponentiated form. For each coefficient, exp(\( \beta \)) rather than \( \beta \) is displayed, and standard errors are transformed appropriately. Display of the intercept, if any, is suppressed.

- varlabel specifies that variable labels be displayed instead of variable names.

- newpanel specifies that the statistics be displayed in a table separated by a blank line from the table with coefficients rather than in the style of another equation in the table of coefficients.

- style(stylespec) specifies the style of the coefficient table.

  - style(oneline) specifies that a vertical line be displayed after the variables but not between the models. This is the default.

  - style(columns) specifies that vertical lines be displayed after each column.

  - style(noline) specifies that no vertical lines be displayed.

- coded specifies that a compact table be displayed. This format is especially useful for comparing variables that are included in a large collection of models.

**Reporting**

- display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels,nofvlabel, fvwrap(#), and fvwrapon(style); see [R] estimation options.

The following option is available with estimates table but is not shown in the dialog box:

title(string) specifies the title to appear above the table.
Remarks and examples

If you type `estimates table` without arguments, a table of the most recent estimation results will be shown:

```
use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
regress mpg weight displ
(output omitted)
estimates table
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>active</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>-.00656711</td>
</tr>
<tr>
<td>displacement</td>
<td>.00528078</td>
</tr>
<tr>
<td>_cons</td>
<td>40.084522</td>
</tr>
</tbody>
</table>

The real use of `estimates table`, however, is for comparing estimation results, and that requires using it after `estimates store`:

```
regress mpg weight displ
(output omitted)
estimates store base
regress mpg weight displ foreign
(output omitted)
estimates store alt
qreg mpg weight displ foreign
(output omitted)
estimates store qreg
estimates table base alt qreg, stats(r2)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>base</th>
<th>alt</th>
<th>qreg</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>-.00656711</td>
<td>-.00677449</td>
<td>-.00595056</td>
</tr>
<tr>
<td>displacement</td>
<td>.00528078</td>
<td>.00192865</td>
<td>.0018552</td>
</tr>
<tr>
<td>foreign</td>
<td>-1.6006312</td>
<td>-2.1326004</td>
<td></td>
</tr>
<tr>
<td>_cons</td>
<td>40.084522</td>
<td>41.847949</td>
<td>39.213348</td>
</tr>
<tr>
<td>r2</td>
<td>.6529307</td>
<td>.66287957</td>
<td></td>
</tr>
</tbody>
</table>

Stored results

`estimates table` stores the following in `r()`:

- **Macros**
  - `r(names)` names of results used
- **Matrices**
  - `r(coef)` matrix $M$: $n \times 2m$
    - $M[i, 2j-1] =$ $i$th parameter estimate for model $j$
    - $M[i, 2j] =$ variance of $M[i, 2j-1]$; $i=1,...,n$; $j=1,...,m$
  - `r(stats)` matrix $S$: $k \times m$ (if option `stats()` specified)
    - $S[i, j] =$ $i$th statistic for model $j$; $i=1,...,k$; $j=1,...,m$
References

estimates title — Set title for estimation results

Syntax

estimates title: [text]

estimates title

Menu

Statistics > Postestimation > Manage estimation results > Title/retitle results

Description

estimates title: (note the colon) sets or clears the title for the current estimation results. The title is used by estimates table and estimates stats (see [R] estimates table and [R] estimates stats).

estimates title without the colon displays the current title.

Remarks and examples

After setting the title, if estimates have been stored, do not forget to store them again:

. use http://www.stata-press.com/data/r13/auto
   (1978 Automobile Data)
. regress mpg gear turn
   (output omitted)
. estimates store reg

Now let’s add a title:

. estimates title: "My regression"
. estimates store reg

Description

This entry describes the options common to many estimation commands. Not all the options documented here work with all estimation commands. See the documentation for the particular estimation command; if an option is listed there, it is applicable.
Options

noconstant suppresses the constant term (intercept) in the model.

offset(varname\_o) specifies that varname\_o be included in the model with the coefficient constrained to be 1.

exposure(varname\_e) specifies a variable that reflects the amount of exposure over which the depvar events were observed for each observation; ln(varname\_e) with coefficient constrained to be 1 is entered into the log-link function.

costRAINTS(numlist | matname) specifies the linear constraints to be applied during estimation. The default is to perform unconstrained estimation. See [R] reg3 for the use of constraints in multiple-equation contexts.

costRAINTS(numlist) specifies the constraints by number after they have been defined by using the constraint command; see [R] constraint. Some commands (for example, s\_logit) allow only constraints(numlist).

costRAINTS(matname) specifies a matrix containing the constraints; see [P] makecns.

costRAINTS(clist) is used by some estimation commands, such as m\_logit, where clist has the form \#[-#] [, #[-#] ...].

collinear specifies that the estimation command not omit collinear variables. Usually, there is no reason to leave collinear variables in place, and, in fact, doing so usually causes the estimation to fail because of the matrix singularity caused by the collinearity. However, with certain models, the variables may be collinear, yet the model is fully identified because of constraints or other features of the model. In such cases, using the collinear option allows the estimation to take place, leaving the equations with collinear variables intact. This option is seldom used.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

noskip specifies that a full maximum-likelihood model with only a constant for the regression equation be fit. This model is not displayed but is used as the base model to compute a likelihood-ratio test for the model test statistic displayed in the estimation header. By default, the overall model test statistic is an asymptotically equivalent Wald test of all the parameters in the regression equation being zero (except the constant). For many models, this option can substantially increase estimation time.

costRAINTSREPORT specifies that no constraints be reported. The default is to display user-specified constraints above the coefficient table.

noomitted specifies that variables that were omitted because of collinearity not be displayed. The default is to include in the table any variables omitted because of collinearity and to label them as “(omitted)”.

vsquish specifies that the blank space separating factor-variable terms or time-series–operated variables from other variables in the model be suppressed.

noemptycells specifies that empty cells for interactions of factor variables not be displayed. The default is to include in the table interaction cells that do not occur in the estimation sample and to label them as “(empty)”.

baselevels and allbaselevels control whether the base levels of factor variables and interactions are displayed. The default is to exclude from the table all base categories.

baselevels specifies that base levels be reported for factor variables and for interactions whose bases cannot be inferred from their component factor variables.

allbaselevels specifies that all base levels of factor variables and interactions be reported.

nofvlabel displays factor-variable level values rather than attached value labels. This option overrides the fvlabel setting; see [R] set showbaselevels.

default. This option overrides the fvwrap setting; see [R] set showbaselevels.

default. This option overrides the fvwrap setting; see [R] set showbaselevels.

default. This option overrides the fvwrap setting; see [R] set showbaselevels.

Integration

intmethod(intmethod) specifies the integration method to be used for the random-effects model. It accepts one of four arguments: mvaghermite, the default for all but a crossed random-effects model, performs mean and variance adaptive Gauss–Hermite quadrature; mcaghermite performs mode and curvature adaptive Gauss–Hermite quadrature; ghermite performs nonadaptive Gauss–Hermite quadrature; and laplace, the default for crossed random-effects models, performs the Laplacian approximation.

intpoints(#) specifies the number of integration points to use for integration by quadrature. The default is intpoints(12); the maximum is intpoints(195). Increasing this value improves the accuracy but also increases computation time. Computation time is roughly proportional to its value.

The following option is not shown in the dialog box:

cfvelgend specifies that the legend of the coefficients and how to specify them in an expression be displayed rather than displaying the statistics for the coefficients.
Syntax

\texttt{exit [ , clear ]}

Description

Typing \texttt{exit} causes Stata to stop processing and return control to the operating system. If the dataset in memory has changed since the last \texttt{save} command, you must specify the \texttt{clear} option before Stata will let you exit.

\texttt{exit} may also be used for exiting do-files or programs; see \texttt{[P] exit}.

Stata for Windows users may also exit Stata by clicking on the \texttt{Close} button or by pressing \texttt{Alt+F4}.

Stata for Mac users may also exit Stata by pressing \texttt{Command+Q}.

Stata(GUI) users may also exit Stata by clicking on the \texttt{Close} button.

Option

\texttt{clear} permits you to \texttt{exit}, even if the current dataset has not been saved.

Remarks and examples

Type \texttt{exit} to leave Stata and return to the operating system. If the dataset in memory has changed since the last time it was saved, however, Stata will refuse. At that point, you can either \texttt{save} the dataset and then type \texttt{exit}, or type \texttt{exit, clear}:

\begin{verbatim}
. exit
no; data in memory would be lost
r(4);
. exit, clear
\end{verbatim}

Statistics > Exact statistics > Exact logistic regression
Description

`exlogistic` fits an exact logistic regression model of `depvar` on `indepvars`.

`exlogistic` is an alternative to `logistic`, the standard maximum-likelihood–based logistic regression estimator; see [R] logistic. `exlogistic` produces more-accurate inference in small samples because it does not depend on asymptotic results and `exlogistic` can better deal with one-way causation, such as the case where all females are observed to have a positive outcome.

`exlogistic` with the group(`varname`) option is an alternative to `clogit`, the conditional logistic regression estimator; see [R] clogit. Like clogit, `exlogistic` conditions on the number of positive outcomes within stratum.

`depvar` can be specified in two ways. It can be zero/nonzero, with zero indicating failure and nonzero representing positive outcomes (successes), or if you specify the binomial(`varname` | #) option, `depvar` may contain the number of positive outcomes within each trial.

`exlogistic` is computationally intensive. Unlike most estimators, rather than calculating coefficients for all independent variables at once, results for each independent variable are calculated separately with the other independent variables temporarily conditioned out. You can save considerable computer time by skipping the parameter calculations for variables that are not of direct interest. Specify such variables in the condvars() option rather than among the `indepvars`; see condvars() below.

Unlike Stata’s other estimation commands, you may not use `test`, `lincom`, or other postestimation commands after `exlogistic`. Given the method used to calculate estimates, hypothesis tests must be performed during estimation by using `exlogistic`’s terms() option; see terms() below.

Options

- **condvars(varlist)** specifies variables whose parameter estimates are not of interest to you. You can save substantial computer time and memory moving such variables from `indepvars` to condvars(). Understand that you will get the same results for `x1` and `x3` whether you type

  . exlogistic y x1 x2 x3 x4

  or

  . exlogistic y x1 x3, condvars(x2 x4)

- **group(varname)** specifies the variable defining the strata, if any. A constant term is assumed for each stratum identified in `varname`, and the sufficient statistics for `indepvars` are conditioned on the observed number of successes within each group. This makes the model estimated equivalent to that estimated by clogit, Stata’s conditional logistic regression command (see [R] clogit). `group()` may not be specified with noconstant or estconstant.

- **binomial(varname | #)** indicates that the data are in binomial form and `depvar` contains the number of successes. `varname` contains the number of trials for each observation. If all observations have the same number of trials, you can instead specify the number as an integer. The number of trials must be a positive integer at least as great as the number of successes. If binomial() is not specified, the data are assumed to be Bernoulli, meaning that `depvar` equaling zero or nonzero records one failure or success.

- **estconstant** estimates the constant term. By default, the models are assumed to have an intercept (constant), but the value of the intercept is not calculated. That is, the conditional distribution of
the sufficient statistics for the `indepvars` is computed given the number of successes in `depvar`, thus conditioning out the constant term of the model. Use `estconstant` if you want the estimate of the intercept reported. `estconstant` may not be specified with `group()`.

noconstant; see [R] estimation options. noconstant may not be specified with `group()`.

__Terms__

`terms(termname = variable ... variable [ , termname = variable ... variable ... ] )` defines additional terms of the model on which you want `exlogistic` to perform joint-significance hypothesis tests. By default, `exlogistic` reports tests individually on each variable in `indepvars`. For instance, if variables `x1` and `x3` are in `indepvars`, and you want to jointly test their significance, specify `terms(t1=x1 x3)`. To also test the joint significance of `x2` and `x4`, specify `terms(t1=x1 x3, t2=x2 x4)`. Each variable can be assigned to only one term.

Joint tests are computed only for the conditional scores tests and the conditional probabilities tests. See the `test()` option below.

__Options__

`memory(# [ b | k | m | g ] )` sets a limit on the amount of memory `exlogistic` can use when computing the conditional distribution of the parameter sufficient statistics. The default is `memory(10m)`, where `m` stands for megabyte, or 1,048,576 bytes. The following are also available: `b` stands for byte; `k` stands for kilobyte, which is equal to 1,024 bytes; and `g` stands for gigabyte, which is equal to 1,024 megabytes. The minimum setting allowed is `1m` and the maximum is `2048m` or `2g`, but do not attempt to use more memory than is available on your computer. Also see the first technical note under example 4 on counting the conditional distribution.

`saving(filename [, replace])` saves the joint conditional distribution to `filename`. This distribution is conditioned on those variables specified in `condvars()`. Use `replace` to replace an existing file with `filename`. A Stata data file is created containing all the feasible values of the parameter sufficient statistics. The variable names are the same as those in `indepvars`, in addition to a variable named `_f_` containing the feasible value frequencies (sometimes referred to as the condition numbers).

__Reporting__

`level(# )`; see [R] estimation options. The `level(#)` option will not work on replay because confidence intervals are based on estimator-specific enumerations. To change the confidence level, you must refit the model.

`coef` reports the estimated coefficients rather than odds ratios (exponentiated coefficients). `coef` may be specified when the model is fit or upon replay. `coef` affects only how results are displayed and not how they are estimated.

`test(sufficient | score | probability)` reports the significance level of the observed sufficient statistics, the conditional scores tests, or the conditional probabilities tests, respectively. The default is `test(sufficient)`. If `terms()` is included in the specification, the conditional scores test and the conditional probabilities test are applied to each term providing conditional inference for several parameters simultaneously. All the statistics are computed at estimation time regardless of which is specified. Each statistic may thus also be displayed postestimation without having to refit the model; see [R] exlogistic postestimation.

`mue(varlist)` specifies that median unbiased estimates (MUEs) be reported for the variables in `varlist`. By default, the conditional maximum likelihood estimates (CMLEs) are reported, except for those parameters for which the CMLEs are infinite. Specify `mue(_all)` if you want MUEs for all the `indepvars`.

midp instructs exlogistic to use the mid-p-value rule when computing the MUEs, significance levels, and confidence intervals. This adjustment is for the discreteness of the distribution and halves the value of the discrete probability of the observed statistic before adding it to the p-value. The mid-p-value rule cannot be applied to MUEs whose corresponding parameter CMLE is infinite.

nolog prevents the display of the enumeration log. By default, the enumeration log is displayed, showing the progress of computing the conditional distribution of the sufficient statistics.

Remarks and examples

Exact logistic regression is the estimation of the logistic model parameters by using the conditional distribution of the parameter sufficient statistics. The estimates are referred to as the conditional maximum likelihood estimates (CMLEs). This technique was first introduced by Cox and Snell (1989) as an alternative to using maximum likelihood estimation, which can perform poorly for small sample sizes. For stratified data, exact logistic regression is a small-sample alternative to conditional logistic regression. See [R] logit, [R] logistic, and [R] clogit to obtain maximum likelihood estimates (MLEs) for the logistic model and the conditional logistic model. For a comprehensive overview of exact logistic regression, see Mehta and Patel (1995).

Let $Y_i$ denote a Bernoulli random variable where we observe the outcome $Y_i = y_i$, $i = 1, \ldots, n$. Associated with each independent observation is a $1 \times p$ vector of covariates, $x_i$. We will denote $\pi_i = \Pr(Y_i | x_i)$ and let the logit function model the relationship between $Y_i$ and $x_i$,

$$\log \left( \frac{\pi_i}{1 - \pi_i} \right) = \theta + x_i \beta$$

where the constant term $\theta$ and the $1 \times p$ vector of regression parameters $\beta$ are unknown. The probability of observing $Y_i = y_i$, $i = 1, \ldots, n$, is

$$\Pr(Y = y) = \prod_{i=1}^{n} \pi_i^{y_i} (1 - \pi_i)^{1-y_i}$$

where $Y = (Y_1, \ldots, Y_n)$ and $y = (y_1, \ldots, y_n)$. The MLEs for $\theta$ and $\beta$ maximize the log of this function.

The sufficient statistics for $\theta$ and $\beta_j$, $j = 1, \ldots, p$, are $M = \sum_{i=1}^{n} Y_i$ and $T_j = \sum_{i=1}^{n} Y_i x_{ij}$, respectively, and we observe $M = m$ and $T_j = t_j$. By default, exlogistic tallies the conditional distribution of $T = (T_1, \ldots, T_p)$ given $M = m$. This distribution will have a size of $\binom{n}{m}$. (It would have a size of $2^n$ without conditioning on $M = m$.) Denote one of these vectors $T^{(k)} = (t_1^{(k)}, \ldots, t_p^{(k)})$, $k = 1, \ldots, N$, with combinatorial coefficient (frequency) $c_k$, $\sum_{k=1}^{N} c_k = \binom{n}{m}$. For each independent variable $x_j$, $j = 1, \ldots, p$, we reduce the conditional distribution further by conditioning on all other observed sufficient statistics $T_l = t_l$, $l \neq j$. The conditional probability of observing $T_j = t_j$ has the form

$$\Pr(T_j = t_j \mid T_l = t_l, l \neq j, M = m) = \frac{c_j e^{t_j \beta_j}}{\sum_k c_k e^{t_j^{(k)} \beta_j}}$$
where the sum is over the subset of $T$ vectors such that $(T_1^{(k)} = t_1, \ldots, T_j^{(k)} = t_j, \ldots, T_p^{(k)} = t_p)$ and $c$ is the combinatorial coefficient associated with the observed $t$. The CMLE for $\beta_j$ maximizes the log of this function.

Specifying nuisance variables in `condvars()` will reduce the size of the conditional distribution by conditioning on their observed sufficient statistics as well as conditioning on $M = m$. This reduces the amount of memory consumed at the cost of not obtaining regression estimates for those variables specified in `condvars()`.

Inferences from MLEs rely on asymptotics, and if your sample size is small, these inferences may not be valid. On the other hand, inferences from the CMLEs are exact in the sense that they use the conditional distribution of the sufficient statistics outlined above.

For small datasets, it is common for the dependent variable to be completely determined by the data. Here the MLEs and the CMLEs are unbounded. `exlogistic` will instead compute the MUE, the regression estimate that places the observed sufficient statistic at the median of the conditional distribution.

### Example 1

One example presented by Mehta and Patel (1995) is data from a prospective study of perinatal infection and human immunodeficiency virus type 1 (HIV-1). We use a variation of this dataset. There was an investigation Hutto et al. (1991) into whether the blood serum levels of glycoproteins CD4 and CD8 measured in infants at 6 months of age might predict their development of HIV infection. The blood serum levels are coded as ordinal values 0, 1, and 2.

```

We first obtain the MLEs from `logistic` so that we can compare the estimates and associated statistics with the CMLEs from `exlogistic`.

exlogistic produced a log showing how many records are generated as it processes each observation. The primary purpose of the log is to provide feedback because generating the distribution can be time consuming, but we also see from the last entry that the joint distribution for the sufficient statistics for cd4 and cd8 conditioned on the total number of successes has 326 unique values (but a size of $\binom{47}{14} = 341,643,774,795$).

The statistics for logistic are based on asymptotics: for a large sample size, each $Z$ statistic will be approximately normally distributed (with a mean of zero and a standard deviation of one) if the associated regression parameter is zero. The question is whether a sample size of 47 is large enough.

On the other hand, the $p$-values computed by exlogistic are from the conditional distributions of the sufficient statistics for each parameter given the sufficient statistics for all other parameters. In this sense, these $p$-values are exact. By default, exlogistic reports the sufficient statistics for the regression parameters and the probability of observing a more extreme value. These are single-parameter tests for $H_0: \beta_{cd4} = 0$ and $H_0: \beta_{cd8} = 0$ versus the two-sided alternatives. The conditional scores test, located in the coefficient table header, is testing that both $H_0: \beta_{cd4} = 0$ and $H_0: \beta_{cd8} = 0$. We find these $p$-values to be in fair agreement with the Wald and likelihood-ratio tests from logistic.

The confidence intervals for exlogistic are computed from the exact conditional distributions. The exact confidence intervals are asymmetrical about the estimate and are wider than the normal-based confidence intervals from logistic.

Both estimation techniques indicate that the incidence of HIV infection decreases with increasing CD4 blood serum levels and increases with increasing CD8 blood serum levels. The constant term is missing from the exact logistic coefficient table because we conditioned out its observed sufficient statistic when tallying the joint distribution of the sufficient statistics for the cd4 and cd8 parameters.

The test() option provides two other test statistics used in exact logistic: the conditional scores test, test(score), and the conditional probabilities test, test(probability). For comparison, we display the individual parameter conditional scores tests.

For the probabilities test, the probability statistic is computed from (1) in *Methods and formulas* with $\beta = 0$. For this example, the significance of the probabilities tests matches the scores tests so they are not displayed here.

### Technical note

Typically, the value of $\theta$, the constant term, is of little interest, as well as perhaps some of the parameters in $\beta$, but we need to include all parameters in the model to correctly specify it. By conditioning out the nuisance parameters, we can reduce the size of the joint conditional distribution that is used to estimate the regression parameters of interest. The `condvars()` option allows you to specify a `varlist` of nuisance variables. By default, `exlogistic` conditions on the sufficient statistic of $\theta$, which is the number of successes. You can save computation time and computer memory by using the `condvars()` option because infeasible values of the sufficient statistics associated with the variables in `condvars()` can be dropped from consideration before all $n$ observations are processed.

Specifying some of your independent variables in `condvars()` will not change the estimated regression coefficients of the remaining independent variables. For instance, in example 1, if we instead type

```
. exlogistic hiv cd4, condvars(cd8) coef
```

the regression coefficient for `cd4` (as well as all associated inference) will be identical.

One reason to have multiple variables in `indepvars` is to make conditional inference of several parameters simultaneously by using the `terms()` option. If you do not wish to test several parameters simultaneously, it may be more efficient to obtain estimates for individual variables by calling `exlogistic` multiple times with one variable in `indepvars` and all other variables listed in `condvars()`. The estimates will be the same as those with all variables in `indepvars`.

### Technical note

If you fit a `clogit` (see [R] `clogit`) model to the HIV data from example 1, you will find that the estimates differ from those with `exlogistic`. (To fit the `clogit` model, you will have to create a group variable that includes all observations.) The regression estimates will be different because `clogit` conditions on the constant term only, whereas the estimates from `exlogistic` condition on the sufficient statistic of the other regression parameter as well as the constant term.

### Example 2

The HIV data presented in table IV of *Mehta and Patel (1995)* are in a binomial form, where the variable `hiv` contains the HIV cases that tested positive and the variable `n` contains the number of individuals with the same CD4 and CD8 levels, the binomial number-of-trials parameter. Here `depvar` is `hiv`, and we use the `binomial(n)` option to identify the number-of-trials variable.
Further, the `cd4` and `cd8` variables of the `hiv` dataset are actually factor variables, where each has the ordered levels of (0, 1, 2). Another approach to the analysis is to use indicator variables, and following Mehta and Patel (1995), we used a 0–1 coding scheme that will give us the odds ratio of level 0 versus 2 and level 1 versus 2.

```
. generate byte cd4_0 = (cd4==0)
. generate byte cd4_1 = (cd4==1)
. generate byte cd8_0 = (cd8==0)
. generate byte cd8_1 = (cd8==1)
```

Here we used `terms()` to specify two terms in the model, `cd4` and `cd8`, that make up the `cd4` and `cd8` indicator variables. By doing so, we obtained a conditional probabilities test for `cd4`, simultaneously testing both `cd4_0` and `cd4_1`, and for `cd8`, simultaneously testing both `cd8_0` and `cd8_1`. The significance levels for the two terms are 0.0055 and 0.0323, respectively.
This example also illustrates instances where the dependent variable is completely determined by the independent variables and CMLEs are infinite. If we try to obtain MLEs, `logistic` will drop each variable and then terminate with a no-data error, error number 2000.

```

        cd8_0 dropped and 2 obs not used
    outcome = cd8_1 <= 0 predicts data perfectly
    r(2000);
```

In example 2, `exlogistic` generated the joint conditional distribution of $T_{cd4_0}$, $T_{cd4_1}$, $T_{cd8_0}$, and $T_{cd8_1}$ given $M = 14$ (the number of individuals that tested positive), and for reference, we listed the observed sufficient statistics that are stored in the matrix `e(sufficient)`. Below we take that distribution and further condition on $T_{cd4_1} = 8$, $T_{cd8_0} = 6$, and $T_{cd8_1} = 4$, giving the conditional distribution of $T_{cd4_0}$. Here we see that the observed sufficient statistic $T_{cd4_0} = 5$ is last in the sorted listing or, equivalently, $T_{cd4_0}$ is at the domain boundary of the conditional probability distribution. When this occurs, the conditional probability distribution is monotonically increasing in $\beta_{cd4_0}$ and a maximum does not exist.

```

</tbody>
</table>

When the CMLEs are infinite, the MUEs are computed (Hirji, Tsiatis, and Mehta 1989). For the $cd4_0$ estimate, we compute the value $\bar{\beta}_{cd4_0}$ such that

$$\Pr(T_{cd4_0} \geq 5 | \beta_{cd4_0} = \bar{\beta}_{cd4_0}, T_{cd4_1} = 8, T_{cd8_0} = 6, T_{cd8_1} = 4, M = 14) = 1/2$$

using (1) in Methods and formulas.
The output is in agreement with example 1: there is an increase in risk of HIV infection for a CD4 blood serum level of 0 relative to a level of 2 and for a level of 1 relative to a level of 2; there is a decrease in risk of HIV infection for a CD8 blood serum level of 0 relative to a level of 2 and for a level of 1 relative to a level of 2.

We also displayed $e(n_{\text{possible}})$. This is the combinatorial coefficient associated with the observed sufficient statistics. The same value is found in the $f$ variable of the conditional distribution dataset listed above. The size of the distribution is $\binom{47}{14} = 341,643,774,795$. This can be verified by summing the $f$ variable of the generated conditional distribution dataset.

```stata
. use dist, clear
. summarize _f_, meanonly
. di %15.1f r(sum)
341643774795.0
```

Example 3

One can think of exact logistic regression as a covariate-adjusted exact binomial. To demonstrate this point, we will use `exlogistic` to compute a binomial confidence interval for $m$ successes of $n$ trials, by fitting the constant-only model, and we will compare it with the confidence interval computed by `ci` (see [R] `ci`). We will use the `saving()` option to retain the dataset containing the feasible values for the constant term sufficient statistic, namely, the number of successes, $m$, given $n$ trials and their associated combinatorial coefficients $\binom{n}{m}$, $m = 0, 1, \ldots, n$.

```stata
. input y
  1. 1
  2. 0
  3. 1
  4. 0
  5. 1
  6. 1
  7. end
. ci y, binomial
```

```stata
Variable |       Obs  Mean  Std. Err. [95% Conf. Interval]
---------|-----------|---------|---------------------|---------------------|
y | 6  | .6666667  | .1924501  | .2227781 .9567281 |
```

```stata
. exlogistic y, estconstant nolog coef saving(binom)
```

```stata
note: saving distribution to file binom.dta
Exact logistic regression
Number of obs = 6

   | Coef.  Suff.  2*Pr(Suff.)  [95% Conf. Interval]
-------------|---------------------|---------------------|
_y_cons | .6931472   | 4       | 0.6875  | -1.24955 3.096017 |
```

We use the postestimation program `estat predict` to transform the estimated constant term and its confidence bounds by using the inverse logit function, `invlogit()` (see [D] `functions`). The standard error for the estimated probability is computed using the delta method.
```
. estat predict

<table>

Examining the listing of the generated data, the values contained in the variable _cons_ are the feasible values of \( M \), and the values contained in the variable _f_ are the binomial coefficients \( \binom{6}{m} \) with total \( \sum_{m=0}^{6} \binom{6}{m} = 2^6 = 64 \). In the coefficient table, the sufficient statistic for the constant term, labeled **Suff.**, is \( m = 4 \). This value is located at record 5 of the dataset. Therefore, the two-tailed probability of the sufficient statistic is computed as \( 0.6875 = \frac{2(15 + 6 + 1)}{64} \).

The constant term is the value of \( \theta \) that maximizes the probability of observing \( M = 4 \); see (1) of **Methods and formulas**:

\[
\Pr(M = 4|\theta) = \frac{15e^{4\alpha}}{1 + 6e^{\alpha} + 15e^{2\alpha} + 20e^{3\alpha} + 15e^{4\alpha} + 6e^{5\alpha} + e^{6\alpha}}
\]

The maximum is at the value \( \theta = \log 2 \), which is demonstrated in the figure below.

![Graph showing the maximum at \( \theta = \log 2 \)](image-url)
The lower and upper confidence bounds are the values of $\theta$ such that $\Pr(M \geq 4|\theta) = 0.025$ and $\Pr(M \leq 4|\theta) = 0.025$, respectively. These probabilities are plotted in the figure below for $\theta \in [-2, 4]$.

![Cumulative probability and confidence bounds](image)

**Example 4**

This example demonstrates the `group()` option, which allows the analysis of stratified data. Here the logistic model is

$$
\log \left( \frac{\pi_{ik}}{1 - \pi_{ik}} \right) = \theta_k + x_{ki}\beta
$$

where $k$ indexes the $s$ strata, $k = 1, \ldots, s$, and $\theta_k$ is the strata-specific constant term whose sufficient statistic is $M_k = \sum_{i=1}^{n_k} Y_{ki}$.

Mehta and Patel (1995) use a case–control study to demonstrate this model, which is useful in comparing the estimates from `exlogistic` and `clogit`. This study was intended to determine the role of birth complications in people with schizophrenia (Garsd 1988). Siblings from seven families took part in the study, and each individual was classified as normal or schizophrenic. A birth complication index is recorded for each individual that ranges from 0, an uncomplicated birth, to 15, a very complicated birth. Some of the frequencies contained in variable `f` are greater than 1, and these count different births at different times where the individual has the same birth complications index, found in variable `BCindex`.

         | Coef.  Std. Err.      z    P>|z|     [95% Conf. Interval]
---------|-----------------------------------------------------------
    schizo |  .3251   .1680     1.94  0.053    -.0039565   .654192
   BCindex |        .1679     1.94  0.053    -.0039565   .654192
---------|-----------------------------------------------------------
```

Both techniques compute the same regression estimate for the BCindex, which might not be too surprising because both estimation techniques condition on the total number of successes in each group. The difference lies in the \( p \)-values and confidence intervals. The \( p \)-value testing \( H_0: \beta_{BCindex} = 0 \) is approximately 0.0167 for the exact conditional scores test and 0.053 for the asymptotic Wald test. Moreover, the exact confidence interval is asymmetric about the estimate and does not contain zero.

### Technical note

The `memory(#)` option limits the amount of memory that `exlogistic` will consume when computing the conditional distribution of the parameter sufficient statistics. `memory()` is independent of the data maximum memory setting (see `set max_memory` in [D] memory), and it is possible for `exlogistic` to exceed the memory limit specified in `set max_memory` without terminating. By default, a log is provided that displays the number of enumerations (the size of the conditional distribution) after processing each observation. Typically, you will see the number of enumerations increase, and then at some point they will decrease as the multivariate shift algorithm (Hirji, Mehta, and Patel 1987) determines that some of the enumerations cannot achieve the observed sufficient statistics of the conditioning variables. When the algorithm is complete, however, it is necessary to store the conditional distribution of the parameter sufficient statistics as a dataset. It is possible, therefore, to get a memory error when the algorithm has completed if there is not enough memory to store the conditional distribution.

### Technical note

Computing the conditional distributions and reported statistics requires data sorting and numerical comparisons. If there is at least one single-precision variable specified in the model, `exlogistic` will make comparisons with a relative precision of \( 2^{-5} \). Otherwise, a relative precision of \( 2^{-11} \) is used. Be careful if you use `recast` to promote a single-precision variable to double precision (see [D] recast). You might try listing the data in full precision (maybe %20.15g; see [D] format) to make sure that this is really what you want. See [D] data types for information on precision of numeric storage types.
exlogistic stores the following in e():

Scalars
- \( e(N) \): number of observations
- \( e(k_{groups}) \): number of groups
- \( e(n_{possible}) \): number of distinct possible outcomes where \( \text{sum(sufficient)} \) equals observed
- \( e(n_{trials}) \): binomial number-of-trials parameter

Methods and formulas

Methods and formulas are presented under the following headings:

Sufficient statistics
Conditional distribution and CMLE
Median unbiased estimates and exact CI
Conditional hypothesis tests
Sufficient-statistic p-value

Sufficient statistics

Let \{Y_1, Y_2, \ldots, Y_n\} be a set of \(n\) independent Bernoulli random variables, each of which can realize two outcomes, \{0, 1\}. For each \(i = 1, \ldots, n\), we observe \(Y_i = y_i\), and associated with each observation is the covariate row vector of length \(p\), \(x_i = (x_{i1}, \ldots, x_{ip})\). Denote \(\beta = (\beta_1, \ldots, \beta_p)^T\) to be the column vector of regression parameters and \(\theta\) to be the constant. The sufficient statistic for \(\beta_j\) is \(T_j = \sum_{i=1}^n Y_i x_{ij}, j = 1, \ldots, p\), and for \(\theta\) is \(M = \sum_{i=1}^n Y_i\). We observe \(T_j = t_j, t_j = \sum_{i=1}^n y_i x_{ij}\), and \(M = m, m = \sum_{i=1}^n y_i\). The probability of observing \((Y_1 = y_1, Y_2 = y_2, \ldots, Y_n = y_n)\) is

\[
\Pr(Y_1 = y_1, \ldots, Y_n = y_n | \beta, X) = \frac{\exp(m\theta + t\beta)}{\prod_{i=1}^n (1 + \exp(\theta + x_i\beta))}
\]

where \(t = (t_1, \ldots, t_p)\) and \(X = (x_1^T, \ldots, x_n^T)^T\).

The joint distribution of the sufficient statistics \(T\) is obtained by summing over all possible binary sequences \(Y_1, \ldots, Y_n\) such that \(T = t\) and \(M = m\). This probability function is

\[
\Pr(T_1 = t_1, \ldots, T_p = t_p, M = m | \beta, X) = \frac{c(t, m) \exp(m\theta + t\beta)}{\prod_{i=1}^n (1 + \exp(\theta + x_i\beta))}
\]

where \(c(t, m)\) is the combinatorial coefficient of \((t, m)\) or the number of distinct binary sequences \(Y_1, \ldots, Y_n\) such that \(T = t\) and \(M = m\) (Cox and Snell 1989).

Conditional distribution and CMLE

Without loss of generality, we will restrict our discussion to computing the CMLE of \(\beta_1\). If we condition on observing \(M = m\) and \(T_2 = t_2, \ldots, T_p = t_p\), the probability function of \((T_1 | \beta_1, T_2 = t_2, \ldots, T_p = t_p, M = m)\) is

\[
\Pr(T_1 = t_1 | \beta_1, T_2 = t_2, \ldots, T_p = t_p, M = m) = \frac{c(t, m)e^{t_1\beta_1}}{\sum_u c(u, t_2, \ldots, t_p, m)e^{u\beta_1}} \tag{1}
\]

where the sum in the denominator is over all possible values of \(T_1\) such that \(M = m\) and \(T_2 = t_2, \ldots, T_p = t_p\) and \(c(u, t_2, \ldots, t_p, m)\) is the combinatorial coefficient of \((u, t_2, \ldots, t_p, m)\) (Cox and Snell 1989). The CMLE for \(\beta_1\) is the value \(\hat{\beta}_1\) that maximizes the log of (1). This optimization task is carried out by \(\texttt{MLE}\), using the conditional frequency distribution of \((T_1 | T_2 = t_2, \ldots, T_p = t_p, M = m)\) as a dataset. Generating the joint conditional distribution is efficiently computed using the multivariate shift algorithm described by Hirji, Mehta, and Patel (1987).

Difficulties in computing \(\hat{\beta}_1\) arise if the observed \((T_1 = t_1, \ldots, T_p = t_p, M = m)\) lies on the boundaries of the distribution of \((T_1 | T_2 = t_2, \ldots, T_p = t_p, M = m)\), where the conditional probability function is monotonically increasing (or decreasing) in \(\beta_1\). Here the CMLE is plus infinity if it is on the upper boundary, \(\Pr(T_1 \leq t_1 | T_2 = t_2, \ldots, T_p = t_p, M = m) = 1\), and is minus infinity if it is on the lower boundary of the distribution, \(\Pr(T_1 \geq t_1 | T_2 = t_2, \ldots, T_p = t_p, M = m) = 1\). This concept is demonstrated in example 2. When infinite CMLEs occur, the MUE is computed.
Median unbiased estimates and exact CI

The MUE is computed using the technique outlined by Hirji, Tsiatis, and Mehta (1989). First, we find the values of $\beta_1^{(u)}$ and $\beta_1^{(l)}$ such that

$$\Pr(T_1 \leq t_1 \mid \beta_1 = \beta_1^{(u)}, T_2 = t_2, \ldots, T_p = t_p, M = m) =$$

$$\Pr(T_1 \geq t_1 \mid \beta_1 = \beta_1^{(l)}, T_2 = t_2, \ldots, T_p = t_p, M = m) = 1/2$$

(2)

The MUE is then $\bar{\beta}_1 = \left(\beta_1^{(l)} + \beta_1^{(u)}\right)/2$. However, if $T_1$ is equal to the minimum of the domain of the conditional distribution, $\beta_1^{(l)}$ does not exist and $\bar{\beta}_1 = \beta_1^{(u)}$. If $T_1$ is equal to the maximum of the domain of the conditional distribution, $\beta_1^{(u)}$ does not exist and $\bar{\beta}_1 = \beta_1^{(l)}$.

Confidence bounds for $\beta$ are computed similarly, except that we substitute $\alpha/2$ for $1/2$ in (2), where $1 - \alpha$ is the confidence level. Here $\beta_1^{(l)}$ would then be the lower confidence bound and $\beta_1^{(u)}$ would be the upper confidence bound (see example 3).

Conditional hypothesis tests

To test $H_0$: $\beta_1 = 0$ versus $H_1$: $\beta_1 \neq 0$, we obtain the exact $p$-value from $\sum_{u \in E} f_1(u) - f_1(t_1)/2$ if the mid-$p$-value rule is used and $\sum_{u \in E} f_1(u)$ otherwise. Here $E$ is a critical region, and we define $f_1(u) = \Pr(T_1 = u \mid \beta_1 = 0, T_2 = t_2, \ldots, T_p = t_p, M = m)$ for ease of notation. There are two popular ways to define the critical region: the conditional probabilities test and the conditional scores test (Mehta and Patel 1995). The critical region when using the conditional probabilities test is all values of the sufficient statistic for $\beta_1$ that have a probability less than or equal to that of the observed $t_1$, $E_p = \{u: f_1(u) \leq f_1(t_1)\}$. The critical region of the conditional scores test is defined as all values of the sufficient statistic for $\beta_1$ such that its score is greater than or equal to that of $t_1$,

$$E_s = \{u: (u - \mu_1)^2/\sigma_1^2 \geq (t_1 - \mu_1)^2/\sigma_1^2\}$$

Here $\mu_1$ and $\sigma_1^2$ are the mean and variance of $(T_1 \mid \beta_1 = 0, T_2 = t_2, \ldots, T_p = t_p, M = m)$.

The score statistic is defined as

$$\left\{\frac{\partial \ell(\beta)}{\partial \beta}\right\}^2 \left[-E \left\{\frac{\partial^2 \ell(\beta)}{\partial \beta^2}\right\}\right]^{-1}$$

evaluated at $H_0$: $\beta = 0$, where $\ell$ is the log of (1). The score test simplifies to $(t - E[T \mid \beta])^2/\text{var}(T \mid \beta)$ (Hirji 2006), where the mean and variance are computed from the conditional distribution of the sufficient statistic with $\beta = 0$ and $t$ is the observed sufficient statistic.

Sufficient-statistic p-value

The $p$-value for testing $H_0$: $\beta_1 = 0$ versus the two-sided alternative when $(T_1 = t_1 | T_2 = t_2, \ldots, T_p = t_p)$ is computed as $2 \times \min(p_l, p_u)$, where

$$p_l = \frac{\sum_{u \leq t_1} c(u, t_2, \ldots, t_p, m)}{\sum_{u} c(u, t_2, \ldots, t_p, m)}$$

$$p_u = \frac{\sum_{u \geq t_1} c(u, t_2, \ldots, t_p, m)}{\sum_{u} c(u, t_2, \ldots, t_p, m)}$$

It is the probability of observing a more extreme $T_1$.

[U] 20 Estimation and postestimation commands
The following postestimation commands are of special interest after `exlogistic`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat predict</code></td>
<td>single-observation prediction</td>
</tr>
<tr>
<td><code>estat se</code></td>
<td>report ORs or coefficients and their asymptotic standard errors</td>
</tr>
</tbody>
</table>

The following standard postestimation command is also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat summarize</code></td>
<td>summary statistics for the estimation sample</td>
</tr>
</tbody>
</table>

`estat summarize` is not allowed if the `binomial()` option was specified in `exlogistic`.

See [R] `estat summarize` for details.

**Special-interest postestimation commands**

`estat predict` computes a predicted probability (or linear predictor), its asymptotic standard error, and its exact confidence interval for 1 observation. Predictions are carried out by estimating the constant coefficient after shifting the independent variables and conditioned variables by the values specified in the `at()` option or by their medians. Therefore, predictions must be done with the estimation sample in memory. If a different dataset is used or if the dataset is modified, then an error will result.

`estat se` reports odds ratio or coefficients and their asymptotic standard errors. The estimates are stored in the matrix `r(estimates)`. 
Syntax for estat

Single-observation prediction

estat predict [, options]

Report ORs or coefficients and their asymptotic standard errors

estat se [, coef]

options Description

pr probability; the default
xb linear effect
at(atspec) use the specified values for the indepvars and condvars()
level(#) set confidence level for the predicted value; default is level(95)
memory(# b|k|m|g) set limit on memory usage; default is memory(10m)
nolog do not display the enumeration log

These statistics are available only for the estimation sample.

Menu for estat

Statistics > Postestimation > Reports and statistics

Options for estat predict

pr, the default, calculates the probability.

xb calculates the linear effect.

at(varname = # [, varname = #] ...) specifies values to use in computing the predicted value. Here varname is one of the independent variables, indepvars, or the conditioned variables, condvars(). The default is to use the median of each independent and conditioned variable.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.7 Specifying the width of confidence intervals.

memory(# b|k|m|g) sets a limit on the amount of memory estat predict can use when generating the conditional distribution of the constant parameter sufficient statistic. The default is memory(10m), where m stands for megabyte, or 1,048,576 bytes. The following are also available: b stands for byte; k stands for kilobyte, which is equal to 1,024 bytes; and g stands for gigabyte, which is equal to 1,024 megabytes. The minimum setting allowed is 1m and the maximum is 512m or 0.5g, but do not attempt to use more memory than is available on your computer. Also see Remarks and examples in [R] exlogistic for details on enumerating the conditional distribution.

nolog prevents the display of the enumeration log. By default, the enumeration log is displayed showing the progress of enumerating the distribution of the observed successes conditioned on the independent variables shifted by the values specified in at() (or by their medians). See Methods and formulas in [R] exlogistic for details of the computations.
**Option for estat se**

c`oef` requests that the estimated coefficients and their asymptotic standard errors be reported. The default is to report the odds ratios and their asymptotic standard errors.

**Remarks and examples**

Predictions must be done using the estimation sample. This is because the prediction is really an estimated constant coefficient (the intercept) after shifting the independent variables and conditioned variables by the values specified in `at()` or by their medians. The justification for this approach can be seen by rewriting the model as

\[
\log \left( \frac{\pi_i}{1 - \pi_i} \right) = (\alpha + x_0\beta) + (x_i - x_0)\beta
\]

where \(x_0\) are the specified values for the `indepvars` (Mehta and Patel 1995). Because the estimation of the constant term is required, this technique is not appropriate for stratified models that used the `group()` option.

**Example 1**

To demonstrate, we return to the example 2 in [R] `exlogistic` using data from a prospective study of perinatal infection and HIV-1. Here there was an investigation into whether the blood serum levels of CD4 and CD8 measured in infants at 6 months of age might predict their development of HIV infection. The blood serum levels are coded as ordinal values 0, 1, and 2. These data are used by Mehta and Patel (1995) as an exposition of exact logistic.

```
use http://www.stata-press.com/data/r13/hiv_n
(propective study of perinatal infection of HIV-1; binomial form)
generate byte cd4_0 = (cd4==0)
generate byte cd4_1 = (cd4==1)
generate byte cd8_0 = (cd8==0)
generate byte cd8_1 = (cd8==1)
exlogistic hiv cd4_0 cd4_1 cd8_0 cd8_1, terms(cd4=cd4_0 cd4_1, cd8=cd8_0 cd8_1) binomial(n) test(probability) saving(dist) (output omitted)
```
. estat predict

(*) identifies median unbiased estimates (MUE); because an MUE is computed, there is no SE estimate

Because we did not specify values by using the at() option, the median values of the indepvars are used for the prediction. By default, medians are used instead of means because we want to use values that are observed in the dataset. If the means of the binary variables cd4_0–cd8_1 were used, we would have created floating point variables in (0, 1) that not only do not properly represent the indicator variables but also would be a source of computational inefficiency in generating the conditional distribution. Because the MUE is computed for the predicted value, there is no standard-error estimate.

From the example discussions in [R] exlogistic, the infants at highest risk are those with a CD4 level of 0 and a CD8 level of 2. Below we use the at() option to make a prediction at these blood serum levels.

. estat predict, at(cd4_0=1 cd4_1=0 cd8_0=0 cd8_1=0) nolog
note: CMLE estimate for _cons is +inf; computing MUE

Description

expoisson fits an exact Poisson regression model of `depvar` on `indepvars`. Exact Poisson regression is an alternative to standard maximum-likelihood–based Poisson regression (see [R] poisson) that offers more accurate inference in small samples because it does not depend on asymptotic results. For stratified data, expoisson is an alternative to fixed-effects Poisson regression (see xtpoisson, fe in [XT] xtpoisson); like fixed-effects Poisson regression, exact Poisson regression conditions on the number of events in each stratum.
Exact Poisson regression is computationally intensive, so if you have regressors whose parameter estimates are not of interest (that is, nuisance parameters), you should specify those variables in the `condvars()` option instead of in `indepvars`.

**Options**

- `condvars(varlist)` specifies variables whose parameter estimates are not of interest to you. You can save substantial computer time and memory by moving such variables from `indepvars` to `condvars()`. Understand that you will get the same results for x1 and x3 whether you type
  
  . expoisson y x1 x2 x3 x4

  or

  . expoisson y x1 x3, condvars(x2 x4)

- `group(varname)` specifies the variable defining the strata, if any. A constant term is assumed for each stratum identified in `varname`, and the sufficient statistics for `indepvars` are conditioned on the observed number of successes within each group (as well as other variables in the model). The group variable must be integer valued.

- `exposure(varname)`, `offset(varname)`, see [R] estimation options.

- `memory(# | b | k | m | g)` sets a limit on the amount of memory expoisson can use when computing the conditional distribution of the parameter sufficient statistics. The default is `memory(25m)`, where `m` stands for megabyte, or 1,048,576 bytes. The following are also available: `b` stands for byte; `k` stands for kilobyte, which is equal to 1,024 bytes; and `g` stands for gigabyte, which is equal to 1,024 megabytes. The minimum setting allowed is `1m` and the maximum is `2048m` or `2g`, but do not attempt to use more memory than is available on your computer. Also see the first technical note under example 3 on counting the conditional distribution.

- `saving(filename [, replace])` saves the joint conditional distribution for each independent variable specified in `indepvars`. There is one file for each variable, and it is named using the prefix `filename` with the variable name appended. For example, `saving(mydata)` with an independent variable named X would generate a data file named `mydata_X.dta`. Use `replace` to replace an existing file. Each file contains the conditional distribution for one of the independent variables specified in `indepvars` conditioned on all other `indepvars` and those variables specified in `condvars()`. There are two variables in each data file: the feasible sufficient statistics for the variable’s parameter and their associated weights. The weights variable is named _w_.

- `level(#);` see [R] estimation options. The `level(#)` option will not work on replay because confidence intervals are based on estimator-specific enumerations. To change the confidence level, you must refit the model.

- `irr` reports estimated coefficients transformed to incidence-rate ratios, that is, \(\exp(\beta)\) rather than \(\beta\). Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. `irr` may be specified at estimation or when replaying previously estimated results.

- `test(sufficient | score | probability)` reports the significance level of the observed sufficient statistic, the conditional scores test, or the conditional probabilities test. The default is `test(sufficient)`. All the statistics are computed at estimation time, and each statistic may be displayed postestimation; see [R] expoisson postestimation.
Remarks and examples

Exact Poisson regression estimates the model parameters by using the conditional distributions of the parameters’ sufficient statistics, and the resulting parameter estimates are known as CMLEs. Exact Poisson regression is a small-sample alternative to the maximum-likelihood ML Poisson model. See [R] poisson and [XT] xtpoisson to obtain maximum likelihood estimates (MLEs) for the Poisson model and the fixed-effects Poisson model.

Let $Y_i$ denote a Poisson random variable where we observe the outcome $Y_i = y_i$, $i = 1, \ldots, n$. Associated with each independent observation is a $1 \times p$ vector of covariates, $x_i$. We will denote $\mu_i = E[Y_i \mid x_i]$ and use the log linear model to model the relationship between $Y_i$ and $x_i$,

$$
\log (\mu_i) = \theta + x_i \beta
$$

where the constant term, $\theta$, and the $p \times 1$ vector of regression parameters, $\beta$, are unknown. The probability of observing $Y_i = y_i$, $i = 1, \ldots, n$, is

$$
\Pr(Y = y) = \prod_{i=1}^{n} \frac{\mu_i^{y_i} e^{-\mu_i}}{y_i!}
$$

where $Y = (Y_1, \ldots, Y_n)$ and $y = (y_1, \ldots, y_n)$. The MLEs for $\theta$ and $\beta$ maximize the log of this function.

The sufficient statistics for $\theta$ and $\beta_j$, $j = 1, \ldots, p$, are $M = \sum_{i=1}^{n} Y_i$ and $T_j = \sum_{i=1}^{n} Y_i x_{ij}$, respectively, and we observe $M = m$ and $T_j = t_j$. expoisson tallies the conditional distribution for each $T_j$, given the other sufficient statistics $T_l = t_l$, $l \neq j$ and $M = m$. Denote one of these values to be $t_j^{(k)}$, $k = 1, \ldots, N$, with weight $w_k$ that accounts for all the generated $Y$ vectors that give rise to $t_j^{(k)}$. The conditional probability of observing $T_j = t_j$ has the form

$$
\Pr(T_j = t_j \mid T_l = t_l, l \neq j, M = m) = \frac{w e^{t_j \beta_j}}{\sum_k w_k e^{t_j^{(k)} \beta_j}}
$$

where the sum is over the subset of $T$ vectors such that $(T_1^{(k)} = t_1, \ldots, T_j^{(k)} = t_j^{(k)}, \ldots, T_p^{(k)} = t_p)$ and $w$ is the weight associated with the observed $t$. The CMLE for $\beta_j$ maximizes the log of this function.

Specifying nuisance variables in condvars() prevents expoisson from estimating their associated regression coefficients. These variables are still conditional variables when tallying the conditional distribution for the variables in indepvars.
Inferences from MLEs rely on asymptotics, and if your sample size is small, these inferences may not be valid. On the other hand, inferences from the CMLEs are exact in that they use the conditional distribution of the sufficient statistics outlined above.

For small datasets, the dependent variable can be completely determined by the data. Here the MLEs and the CMLEs are unbounded. When this occurs, expoisson will compute the MUE, the regression estimate that places the observed sufficient statistic at the median of the conditional distribution.

See [R] exlogistic for a more thorough discussion of exact estimation and related statistics.

Example 1

Armitage, Berry, and Matthews (2002, 499–501) fit a log-linear model to data containing the number of cerebrovascular accidents experienced by 41 men during a fixed period, each of whom had recovered from a previous cerebrovascular accident and was hypertensive. Sixteen men received treatment, and in the original data, there are three age groups (40–49, 50–59, ≥60), but we pool the first two age groups to simplify the example. Armitage, Berry, and Matthews point out that this was not a controlled trial, but the data are useful to inquire whether there is evidence of fewer accidents for the treatment group and if age may be an important factor. The dependent variable count contains the number of accidents, variable treat is an indicator for the treatment group (1 = treatment, 0 = control), and variable age is an indicator for the age group (0 = 40–59; 1 = ≥60).

First, we load the data, list it, and tabulate the cerebrovascular accident counts by treatment and age group.

```

```

`expoisson` generates an enumeration log for each independent variable in `indepvars`. The conditional distribution of the parameter sufficient statistic is tallied for each independent variable. The conditional distribution for `treat`, for example, has 30 records containing the weights, $w_k$, and feasible sufficient statistics, $t_{treat}^{(k)}$. In essence, the set of points $(w_k, t_{treat}^{(k)})$, $k = 1, \ldots, 30$, tallied by `expoisson` now become the data to estimate the regression coefficient for `treat`, using (1) as the likelihood. Remember that one of the 30 $(w_k, t_{treat}^{(k)})$ must contain the observed sufficient statistic, $t_{treat} = \sum_{i=1}^{41} \text{treat}_i \times \text{count}_i = 4$, and its relative position in the sorted set of points (sorted by $t_{treat}^{(k)}$) is how the sufficient-statistic significance is computed. This algorithm is repeated for the `age` variable.

The regression coefficients for `treat` and `age` are numerically identical for both Poisson models. Both models indicate that the treatment is significant at reducing the rate of cerebrovascular accidents, $\approx e^{-1.59} \approx 0.204$, or a reduction of about 80%. There is no significant age effect.
The $p$-value for the treatment regression-coefficient sufficient statistic indicates that the treatment effect is a bit more significant than for the corresponding asymptotic $Z$ statistic from `poisson`. However, the exact confidence intervals are wider than their asymptotic counterparts.

Example 2

Agresti (2013, 129) used the data from Laird and Olivier (1981) to demonstrate the Poisson model for modeling rates. The data consist of patient survival after heart valve replacement operations. The sample consists of 109 patients that are classified by type of heart valve (aortic, mitral) and by age (<55, ≥55). Follow-up observations cover lengths from 3 to 97 months, and the time at risk, or exposure, is stored in the variable `TAR`. The response is whether the subject died. First, we take a look at the data and then estimate the incidence rates (IRs) with `expoisson` and `poisson`.

```
use http://www.stata-press.com/data/r13/heartvalve
(heart valve replacement data)
list
1.  < 55 aortic 4 1259
2.  < 55 mitral 1 2082
3.  ≥ 55 aortic 7 1417
4.  ≥ 55 mitral 9 1647
```

The `age` variable is coded 0 for age <55 and 1 for age ≥55, and the `valve` variable is coded 0 for the aortic valve and 1 for the mitral valve. The total number of deaths, $M = 21$, is small enough that enumerating the conditional distributions for age and valve type is feasible and asymptotic inferences associated with standard ML Poisson regression may be questionable.

```
expoisson deaths age valve, exposure(TAR) irr
Estimating: age
Enumerating sample-space combinations:
observation 1: enumerations = 11
observation 2: enumerations = 11
observation 3: enumerations = 132
observation 4: enumerations = 22

</tbody>
</table>
The CMLE and the MLE are numerically identical. The death rate for the older age group is about 3.4 times higher than the younger age group, and this difference is significant at the 5% level. This means that for every death in the younger group each month, we would expect about three deaths in the older group. The IR estimate for valve type is approximately 0.72, but it is not significantly different from one. The exact Poisson confidence intervals are a bit wider than the asymptotic CIs.

You can use `ir` (see [ST] epitab) to estimate IRs and exact CIs for one covariate, and we compare these CIs with those from `expoisson`, where we estimate the incidence rate by using age only.

```

Both `ir` and `expoisson` give identical IRs and p-values. Both report the two-sided exact significance by using the mid-p-value rule that accounts for the discreteness in the distribution by subtracting $p_{1/2} = Pr(T = t)/2$ from $p_l = Pr(T \leq t)$ and $p_g = Pr(T \geq t)$, computing $2 \times \min(p_l - p_{1/2}, p_g - p_{1/2})$. By default, `expoisson` will not use the mid-p-value rule (when you exclude the `midp` option), and here the two-sided exact significance would be $2 \times \min(p_l, p_g) = 0.0158$. The confidence intervals differ because `expoisson` uses the mid-p-value rule when computing the confidence intervals, yet
ir does not. You can verify this by executing `expoisson` without the `midp` option for this example; you will get the same CIs as `ir`.

You can replay `expoisson` to view the conditional scores test or the conditional probabilities test by using the `test()` option.

mid-p-value computed for the probabilities and CIs

All the statistics for `expoisson` are defined in `Methods and formulas` of `[R] exlogistic`. Apart from enumerating the conditional distributions for the logistic and Poisson sufficient statistics, computationally, the primary difference between `exlogistic` and `expoisson` is the weighting values in the likelihood for the parameter sufficient statistics.

Example 3

In this example, we fabricate data that will demonstrate the difference between the CMLE and the MUE when the CMLE is not infinite. A difference in these estimates will be more pronounced when the probability of the coefficient sufficient statistic is skewed when plotted as a function of the regression coefficient.

(*) median unbiased estimates (MUE)

We observe \((x_i, y_i), i = 1, \ldots, 9\). If we condition on \(m = \sum_{i=1}^{9} y_i = 12\), the conditional distribution of \(T_x = \sum_i Y_i x_i\) has a size of 5,479 elements. For each entry in this enumeration, a realization of \(Y_i = y_i^{(k)}, k = 1, \ldots, 5,479\), is generated such that \(\sum_i y_i^{(k)} = 12\). One of these realizations produces the observed \(t_x = \sum_i y_i x_i \approx 1.5234\).

Below is a graphical display comparing the CMLE with the MUE. We plot \(\Pr(T_x = t_x \mid M = 12, \beta_x)\) versus \(\beta_x, -6 \leq \beta_x \leq 1\), in the upper panel and the cumulative probabilities, \(\Pr(T_x \leq t_x \mid M = 12, \beta_x)\) and \(\Pr(T_x \geq t_x \mid M = 12, \beta_x)\), in the lower panel.

![Graphical display comparing CMLE with MUE](chart.png)

The location of the CMLE, indicated by the dashed line, is at the mode of the probability profile, and the MUE, indicated by the dotted line, is to the right of the mode. If we solve for the \(\beta_x^{(u)}\) and \(\beta_x^{(l)}\) such that \(\Pr(T_x \leq t_x \mid M = 12, \beta_x^{(u)}) = 1/2\) and \(\Pr(T_x \geq t_x \mid M = 12, \beta_x^{(l)}) = 1/2\), the MUE is \((\beta_x^{(u)} + \beta_x^{(l)})/2\). As you can see in the lower panel, the MUE cuts through the intersection of these cumulative probability profiles.
Technical note

The `memory(#)` option limits the amount of memory that `expoisson` will consume when computing the conditional distribution of the parameter sufficient statistics. `memory()` is independent of the data maximum memory setting (see `set max_memory` in [D] memory), and it is possible for `expoisson` to exceed the memory limit specified in `set max_memory` without terminating. By default, a log is provided that displays the number of enumerations (the size of the conditional distribution) after processing each observation. Typically, you will see the number of enumerations increase, and then at some point they will decrease as the multivariate shift algorithm (Hirji, Mehta, and Patel 1987) determines that some of the enumerations cannot achieve the observed sufficient statistics of the conditioning variables. When the algorithm is complete, however, it is necessary to store the conditional distribution of the parameter sufficient statistics as a dataset. It is possible, therefore, to get a memory error when the algorithm has completed if there is not enough memory to store the conditional distribution.

Technical note

Computing the conditional distributions and reported statistics requires data sorting and numerical comparisons. If there is at least one single-precision variable specified in the model, `expoisson` will make comparisons with a relative precision of $2^{-5}$. Otherwise, a relative precision of $2^{-11}$ is used. Be careful if you use `recast` to promote a single-precision variable to double precision (see [D] recast). You might try listing the data in full precision (maybe `%20.15g`; see [D] format) to make sure that this is really what you want. See [D] data types for information on precision of numeric storage types.

Stored results

`expoisson` stores the following in `e()`:

Scalars

- `e(N)` number of observations
- `e(k_groups)` number of groups
- `e(relative_weight)` relative weight for the observed `e(sufficient)` and `e(condvars)`
- `e(sum_y)` sum of `depvar`
- `e(k_indvars)` number of independent variables
- `e(k_condvars)` number of conditioning variables
- `e(midp)` mid-$p$-value rule indicator
- `e(eps)` relative difference tolerance

Macros

- `e(cmd)` `expoisson`
- `e(cmdline)` command as typed
- `e(title)` title in estimation output
- `e(depvar)` name of dependent variable
- `e(indvars)` independent variables
- `e(condvars)` conditioning variables
- `e(groupvar)` group variable
- `e(exposure)` exposure variable
- `e(offset)` linear offset variable
- `e(level)` confidence level
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(datasignature)` the checksum
- `e(datasignaturevars)` variables used in calculation of checksum
- `e(properties)` `b V`
- `e(estat_cmd)` program used to implement `estat`
- `e(marginsnotok)` predictions disallowed by `margins`
Methods and formulas

Let \( \{Y_1, Y_2, \ldots, Y_n\} \) be a set of \( n \) independent Poisson random variables. For each \( i = 1, \ldots, n \), we observe \( Y_i = y_i \geq 0 \), and associated with each observation is the covariate row vector of length \( p \), \( x_i = (x_{i1}, \ldots, x_{ip}) \). Denote \( \beta = (\beta_1, \ldots, \beta_p)^T \) to be the column vector of regression parameters and \( \theta \) to be the constant. The sufficient statistic for \( \beta_j \) is \( T_j = \sum_{i=1}^{n} Y_i x_{ij}, j = 1, \ldots, p \), and for \( \theta \) is \( M = \sum_{i=1}^{n} Y_i \). We observe \( T_j = t_j \), \( t_j = \sum_{i=1}^{n} y_i x_{ij} \), and \( M = m \), \( m = \sum_{i=1}^{n} y_i \). Let \( \kappa_i \) be the exposure for the \( i \)th observation. Then the probability of observing \( (Y_1 = y_1, Y_2 = y_2, \ldots, Y_n = y_n) \) is

\[
\Pr(Y_1 = y_1, \ldots, Y_n = y_n \mid \beta, X, \kappa) = \frac{\exp(m \theta + t \beta)}{\exp(\sum_{i=1}^{n} \kappa_i \exp(\theta + x_i \beta))} \prod_{i=1}^{n} \frac{\kappa_i^{y_i}}{y_i!}
\]

where \( t = (t_1, \ldots, t_p) \), \( X = (x_1^T, \ldots, x_n^T)^T \), and \( \kappa = (\kappa_1, \ldots, \kappa_n)^T \).

The joint distribution of the sufficient statistics \((T, M)\) is obtained by summing over all possible sequences \( Y_1 \geq 0, \ldots, Y_n \geq 0 \) such that \( T = t \) and \( M = m \). This probability function is

\[
\Pr(T_1 = t_1, \ldots, T_p = t_p, M = m \mid \beta, X, \kappa) = \frac{\exp(m \theta + t \beta)}{\exp(\sum_{i=1}^{n} \kappa_i \exp(\theta + x_i \beta))} \left( \sum_{\mathbf{u}} \prod_{i=1}^{n} \frac{\kappa_i^{u_i}}{u_i!} \right)
\]

where the sum \( \sum_{\mathbf{u}} \) is over all nonnegative vectors \( \mathbf{u} \) of length \( n \) such that \( \sum_{i=1}^{n} u_i = m \) and \( \sum_{i=1}^{n} u_i x_i = t \).

Conditional distribution

Without loss of generality, we will restrict our discussion to the conditional distribution of the sufficient statistic for \( \beta_1 \), \( T_1 \). If we condition on observing \( M = m \) and \( T_2 = t_2, \ldots, T_p = t_p \), the probability function of \( (T_1 \mid \beta_1, T_2 = t_2, \ldots, T_p = t_p, M = m) \) is

\[
\Pr(T_1 = t_1 \mid \beta_1, T_2 = t_2, \ldots, T_p = t_p, M = m) = \frac{\left( \sum_{\mathbf{u}} \prod_{i=1}^{n} \frac{\kappa_i^{u_i}}{u_i!} \right) e^{t_1 \beta_1}}{\sum_{\mathbf{v}} \left( \prod_{i=1}^{n} \frac{\kappa_i^{v_i}}{v_i!} \right) e^{\beta_1 \sum_{i=1}^{n} v_i x_{i1}}}
\]
where the sum \( \sum_{\text{\textbf{u}}} \) is over all nonnegative vectors \( \textbf{u} \) of length \( n \) such that \( \sum_{i=1}^{n} u_i = m \) and \( \sum_{i=1}^{n} u_i x_i = t \), and the sum \( \sum_{\textbf{v}} \) is over all nonnegative vectors \( \textbf{v} \) of length \( n \) such that \( \sum_{i=1}^{n} v_i = m \), \( \sum_{i=1}^{n} v_i x_i = t_2 \), \ldots, \sum_{i=1}^{n} v_i x_{ip} = t_p \). The CMLE for \( \beta_1 \) is the value that maximizes the log of (1). This optimization task is carried out by \texttt{ml} (see \texttt{[R] ml}), using the conditional distribution of \( (T_1 \mid T_2 = t_2, \ldots, T_p = t_p, M = m) \) as a dataset. This dataset consists of the feasible values and weights for \( T_1 \),

\[
\left\{ \left( s_1, \prod_{i=1}^{n} \frac{K_i^{v_i}}{v_i!} \right) : \sum_{i=1}^{n} v_i = m, \sum_{i=1}^{n} v_i x_{i1} = s_1, \sum_{i=1}^{n} v_i x_{i2} = t_2, \ldots, \sum_{i=1}^{n} v_i x_{ip} = t_p \right\}
\]

Computing the CMLE, MUE, confidence intervals, conditional hypothesis tests, and sufficient statistic \( p \)-values is discussed in \textit{Methods and formulas} of \texttt{[R] exlogistic}. The only difference between the two techniques is the use of the weights; that is, the weights for exact logistic are the combinatorial coefficients, \( c(t, m) \), in (1) of \textit{Methods and formulas} in \texttt{[R] exlogistic}. \texttt{expoisson} and \texttt{exlogistic} use the same \texttt{ml} likelihood evaluator to compute the CMLEs as well as the same ado-programs and Mata functions to compute the MUEs and estimate statistics.

The following postestimation command is of special interest after `expoisson`:

**Command** | **Description**
---|---
`estat se` | report coefficients or IRRs and their asymptotic standard errors

The following standard postestimation command is also available:

**Command** | **Description**
---|---
`estat summarize` | summary statistics for the estimation sample

See [R] `estat summarize` for details.

**Special-interest postestimation command**

`estat se` reports regression coefficients or incidence-rate asymptotic standard errors. The estimates are stored in the matrix `r(estimates)`.

**Syntax for estat se**

```
estat se [, irr]
```

**Menu for estat**

Statistics > Postestimation > Reports and statistics

**Option for estat se**

`irr` requests that the incidence-rate ratios and their asymptotic standard errors be reported. The default is to report the coefficients and their asymptotic standard errors.
Remarks and examples

Example 1

To demonstrate estat se after expoisson, we use the British physicians smoking data.

. use http://www.stata-press.com/data/r13/smokes
   (cigarette smoking and lung cancer among British physicians (45-49 years))
. expoisson cases smokes, exposure(peryrs) irr nolog

[U] 20 Estimation and postestimation commands
Syntax

**Estimation**

\[ \texttt{fp} \ <\texttt{term}> \ [\ , \ \texttt{est\_options}] \ : \ \texttt{est\_cmd} \]

\textit{est\_cmd} may be almost any estimation command that stores the \texttt{e(11)} result. To confirm whether \texttt{fp} works with a specific \textit{est\_cmd}, see the documentation for that \textit{est\_cmd}.

Instances of \texttt{<term>} (with the angle brackets) that occur within \textit{est\_cmd} are replaced in \textit{est\_cmd} by a varlist containing the fractional powers of the variable \textit{term}. These variables will be named \textit{term\_1}, \textit{term\_2}, \ldots.

\texttt{fp} performs \textit{est\_cmd} with this substitution, fitting a fractional polynomial regression in \textit{term}.

\textit{est\_cmd} in either this or the following syntax may not contain other prefix commands; see [U] 11.1.10 Prefix commands.

**Estimation (alternate syntax)**

\[ \texttt{fp} \ <\texttt{term}> (\texttt{varname}) \ [\ , \ \texttt{est\_options}] \ : \ \texttt{est\_cmd} \]

Use this syntax to specify that fractional powers of \textit{varname} are to be calculated. The fractional polynomial power variables will still be named \textit{term\_1}, \textit{term\_2}, \ldots.

**Replay estimation results**

\[ \texttt{fp} \ [\ , \ \texttt{replay\_options}] \]

**Create specified fractional polynomial power variables**

\[ \texttt{fp generate} \ [\ \texttt{type}] \ [\ \texttt{newvar} =] \ \texttt{varname}^{\texttt{(numlist)}} \ [\ \texttt{if}] \ [\ \texttt{in}] \ [\ , \ \texttt{gen\_options}] \]

fp
Statistics > Linear models and related > Fractional polynomials > Fractional polynomial regression

fp generate
Statistics > Linear models and related > Fractional polynomials > Create fractional polynomial variables

Description

**fp <term>: est_cmd** fits models with the “best”-fitting fractional polynomial substituted for <term> wherever it appears in est_cmd. fp <weight>: regress mpg <weight> foreign would fit a regression model of mpg on a fractional polynomial in weight and (linear) foreign.

By specifying option fp(), you may set the exact powers to be used. Otherwise, a search through all possible fractional polynomials up to the degree set by dimension() with the powers set by powers() is performed.

fp without arguments redisplay the previous estimation results, just as typing est_cmd would. You can type either one. fp will include a fractional polynomial comparison table.

fp generate creates fractional polynomial power variables for a given set of powers. For instance, fp <weight>: regress mpg <weight> foreign might produce the fractional polynomial weight\(^{-2,-1}\) and store weight\(^{-2}\) in weight\(_1\) and weight\(^{-1}\) in weight\(_2\). Typing fp generate weight\(^{-2 -1}\) would allow you to create the same variables in another dataset.

See [R] mfp for multivariable fractional polynomial models.

Options for fp

- **powers(# # ... #)** specifies that a search be performed and details about the search provided.
- powers() works with the dimension() option; see below. The default is powers(-2 -1 -.5 0 .5 1 2 3).
- **dimension(#)** specifies the maximum degree of the fractional polynomial to be searched. The default is dimension(2).

If the defaults for both powers() and dimension() are used, then the fractional polynomial could be any of the following 44 possibilities:
fp(# # ... #) specifies that no search be performed and that the fractional polynomial specified be used. fp() is an alternative to powers() and dimension().

Options

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>classic</td>
<td>performs automatic scaling and centering and omits the comparison table. Specifying classic is equivalent to specifying scale, center, and nocompare.</td>
</tr>
<tr>
<td>replace</td>
<td>replaces existing fractional polynomial power variables named term_1, term_2, ....</td>
</tr>
<tr>
<td>all</td>
<td>specifies that term_1, term_2, ... be filled in for all observations in the dataset rather than just for those in e(sample).</td>
</tr>
<tr>
<td>scale(#_a #_b)</td>
<td>specifies that term be scaled in the way specified, namely, that ((term+a)/b) be calculated. All values of scaled term are required to be greater than zero unless you specify options zero or catzero. Values should not be too large or too close to zero, because by default, cubic powers and squared reciprocal powers will be considered. When scale(a b) is specified, values in the variable term are not modified; fp merely remembers to scale the values whenever powers are calculated.</td>
</tr>
</tbody>
</table>

You will probably not use scale(a b) for values of \(a\) and \(b\) that you create yourself, although you could. It is usually easier just to generate a scaled variable. For instance, if term is age, and age in your data is required to be greater than or equal to 20, you might generate an age5 variable, for use as term:

```
. generate age5 = (age-19)/5
```

scale(a b) is useful when you previously fit a model using automatic scaling (option scale) in one dataset and now want to create the fractional polynomials in another. In the first dataset, fp with scale added notes to the dataset concerning the values of \(a\) and \(b\). You can see them by typing

```
. notes
```

You can then use fp generate, scale(a b) in the second dataset.

The default is to use term as it is used in calculating fractional powers; thus term’s values are required to be greater than zero unless you specify options zero or catzero. Values should not be too large, because by default, cubic powers will be considered.

scale specifies that term be scaled to be greater than zero and not too large in calculating fractional powers. See Scaling for more details. When scale is specified, values in the variable term are not modified; fp merely remembers to scale the values whenever powers are calculated.
center(#_c) reports results for the fractional polynomial in (scaled) term, centered on c. The default is to perform no centering.

term\(^{p_1,p_2,\ldots,p_m}\)\(_c^{p_1,p_2,\ldots,p_m}\) is reported. This makes the constant coefficient (intercept) easier to interpret. See Centering for more details.

center performs center(c), where c is the mean of (scaled) term.

zero and catzero specify how nonpositive values of term are to be handled. By default, nonpositive values of term are not allowed, because we will be calculating natural logarithms and fractional powers of term. Thus an error message is issued.

zero sets the fractional polynomial value to zero for nonpositive values of (scaled) term.

catzero sets the fractional polynomial value to zero for nonpositive values of (scaled) term and includes a dummy variable indicating where nonpositive values of (scaled) term appear in the model.

Reporting

nocompare suppresses display of the comparison tests.

reporting_options are any options allowed by est_cmd for replaying estimation results.

Options for fp generate

replace replaces existing fractional polynomial power variables named term_1, term_2, ....

scale(#_a #_b) specifies that term be scaled in the way specified, namely, that (term+a)/b be calculated. All values of scaled term are required to be greater than zero unless you specify options zero or catzero. Values should not be too large or too close to zero, because by default, cubic powers and squared reciprocal powers will be considered. When scale(a b) is specified, values in the variable term are not modified; fp merely remembers to scale the values whenever powers are calculated.

You will probably not use scale(a b) for values of a and b that you create yourself, although you could. It is usually easier just to generate a scaled variable. For instance, if term is age, and age in your data is required to be greater than or equal to 20, you might generate an age5 variable, for use as term:

\[
\text{generate age5 = (age-19)/5}
\]

scale(a b) is useful when you previously fit a model using automatic scaling (option scale) in one dataset and now want to create the fractional polynomials in another. In the first dataset, fp with scale added notes to the dataset concerning the values of a and b. You can see them by typing

\[
\text{notes}
\]

You can then use fp generate, scale(a b) in the second dataset.

The default is to use term as it is used in calculating fractional powers; thus term’s values are required to be greater than zero unless you specify options zero or catzero. Values should not be too large, because by default, cubic powers will be considered.

scale specifies that term be scaled to be greater than zero and not too large in calculating fractional powers. See Scaling for more details. When scale is specified, values in the variable term are not modified; fp merely remembers to scale the values whenever powers are calculated.
center(#) reports results for the fractional polynomial in (scaled) term, centered on c. The default is to perform no centering.

\[ \text{term}^{(p_1, p_2, \ldots, p_m)} - c^{(p_1, p_2, \ldots, p_m)} \] is reported. This makes the constant coefficient (intercept) easier to interpret. See Centering for more details.

center performs center(c), where c is the mean of (scaled) term.

zero and catzero specify how nonpositive values of term are to be handled. By default, nonpositive values of term are not allowed, because we will be calculating natural logarithms and fractional powers of term. Thus an error message is issued.

zero sets the fractional polynomial value to zero for nonpositive values of (scaled) term.

catzero sets the fractional polynomial value to zero for nonpositive values of (scaled) term and includes a dummy variable indicating where nonpositive values of (scaled) term appear in the model.

Remarks and examples

Remarks are presented under the following headings:

- Fractional polynomial regression
- Scaling
- Centering
- Examples

Fractional polynomial regression

Regression models based on fractional polynomial functions of a continuous covariate are described by Royston and Altman (1994).

Fractional polynomials increase the flexibility afforded by the family of conventional polynomial models. Although polynomials are popular in data analysis, linear and quadratic functions are limited in their range of curve shapes, whereas cubic and higher-order curves often produce undesirable artifacts such as edge effects and waves.

Fractional polynomials differ from regular polynomials in that 1) they allow logarithms, 2) they allow noninteger powers, and 3) they allow powers to be repeated.

We will write a fractional polynomial in x as

\[ x^{(p_1, p_2, \ldots, p_m)} \beta \]

We will write \( x^{(p)} \) to mean a regular power except that \( x^{(0)} \) is to be interpreted as meaning \( \ln(x) \) rather than \( x^{(0)} = 1 \).

Then if there are no repeated powers in \( (p_1, p_2, \ldots, p_m) \),

\[ x^{(p_1, p_2, \ldots, p_m)} \beta = \beta_0 + \beta_1 x^{(p_1)} + \beta_2 x^{(p_2)} + \cdots + \beta_m x^{(p_m)} \]

Powers are allowed to repeat in fractional polynomials. Each time a power repeats, it is multiplied by another \( \ln(x) \). As an extreme case, consider the fractional polynomial with all-repeated powers, say, \( m \) of them,

\[ x^{(p, p, \ldots, p)} \beta = \beta_0 + \beta_1 x^{(p)} + \beta_2 x^{(p)} \ln(x) + \cdots + \beta_m x^{(p)} \{\ln(x)\}^{m-1} \]
Thus the fractional polynomial $x^{(0,0,2)}\beta$ would be

$$x^{(0,0,2)}\beta = \beta_0 + \beta_1 x^{(0)} + \beta_2 x^{(0)} \ln(x) + \beta_3 x^{(2)}$$

$$= \beta_0 + \beta_1 \ln(x) + \beta_2 \{\ln(x)\}^2 + \beta_3 x^2$$

With this definition, we can obtain a much wider range of shapes than can be obtained with regular polynomials. The following graphs appeared in Royston and Sauerbrei (2008, sec. 4.5). The first graph shows the shapes of differing fractional polynomials.
The second graph shows some of the curve shapes available with different $\beta$s for the degree-2 fractional polynomial, $x^{(-2,2)}$.

In modeling a fractional polynomial, Royston and Sauerbrei (2008) recommend choosing powers from among $\{-2, -1, -0.5, 0, 0.5, 1, 2, 3\}$. By default, \texttt{fp} chooses powers from this set, but other powers can be explicitly specified in the \texttt{powers()} option.

\texttt{fp <term>: est\_cmd} fits models with the terms of the best-fitting fractional polynomial substituted for \texttt{<term>} wherever it appears in \texttt{est\_cmd}. We will demonstrate with \texttt{auto.dta}, which contains repair records and other information about a variety of vehicles in 1978.

We use \texttt{fp} to find the best fractional polynomial in automobile weight (lbs.) (\texttt{weight}) for the linear regression of miles per gallon (\texttt{mpg}) on \texttt{weight} and an indicator of whether the vehicle is foreign (\texttt{foreign})

By default, \texttt{fp} will fit degree-2 fractional polynomial (FP2) models and choose the fractional powers from the set $\{-2, -1, -0.5, 0, 0.5, 1, 2, 3\}$. Because car weight is measured in pounds and will have a cubic transformation applied to it, we shrink it to a smaller scale before estimation by dividing by 1,000.

We modify the existing \texttt{weight} variable for conciseness and to facilitate the comparison of tables. When applying a data transformation in practice, rather than modifying the existing variables, you should create new variables that hold the transformed values.
fp begins by showing the model-comparison table. This table shows the best models of each examined degree, obtained by searching through all possible power combinations. The fractional powers of the models are shown in the Powers column. A separate row is provided for the linear fractional polynomial because it is often the default used when including a predictor in the model. The null model does not include any fractional polynomial terms for `weight`. The df column shows the count of the additional parameters used in each model beyond the quantity of parameters used in the null model. The model deviance, which we define as twice the negative log likelihood, is given in the Deviance column. The difference of the model deviance from the deviance of the model with the lowest deviance is given in the Dev. dif. column. The p-value for the partial F test comparing the models and the lowest deviance model is given in the P(*) column. An estimate of the residual standard error is given in the Res. Sd. column. Under linear regression, a partial F test is used in the model-comparison table. In other settings, a \( \chi^2 \) statistic is reported.

Under robust variance estimation and some other cases (see \[R\] `lrtest`), the likelihood-ratio test cannot be performed. When the likelihood-ratio test cannot be performed on the model specified in `est_cmd`, `fp` still reports the model-comparison table, but the comparison tests are not performed.

`fp` reports the “best” model as the model with the lowest deviance; however, users may choose a more efficient model based on the comparison table. They may choose the lowest degree model that the partial F test (or likelihood-ratio test) fails to reject in favor of the lowest deviance model.

After the comparison table, the results of the estimation command for the lowest deviance model are shown. Here the best model has terms `weight^{(-2,-2)}`. However, based on the model-comparison
table, we can reject the model without weight and the linear model at the 0.1 significance level. We fail to reject the $m = 1$ model at any reasonable level. We will choose the FP1 model, which includes \textit{weight}^{(-.5)}.

We use \texttt{fp} again to estimate the parameters for this model. We use the \texttt{fp()} option to specify what powers we want to use; this option specifies that we do not want to perform a search for the best powers. We also specify the \texttt{replace} option to overwrite the previously created fractional polynomial power variables.

\begin{verbatim}
   . fp <weight>, fp(-.5) replace: regress mpg <weight> foreign
   -> regress mpg weight_1 foreign

   Source | SS df MS
----------|--------|--------
   Model   | 1689.20865 2 844.604325

\end{verbatim}

\textbf{Scaling}

Fractional polynomials are only defined for positive \textit{term} variables. By default, \texttt{fp} will assume that the variable \textit{x} is positive and attempt to compute fractional powers of \textit{x}. If the positive value assumption is incorrect, an error will be reported and estimation will not be performed.

If the values of the variable are too large or too small, the reported results of \texttt{fp} may be difficult to interpret. By default, cubic powers and squared reciprocal powers will be considered in the search for the best fractional polynomial in \textit{term}.

We can scale the variable \textit{x} to 1) make it positive and 2) ensure its magnitude is not too large or too small.

Suppose you have data on hospital patients with \textit{age} as a fractional polynomial variable of interest. \textit{age} is required to be greater than or equal to 20, so you might generate an \textit{age5} variable by typing
A unit change in \texttt{age5} is equivalent to a five-year change in age, and the minimum value of \texttt{age5} is $1/5$ instead of 20.

In the automobile example of \textit{Fractional polynomial regression}, our \textit{term} variable was automobile weight (lbs.). Cars weigh in the thousands of pounds, so cubing their weight figures results in large numbers. We prevented this from being a problem by shrinking the weight by 1,000; that is, we typed

\begin{verbatim}
   . replace weight = weight/1000
\end{verbatim}

Calendar year is another type of variable that can have a problematically large magnitude. We can shrink this by dividing by 10, making a unit change correspond to a decade.

\begin{verbatim}
   . generate decade = calendar_year/10
\end{verbatim}

You may also have a variable that measures deviation from zero. Perhaps \textit{x} has already been demeaned and is symmetrically about zero. The fractional polynomial in \textit{x} will be undefined for half of its domain. We can shift the location of \textit{x}, making it positive by subtracting its minimum and adding a small number to it. Suppose \textit{x} ranges from $-4$ to 4; we could use

\begin{verbatim}
   . generate newx = x+5
\end{verbatim}

Rescaling ourselves provides easily communicated results. We can tell exactly how the scaling was performed and how it should be performed in similar applications.

Alternatively, \texttt{fp} can scale the fractional polynomial variable so that its values are positive and the magnitude of the values are not too large. This can be done automatically or by directly specifying the scaling values.

Scaling can be automatically performed with \texttt{fp} by specifying the \texttt{scale} option. If \textit{term} has nonpositive values, the minimum value of \textit{term} is subtracted from each observation of \textit{term}. In this case, the counting interval, the minimum distance between the sorted values of \textit{term}, is also added to each observation of \textit{term}.

After adjusting the location of \textit{term} so that its minimum value is positive, creating \textit{term*}, automatic scaling will divide each observation of \textit{term} by a power of ten. The exponent of this scaling factor is given by

\[
p = \log_{10} \left\{ \max(\textit{term}^*) - \min(\textit{term}^*) \right\}
\]

\[
p^* = \text{sign}(p) \text{floor}(|p|)
\]

Rather than letting \texttt{fp} automatically choose the scaling of \textit{term}, you may specify adjustment and scale factors \textit{a} and \textit{b} by using the \texttt{scale(a b)} option. Fractional powers are then calculated using the \texttt{(term+a)/b} values.

When \texttt{scale} or \texttt{scale(a b)} is specified, values in the variable \textit{term} are not modified; \texttt{fp} merely remembers to scale the values whenever powers are calculated.

In addition to \texttt{fp}, both \texttt{scale} and \texttt{scale(a b)} may be used with \texttt{fp generate}.

You will probably not use \texttt{scale(a b)} with \texttt{fp} for values of \textit{a} and \textit{b} that you create yourself, although you could. As we demonstrated earlier, it is usually easier just to \texttt{generate} a scaled variable.

\texttt{scale(a b)} is useful when you previously fit a model using \texttt{scale} in one dataset and now want to create the fractional polynomials in another. In the first dataset, \texttt{fp} with \texttt{scale added notes} to the dataset concerning the values of \textit{a} and \textit{b}. You can see them by typing

\begin{verbatim}
   . notes
\end{verbatim}
You can then use `fp generate, scale(a b)` in the second dataset.

When you apply the scaling rules of a previously fit model to new data with the `scale(a b)` option, it is possible that the scaled term may have nonpositive values. `fp` will be unable to calculate the fractional powers of the term in this case and will issue an error.

The options `zero` and `catzero` cause `fp` and `fp generate` to output zero values for each fractional polynomial variable when the input (scaled) fractional polynomial variable is nonpositive. Specifying `catzero` causes a dummy variable indicating nonpositive values of the (scaled) fractional polynomial variable to be included in the model. A detailed example of the use of `catzero` and `zero` is shown in example 3 below.

Using the scaling options, we can fit our previous model again using the `auto.dta`. We specify `scale(0 1000)` so that `fp` will shrink the magnitude of `weight` in estimating the regression. This is done for demonstration purposes because our scaling rule is simple. As mentioned before, in practice, you would probably only use `scale(a b)` when applying the scaling rules from a previous analysis. Allowing `fp` to scale does have the advantage of not altering the original variable, `weight`.

```
use http://www.stata-press.com/data/r13/auto, clear
(1978 Automobile Data)

. fp <weight>, fp(-.5) scale(0 1000): regress mpg <weight> foreign
```

Source | SS df MS
-------+--------------------------------------------------
Model | 1689.20861 2 844.604307
Residual | 754.250846 71 10.6232514
Total | 2443.45946 73 33.4720474

Number of obs = 74
F( 2, 71) = 79.51
Prob > F = 0.0000
R-squared = 0.6913
Adj R-squared = 0.6826
Root MSE = 3.2593

mpg | Coef. Std. Err. t P>|t| [95% Conf. Interval]
-----+--------------------------------------------------
weight_1 | 66.89665 6.021749 11.11 0.000 54.88963 78.90368
foreign | -2.095622 1.043513 -2.01 0.048 -4.176329 -.0149159
_cons | -17.58651 3.397992 -5.18 0.000 -24.36192 -10.81111

The scaling is clearly indicated in the variable notes for the generated variable `weight_1`.

```
. notes weight_1
weight_1:
1. fp term 1 of x^(-.5), where x is weight scaled.
2. Scaling was user specified: x = (weight+a)/b where a=0 and b=1000
3. Fractional polynomial variables created by `fp <weight>, fp(-.5) scale(0
   1000): regress mpg <weight> foreign`
4. To re-create the fractional polynomial variables, for instance, in another
   dataset, type `fp gen double weight^(-.5), scale(0 1000)`
```

Centering

The fractional polynomial of `term`, centered on `c` is

\[
\left(\text{term}^{(p_1, \ldots, p_m)} - c^{(p_1, \ldots, p_m)}\right) \beta
\]

The intercept of a centered fractional polynomial can be interpreted as the effect at zero for all the covariates. When we center the fractional polynomial terms using `c`, the intercept is now interpreted as the effect at `term = c` and zero values for the other covariates.
Suppose we wanted to center the fractional polynomial of $x$ with powers $(0, 0, 2)$ at $x = c$.

\[
\left( x^{(0,0,2)} - c^{(0,0,2)} \right)'\beta
\]

\[= \beta_0 + \beta_1 \left( x^{(0)} - c^{(0)} \right) + \beta_2 \left\{ x^{(0)} \ln(x) - c^{(0)} \ln(c) \right\} + \beta_3 \left( x^{(2)} - c^{(2)} \right)
\]

\[= \beta_0 + \beta_1 \{\ln(x) - \ln(c)\} + \beta_2 \left[ \{\ln(x)\}^2 - \{\ln(c)\}^2 \right] + \beta_3 \left( x^2 - c^2 \right)
\]

When `center` is specified, `fp` centers based on the sample mean of (scaled) term. A previously chosen value for centering, $c$, may also be specified in `center(c)`. This would be done when applying the results of a previous model fitting to a new dataset.

The `center` and `center(c)` options may be used in `fp` or `fp generate`.

Returning to the model of mileage per gallon based on automobile weight and foreign origin, we refit the model with the fractional polynomial of weight centered at its scaled mean.

```
. use http://www.stata-press.com/data/r13/auto, clear
  (1978 Automobile Data)
. fp <weight>, fp(-.5) scale(0 1000) center: regress mpg <weight> foreign
-> regress mpg weight_1 foreign
```

Note that the coefficients for `weight_1` and `foreign` do not change. Only the intercept `_cons` changes. It can be interpreted as the estimated average miles per gallon of an American-made car of average weight.
Examples

Example 1: Linear regression

Consider the serum immunoglobulin G (IgG) dataset from Isaacs et al. (1983), which consists of 298 independent observations in young children. The dependent variable \( \sqrt{\text{IgG}} \) is the square root of the IgG concentration, and the independent variable \( \text{age} \) is the age of each child. (Preliminary Box–Cox analysis shows that a square root transformation removes the skewness in IgG.)

The aim is to find a model that accurately predicts the mean of \( \sqrt{\text{IgG}} \) given \( \text{age} \). We use \texttt{fp} to find the best FP2 model (the default option). We specify \texttt{center} for automatic centering. The age of each child is small in magnitude and positive, so we do not use the scaling options of \texttt{fp} or scale ourselves.

The new variables created by \texttt{fp} contain the best-fitting fractional polynomial powers of \texttt{age}, as centered by \texttt{fp}. For example, \texttt{age_1} is centered by subtracting the mean of \texttt{age} raised to the power \(-2\).

The variables created by \texttt{fp} and \texttt{fp generate} are centered or scaled as specified by the user, which is reflected in the estimated regression coefficients and intercept. Centering does have its advantages (see \texttt{Centering} earlier in this entry). By default, \texttt{fp} will not perform scaling or centering. For a more detailed discussion, see Royston and Sauerbrei (2008, sec. 4.11).

The fitted curve has an asymmetric S shape. The best model has powers \((-2, 2)\) and deviance 319.448. We reject lesser degree models: the null, linear, and natural log power models at the 0.05 level. As many as 44 models have been fit in the search for the best powers. Now let’s look at models of degree \(\leq 4\). The highest allowed degree is specified in \texttt{dimension()}. We overwrite the previously generated fractional polynomial power variables by including \texttt{replace}.

It appears that the FP4 model is not significantly different from the other fractional polynomial models (at the 0.05 level).

Let’s compare the curve shape from the $m = 2$ model with that from a conventional quartic polynomial whose fit turns out to be significantly better than a cubic (not shown). We use the ability of fp both to generate the required powers of age, namely, (1, 2, 3, 4) for the quartic and (−2, 2) for the second-degree fractional polynomial, and to fit the model. The fp() option is used to specify the powers. We use predict to obtain the fitted values of each regression. We fit both models with fp and graph the resulting curves with twoway scatter.

The quartic curve has an unsatisfactory wavy appearance that is implausible for the known behavior of IgG, the serum level of which increases throughout early life. The fractional polynomial curve (FP2) increases monotonically and is therefore biologically the more plausible curve. The two models have approximately the same deviance.

Example 2: Cox regression

Data from Smith et al. (1992) contain times to complete healing of leg ulcers in a randomized, controlled clinical trial of two treatments in 192 elderly patients. Several covariates were available, of which an important one is \( mthson \), the number of months since the recorded onset of the ulcer. This time is recorded in whole months, not fractions of a month; therefore, some zero values are recorded.

Because the response variable is time to an event of interest and some (in fact, about one-half) of the times are censored, using Cox regression to analyze the data is appropriate. We consider fractional polynomials in \( mthson \), adjusting for four other covariates: \( age \); \( ulcarea \), the area of tissue initially affected by the ulcer; \( deeppg \), a binary variable indicating the presence or absence of deep vein involvement; and \( treat \), a binary variable indicating treatment type.

We fit fractional polynomials of degrees 1 and 2 with \texttt{fp}. We specify \texttt{scale} to perform automatic scaling on \( mthson \). This makes it positive and ensures that its magnitude is not too large. (See \textit{Scaling} for more details.) The display option \texttt{nohr} is specified before the colon so that the coefficients and not the hazard ratios are displayed.

The \texttt{center} option is specified to obtain automatic centering. \( age \) and \( ulcarea \) are also demeaned by using \texttt{summarize} and then subtracting the returned result \( r(mean) \).

In Cox regression, there is no constant term, so we cannot see the effects of centering in the table of regression estimates. The effects would be present if we were to graph the baseline hazard or survival function because these functions are defined with all predictors set equal to 0.

In these graphs, we will see the estimated baseline hazard or survival function under no deep vein involvement or treatment and under mean age, ulcer area, and number of months since the recorded onset of the ulcer.

The best-fitting fractional polynomial of degree 2 has powers (0.5, 0.5) and deviance 736.709. However, this model does not fit significantly better than the fractional polynomial of degree 1 (at the 0.05 level), which has power −0.5 and deviance 738.969. We prefer the model with \( m = 1 \).
The hazard for healing is much higher for patients whose ulcer is of recent onset than for those who have had an ulcer for many months.

A more appropriate analysis of this dataset, if one wanted to model all the predictors, possibly with fractional polynomial functions, would be to use `mfp`; see \[R\] `mfp`.

#### Example 3: Logistic regression

The `zero` option permits fitting a fractional polynomial model to the positive values of a covariate, taking nonpositive values as zero. An application is the assessment of the effect of cigarette smoking as a risk factor. Whitehall I is an epidemiological study, which was examined in Royston and Sauerbrei (2008), of 18,403 male British Civil Servants employed in London. We examine the data collected in Whitehall I and use logistic regression to model the odds of death based on a fractional polynomial in the number of cigarettes smoked.

Non-smokers may be qualitatively different from smokers, so the effect of smoking (regarded as a continuous variable) may not be continuous between zero cigarettes and one cigarette. To allow for this possibility, we model the risk as a constant for the non-smokers and as a fractional polynomial function of the number of cigarettes for the smokers, adjusted for age.

The dependent variable `all10` is an indicator of whether the individual passed away in the 10 years under study. `cigs` is the number of cigarettes consumed per day. After loading the data, we demean `age` and create a dummy variable, `nonsmoker`. We then use `fp` to fit the model.

Omission of the zero option would cause fp to halt with an error message because nonpositive covariate values (for example, values of cigs) are invalid unless the scale option is specified.

A closely related approach involves the catzero option. Here we no longer need to have nonsmoker in the model, because fp creates its own dummy variable cigs_0 to indicate whether the individual does not smoke on that day.
. fp <cigs>, catzero replace: logit all10 <cigs> age

The high p-value for cigs_0 in the output indicates that we cannot reject that there is no extra effect at zero for nonsmokers.
Stored results

In addition to the results that `est_cmd` stores, `fp` stores the following in `e()`:

Scalars
- `e(fp_dimension)` degree of fractional polynomial
- `e(fp_center_mean)` value used for centering or .
- `e(fp_scale_a)` value used for scaling or .
- `e(fp_scale_b)` value used for scaling or .
- `e(fp_compare_df2)` denominator degree of freedom in $F$ test

Macros
- `e(fp_cmd)` `fp, search()`: or `fp, powers()`:
- `e(fp_cmdline)` full `fp` command as typed
- `e(fp_variable)` fractional polynomial variable
- `e(fp_terms)` generated `fp` variables
- `e(fp_gen_cmdline)` `fp generate` command to re-create `e(fp_terms)` variables
- `e(fp_catzero)` `catzero`, if specified
- `e(fp_zero)` zero, if specified
- `e(fp_compare_type)` $F$ or `chi2`

Matrices
- `e(fp_fp)` powers used in fractional polynomial
- `e(fp_compare)` results of model comparisons
- `e(fp_compare_stat)` $F$ test statistics
- `e(fp_compare_df1)` numerator degree of $F$ test
- `e(fp_compare_fp)` powers of comparison models
- `e(fp_compare_length)` encoded string for display of row titles
- `e(fp_powers)` powers that are searched

`fp generate` stores the following in `r()`:

Scalars
- `r(fp_center_mean)` value used for centering or .
- `r(fp_scale_a)` value used for scaling or .
- `r(fp_scale_b)` value used for scaling or .

Macros
- `r(fp_cmdline)` full `fp generate` command as typed
- `r(fp_variable)` fractional polynomial variable
- `r(fp_terms)` generated `fp` variables
- `r(fp_catzero)` `catzero`, if specified
- `r(fp_zero)` zero, if specified

Matrices
- `r(fp_fp)` powers used in fractional polynomial

Methods and formulas

The general definition of a fractional polynomial, accommodating possible repeated powers, may be written for functions $H_1(x), \ldots, H_m(x)$ of $x > 0$ as

$$
\beta_0 + \sum_{j=1}^{m} \beta_j H_j(x)
$$

where $H_1(x) = x^{(p_1)}$ and for $j = 2, \ldots, m$,

$$
H_j(x) = \begin{cases} 
x^{(p_j)} & \text{if } p_j \neq p_{j-1} \\
H_{j-1}(x) \ln(x) & \text{if } p_j = p_{j-1}
\end{cases}
$$
For example, a fractional polynomial of degree 3 with powers \( (1, 3, 3) \) has \( H_1(x) = x, \ H_2(x) = x^3, \) and \( H_3(x) = x^3 \ln(x) \) and equals \( \beta_0 + \beta_1 x + \beta_2 x^3 + \beta_3 x^3 \ln(x) \).

We can express a fractional polynomial in vector notation by using \( \mathbf{H}(x) = [H_1(x), \ldots, H_d(x)]' \). We define \( x^{(p_1, p_2, \ldots, p_m)} = [H(x)', 1]' \). Under this notation, we can write

\[
x^{(1,3,3)'} \beta = \beta_0 + \beta_1 x + \beta_2 x^3 + \beta_3 x^3 \ln(x)
\]

The fractional polynomial may be centered so that the intercept can be more easily interpreted. When centering the fractional polynomial of \( x \) at \( c \), we subtract \( c \) from \( x^{(p_1, p_2, \ldots, p_m)} \), where \( c^{(p_1, p_2, \ldots, p_d)} = [\mathbf{H}(x)', 0]' \). The centered fractional polynomial is

\[
\left( x^{(p_1, \ldots, p_d)} - c^{(p_1, \ldots, p_d)} \right)' \beta
\]

The definition may be extended to allow \( x \leq 0 \) values. For these values, the fractional polynomial is equal to the intercept \( \beta_0 \) or equal to a zero-offset term \( \alpha_0 \) plus the intercept \( \beta_0 \).

A fractional polynomial model of degree \( m \) is taken to have \( 2m + 1 \) degrees of freedom (df): one for \( \beta_0 \) and one for each \( \beta_j \) and its associated power. Because the powers in a fractional polynomial are chosen from a finite set rather than from the entire real line, the df defined in this way are approximate.

The deviance \( D \) of a model is defined as \(-2\) times its maximized log likelihood. For normal-errors models, we use the formula

\[
D = n \left( 1 - \bar{l} + \ln \frac{2\pi \text{RSS}}{n} \right)
\]

where \( n \) is the sample size, \( \bar{l} \) is the mean of the lognormalized weights (\( \bar{l} = 0 \) if the weights are all equal), and \( \text{RSS} \) is the residual sum of squares as fit by \texttt{regress}.

\texttt{fp} reports a table comparing fractional polynomial models of degree \( k < m \) with the degree \( m \) fractional polynomial model, which will have the lowest deviance.

The \( p \)-values reported by \texttt{fp} are calculated differently for normal and nonnormal regressions. Let \( D_k \) and \( D_m \) be the deviances of the models with degrees \( k \) and \( m \), respectively. For normal-errors models, a variance ratio \( F \) is calculated as

\[
F = \frac{n_2}{n_1} \left\{ \exp \left( \frac{D_k - D_m}{n} \right) - 1 \right\}
\]

where \( n_1 \) is the numerator df, the quantity of the additional parameters that the degree \( m \) model has over the degree \( k \) model. \( n_2 \) is the denominator df and equals the residual degrees of freedom of the degree \( m \) model, minus the number of powers estimated, \( m \). The \( p \)-value is obtained by referring \( F \) to an \( F \) distribution on \((n_1, n_2)\) df.

For nonnormal models, the \( p \)-value is obtained by referring \( D_k - D_m \) to a \( \chi^2 \) distribution on \( 2m - 2k \) df. These \( p \)-values for comparing models are approximate and are typically somewhat conservative (Royston and Altman 1994).
Acknowledgment

We thank Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model* for writing fracpoly and fracgen, the commands on which `fp` and `fp generate` are based. We also thank Professor Royston for his advice on and review of the new `fp` commands.

[U] 20 Estimation and postestimation commands
### Description

The following postestimation commands are of special interest after `fp`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>fp plot</code></td>
<td>component-plus-residual plot from most recently fit fractional polynomial model</td>
</tr>
<tr>
<td><code>fp predict</code></td>
<td>create variable containing prediction or SEs of fractional polynomials</td>
</tr>
</tbody>
</table>

The following standard postestimation commands are also available if available after `est_cmd`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>contrast</code></td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td><code>estat ic</code></td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td><code>estat summarize</code></td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>hausman</code></td>
<td>Hausman’s specification test</td>
</tr>
<tr>

Special-interest postestimation commands

`fp plot` produces a component-plus-residual plot. The fractional polynomial comprises the component, and the residual is specified by the user in `residuals()`. The component-plus-residuals are plotted against the fractional polynomial variable. If you only want to plot the component fit, without residuals, you would specify `residuals(none)`.

`fp predict` generates the fractional polynomial or the standard error of the fractional polynomial. The fractional polynomial prediction is equivalent to the fitted values prediction given by `predict`, `xb`, with the covariates other than the fractional polynomial variable set to zero. The standard error may be quite large if the range of the other covariates is far from zero. In this situation, the covariates would be centered and their range would include, or come close to including, zero.

These postestimation commands can be used only when the fractional polynomial variables do not interact with other variables in the specification of `est_cmd`. See [U] 11.4.3 Factor variables for more information about interactions.

Syntax for predict

The behavior of `predict` following `fp` is determined by `est_cmd`. See the corresponding `est_cmd` postestimation entry for available `predict` options.

Also see information on `fp predict` below.

Syntax for `fp plot` and `fp predict`

Component-plus-residual plot for most recently fit fractional polynomial model

```
fp plot [if] [in], residuals(res_option) [graph_options]
```

Create variable containing the prediction or SEs of fractional polynomials

```
fp predict [type] newvar [if] [in] [, predict_options]
```
### fp postestimation

- **graph_options**
  - **Description**
  - **Main**
    - `*residuals(res_option)` residual option name to use in `predict` after `est_cmd`, or `residuals(none)` if residuals are not to be graphed
    - `equation(eqno)` specify equation
    - `level(#)` set confidence level; default is `level(95)`
  - **Plot**
    - `plotopts(scatter_options)` affect rendition of the component-plus-residual scatter points
  - **Fitted line**
    - `lineopts(cline_options)` affect rendition of the fitted line
  - **CI plot**
    - `ciopts(area_options)` affect rendition of the confidence bands
  - **Add plots**
    - `addplot(plot)` add other plots to the generated graph
  - **Y axis, X axis, Titles, Legend, Overall**
    - `twoway_options` any options other than `by()` documented in [G-3] `twoway_options`

- **predict_options**
  - **Description**
  - **Main**
    - `fp` calculate the fractional polynomial; the default
    - `stdp` calculate the standard error of the fractional polynomial
    - `equation(eqno)` specify equation

---

**Menu for fp plot and fp predict**

- **fp plot**
  - Statistics > Linear models and related > Fractional polynomials > Component-plus-residual plot

- **fp predict**
  - Statistics > Linear models and related > Fractional polynomials > Fractional polynomial prediction

**Options for fp plot**

- **Main**
  - `residuals(res_option)` specifies what type of residuals to plot in the component-plus-residual plot. `res_option` is the same option that would be specified to `predict` after `est_cmd`. Residuals can be omitted from the plot by specifying `residuals(none)`. `residuals()` is required.
  - `equation(eqno)` is relevant only when you have previously fit a multiple-equation model in `est_cmd`. It specifies the equation to which you are referring.
equation(#1) would mean that the calculation is to be made for the first equation, equation(#2) would mean the second, and so on. You could also refer to the equations by their names: equation(income) would refer to the equation name income, and equation(hours) would refer to the equation named hours.

If you do not specify equation(), the results are the same as if you specified equation(#1).

level(#); see [R] estimation options.

Plot

plotopts(scatter_options) affects the rendition of the component-plus-residual scatter points; see [G-2] graph twoway scatter.

Fitted line

lineopts(cline_options) affects the rendition of the fitted line; see [G-3] cline_options.

CI plot

ciopts(area_options) affects the rendition of the confidence bands; see [G-3] area_options.

Add plots

addplot(plot) provides a way to add other plots to the generated graph. See [G-3] addplot_option.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Options for fp predict

Main

fp calculates the fractional polynomial, the linear prediction with other variables set to zero. This is the default.

stdp calculates the standard error of the fractional polynomial.

equation(eqno) is relevant only when you have previously fit a multiple-equation model in est_cmd. It specifies the equation to which you are referring.

equation(#1) would mean that the calculation is to be made for the first equation, equation(#2) would mean the second, and so on. You could also refer to the equations by their names: equation(income) would refer to the equation name income, and equation(hours) would refer to the equation named hours.

If you do not specify equation(), the results are the same as if you specified equation(#1).
Remarks and examples

After a model is fit using \texttt{fp}, the estimated fractional polynomial may be of interest. This is the linear combination of the fractional polynomial terms and the constant intercept using the model coefficients estimated by \texttt{fp}. It is equivalent to the fitted values prediction given by \texttt{predict,xb}, with the covariates and the fractional polynomial variable set to zero. When these other covariates have been centered, the prediction is made at the centering values of the covariates.

A component-plus-residual plot is generated by \texttt{fp plot}. The fractional polynomial comprises the component, and the residual is specified by the user in \texttt{residuals()}. The \texttt{residuals()} option takes the same argument that would be supplied to \texttt{predict} after \texttt{est\_cmd} to obtain the desired type of residuals. If you only want to plot the component fit, without residuals, you would specify \texttt{residuals(none)}.

\texttt{fp predict} generates the fractional polynomial. If the \texttt{stdp} option is specified, the standard error of the fractional polynomial is generated instead. This standard error may be quite large if the range of the other covariates is far from zero. In this situation, the covariates would be centered and their range would include, or come close to including, zero.

These postestimation commands can be used only when the fractional polynomial terms do not interact with other variables in the specification of \texttt{est\_cmd}. See \texttt{[U]} 11.4.3 Factor variables for more information about interactions.

Examples

\textbf{Example 1: fp plot after linear regression}

In example 1 of \texttt{R fp}, we modeled the mean of the square root of a child’s serum immunoglobulin G (IgG) level as a fractional polynomial function of the child’s age. An FP2 model with powers $(-2, 2)$ is chosen.

We load the data and then fit the model with \texttt{fp}. Then we use \texttt{fp plot} to draw the component-plus-residual plot. A 95\% confidence interval is produced for the fractional polynomial in age (the component). The \texttt{residuals} prediction option for \texttt{regress} is specified in the \texttt{residuals()} option in \texttt{fp plot} so that the residuals are rendered.
Example 2: fp plot after Cox regression

In example 2 of [R] fp, we modeled the time to complete healing of leg ulcers for 192 elderly patients using a Cox regression. A one-degree fractional polynomial in \texttt{mthson}, the number of months since the onset of the ulcer, is used as a predictor in the regression. The power $-0.5$ is used for \texttt{mthson}. Other covariates are age (\texttt{age}), ulcer area (\texttt{ulcarea}), treatment type, and a binary indicator of deep vein involvement (\texttt{deepppg}).

We load the data and then demean ulcer area and age. Then we fit the model with \texttt{fp} and draw the component-plus-residual plot with \texttt{fp plot}. \texttt{mgale} is specified in the \texttt{residuals()} option to obtain martingale residuals. See \texttt{[ST] stcox postestimation} for more details.

```stata
use http://www.stata-press.com/data/r13/legulcer1, clear
quietly stset ttevent, failure(cens)
quietly summarize age
replace age = age - r(mean)
age was byte now float
(192 real changes made)
quietly summarize ulcarea
replace ulcarea = ulcarea - r(mean)
ulcarea was int now float
(192 real changes made)
fp <mthson>, replace center scale nohr fp(-.5): stcox <mthson> age ulcarea > deepppg treat
(output omitted)
fp plot, residuals(mgale)
```
Example 3: fp plot and fp predict after logistic regression

In example 3 of [R] fp, we used logistic regression to model the odds of death for male civil servants in Britain conditional on cigarette consumption. The dependent variable all10 is an indicator of whether the individual passed away in the 10 years under study.

Nonsmokers may be qualitatively different from smokers, so the effect of smoking (regarded as a continuous variable) may not be continuous between zero cigarettes and one cigarette. To allow for this possibility, we model the risk as constant intercept for the nonsmokers and as a fractional polynomial function of the number of cigarettes for the smokers, cigs, adjusted for age. An FP1 model with power 0 is chosen.

We load the data and demean age. Then we fit the model using fp and graph the fit of the model and 95% confidence interval using fp plot. Only the component fit is graphed by specifying residuals(none).

```
. use http://www.stata-press.com/data/r13/smoking, clear
(Smoking and mortality data)
. quietly summarize age
. replace age = age - r(mean)
age was byte now float
(17260 real changes made)
. fp <cigs>, catzero replace fp(0): logit all10 <cigs> age
   -> logit all10 cigs_0 cigs_1 age
```

## Logistic regression

```
Logistic regression

| Coef.     | Std. Err. | z    | P>|z|   | [95% Conf. Interval] |
|------------|-----------|------|-------|----------------------|
| all10      |           |      |       |                      |
| cigs_0     | .1883732  | .1553093 | 1.21  | 0.225    | -.1160274 .4927738 |
| cigs_1     | .3469842  | .0543552 | 6.38  | 0.000    | .2404499 .4535185 |
| age        | .1194976  | .0045818 | 26.08 | 0.000    | .1105174 .1284778 |
| _cons      | -3.003767 | .1514909 | -19.83| 0.000    | -3.300683 -2.70685 |
```
We see a small spike at zero for cigs because of the effect of cigs_0 on the fractional polynomial; however, the high p-value for cigs_0 in the model output indicates that we cannot reject that there is no extra effect at zero for nonsmokers.

We can also use fp predict to predict the fractional polynomial for nonsmokers and the mean of age. This is the value at the spike. We store the result in fp0. We see it is equivalent to the sum of the constant intercept estimate and the estimate of the cigs_0 coefficient.

```
. fp predict fp0 if cigs == 0
(7157 missing values generated)
. summarize fp0
    Variable |     Obs   Mean    Std. Dev.     Min     Max
-------------|-----------|------------|----------------|--------|--------|
         fp0 |     10103  -2.815393      0  -2.815393  -2.815393
. display _b[cigs_0]+_b[_cons]
  -2.8153935
```

**Methods and formulas**

Let the data consist of triplets \((y_i, x_i, z_i)\), \(i = 1, \ldots, n\), where \(z_i\) is the vector of covariates for the \(i\)th observation and \(x_i\) is the fractional polynomial variable.

\[ \hat{\eta}_i = (x_i^{(p_1, \ldots, p_d)} - x_0^{(p_1, \ldots, p_m)})'\hat{\beta} \]

This is equivalent to the linear predictor of the model at \(z_i = 0\). The standard error is calculated from the variance–covariance matrix of \(\hat{\beta}\), ignoring estimation of the powers. When \(x_i \leq 0\), \(H(x_i)\), and thus \(x_i^{(p_1, \ldots, p_m)}\), is either undefined or zero. A zero offset term, \(\alpha_0\), may be added to \(\hat{\eta}_i\) for these nonpositive \(x_i\) values.

The values \(\hat{\eta}_i\) represent the behavior of the fractional polynomial model for \(x\) at fixed values \(z = 0\) of the (centered) covariates. The \(i\)th component-plus-residual is defined as \(\hat{\eta}_i + d_i\), where \(d_i\) is the residual for the \(i\)th observation. The definition of \(d_i\) will change according to the type of model used and the preference of the user. fp plot plots \(\hat{\eta}_i + d_i\) versus \(x_i\), overlaying \(\hat{\eta}_i\) and its confidence interval.
Acknowledgment

We thank Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model* for writing fracplot and fracpred, the commands on which *fp* plot and *fp* predict are based. We also thank Professor Royston for his advice on and review of *fp* plot and *fp* predict.

Statistics > Linear models and related > Frontier models

Description

`frontier` fits stochastic production or cost frontier models; the default is a production frontier model. It provides estimators for the parameters of a linear model with a disturbance that is assumed to be a mixture of two components, which have a strictly nonnegative and symmetric distribution, respectively. `frontier` can fit models in which the nonnegative distribution component (a measurement of inefficiency) is assumed to be from a half-normal, exponential, or truncated-normal distribution. See Kumbhakar and Lovell (2000) for a detailed introduction to frontier analysis.

Options

```
noconstant; see [R] estimation options.
distribution(distname) specifies the distribution for the inefficiency term as half-normal (hnormal), exponential, or truncated-normal (tnormal). The default is hnormal.
ufrom(matrix) specifies a 1 × K matrix of untransformed starting values when the distribution is truncated-normal (tnormal). frontier can estimate the parameters of the model by maximizing either the log likelihood or a transformed log likelihood (see Methods and formulas). frontier automatically transforms the starting values before passing them on to the transformed log likelihood. The matrix must have the same number of columns as there are parameters to estimate.

cm(varlist[, noconstant]) may be used only with distribution(tnormal). Here frontier will fit a conditional mean model in which the mean of the truncated-normal distribution is modeled as a linear function of the set of covariates specified in varlist. Specifying noconstant suppresses the constant in the mean function.
```

```
_model2_

constraints(constraints), collinear; see [R] estimation options.

By default, when fitting the truncated-normal model or the conditional mean model, frontier maximizes a transformed log likelihood. When constraints are applied, frontier will maximize the untransformed log likelihood with constraints defined in the untransformed metric.

uhet(varlist[, noconstant]) specifies that the technical inefficiency component is heteroskedastic, with the variance function depending on a linear combination of varlist_u. Specifying noconstant suppresses the constant term from the variance function. This option may not be specified with distribution(tnormal).

vhet(varlist[, noconstant]) specifies that the idiosyncratic error component is heteroskedastic, with the variance function depending on a linear combination of varlist_v. Specifying noconstant suppresses the constant term from the variance function. This option may not be specified with distribution(tnormal).

cost specifies that frontier fit a cost frontier model.
```
vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg) and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting level(#); see [R] estimation options.
nocnsreport; see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following option is available with frontier but is not shown in the dialog box: coeflegend; see [R] estimation options.

Remarks and examples

Stochastic production frontier models were introduced by Aigner, Lovell, and Schmidt (1977) and Meeusen and van den Broeck (1977). Since then, stochastic frontier models have become a popular subfield in econometrics. Kumbhakar and Lovell (2000) provide a good introduction.

frontier fits three stochastic frontier models with distinct parameterizations of the inefficiency term and can fit stochastic production or cost frontier models.

Let’s review the nature of the stochastic frontier problem. Suppose that a producer has a production function \( f(z_i, \beta) \). In a world without error or inefficiency, the \( i \)th firm would produce

\[
q_i = f(z_i, \beta)
\]

Stochastic frontier analysis assumes that each firm potentially produces less than it might due to a degree of inefficiency. Specifically,

\[
q_i = f(z_i, \beta) \xi_i
\]

where \( \xi_i \) is the level of efficiency for firm \( i \); \( \xi_i \) must be in the interval \((0, 1]\). If \( \xi_i = 1 \), the firm is achieving the optimal output with the technology embodied in the production function \( f(z_i, \beta) \). When \( \xi_i < 1 \), the firm is not making the most of the inputs \( z_i \) given the technology embodied in the production function \( f(z_i, \beta) \). Because the output is assumed to be strictly positive (that is, \( q_i > 0 \)), the degree of technical efficiency is assumed to be strictly positive (that is, \( \xi_i > 0 \)).

Output is also assumed to be subject to random shocks, implying that

\[
q_i = f(z_i, \beta) \xi_i \exp(v_i)
\]
Taking the natural log of both sides yields

$$\ln(q_i) = \ln\{f(z_i, \beta)\} + \ln(\xi_i) + v_i$$

Assuming that there are $k$ inputs and that the production function is linear in logs, defining $u_i = -\ln(\xi_i)$ yields

$$\ln(q_i) = \beta_0 + \sum_{j=1}^{k} \beta_j \ln(z_{ji}) + v_i - u_i \quad (1)$$

Because $u_i$ is subtracted from $\ln(q_i)$, restricting $u_i \geq 0$ implies that $0 < \xi_i \leq 1$, as specified above.

Kumbhakar and Lovell (2000) provide a detailed version of the above derivation, and they show that performing an analogous derivation in the dual cost function problem allows us to specify the problem as

$$\ln(c_i) = \beta_0 + \beta_q \ln(q_i) + \sum_{j=1}^{k} \beta_j \ln(p_{ji}) + v_i + u_i \quad (2)$$

where $q_i$ is output, $z_{ji}$ are input quantities, $c_i$ is cost, and the $p_{ji}$ are input prices.

Intuitively, the inefficiency effect is required to lower output or raise expenditure, depending on the specification.

**Technical note**

The model that frontier actually fits is of the form

$$y_i = \beta_0 + \sum_{j=1}^{k} \beta_j x_{ji} + v_i - su_i$$

where

$$s = \begin{cases} 
1, & \text{for production functions} \\
-1, & \text{for cost functions}
\end{cases}$$

so, in the context of the discussion above, $y_i = \ln(q_i)$, and $x_{ji} = \ln(z_{ji})$ for a production function; and for a cost function, $y_i = \ln(c_i)$, and the $x_{ji}$ are the $\ln(p_{ji})$ and $\ln(q_i)$. You must take the natural logarithm of the data before fitting a stochastic frontier production or cost model. frontier performs no transformations on the data.

Different specifications of the $u_i$ and the $v_i$ terms give rise to distinct models. frontier provides estimators for the parameters of three basic models in which the idiosyncratic component, $v_i$, is assumed to be independently $N(0, \sigma_v^2)$ distributed over the observations. The basic models differ in their specification of the inefficiency term, $u_i$, as follows:

- **exponential**: the $u_i$ are independently exponentially distributed with variance $\sigma_u^2$
- **hnormal**: the $u_i$ are independently half-normally $N^+(0, \sigma_u^2)$ distributed
- **tnormal**: the $u_i$ are independently $N^+(\mu, \sigma_u^2)$ distributed with truncation point at 0

For half-normal or exponential distributions, frontier can fit models with heteroskedastic error components, conditional on a set of covariates. For a truncated-normal distribution, frontier can also fit a conditional mean model in which the mean is modeled as a linear function of a set of covariates.
Example 1: The half-normal and the exponential models

For our first example, we demonstrate the half-normal and exponential models by reproducing a study found in Greene (2003, 505), which uses data originally published in Zellner and Revankar (1969). In this study of the transportation-equipment manufacturing industry, observations on value added, capital, and labor are used to estimate a Cobb–Douglas production function. The variable $\ln v$ is the log-transformed value added, $\ln k$ is the log-transformed capital, and $\ln l$ is the log-transformed labor. OLS estimates are compared with those from stochastic frontier models using both the half-normal and exponential distribution for the inefficiency term.

</table>
The parameter estimates and the estimates of the inefficiency terms closely match those published in Greene (2003, 505), but the standard errors of the parameter estimates are estimated differently (see the technical note below).

The output from `frontier` includes estimates of the standard deviations of the two error components, $\sigma_v$ and $\sigma_u$, which are labeled `sigma_v` and `sigma_u`, respectively. In the log likelihood, they are parameterized as $\ln \sigma_v^2$ and $\ln \sigma_u^2$, and these estimates are labeled `/lnsig2v` and `/lnsig2u` in the output. `frontier` also reports two other useful parameterizations. The estimate of the total error variance, $\sigma_S^2 = \sigma_v^2 + \sigma_u^2$, is labeled `sigma2`, and the estimate of the ratio of the standard deviation of the inefficiency component to the standard deviation of the idiosyncratic component, $\lambda = \sigma_u / \sigma_v$, is labeled `lambda`.

At the bottom of the output, `frontier` reports the results of a test that there is no technical inefficiency component in the model. This is a test of the null hypothesis $H_0 : \sigma_u^2 = 0$ against the alternative hypotheses $H_1 : \sigma_u^2 > 0$. If the null hypothesis is true, the stochastic frontier model reduces to an OLS model with normal errors. However, because the test lies on the boundary of the parameter space of $\sigma_u^2$, the standard likelihood-ratio test is not valid, and a one-sided generalized likelihood-ratio test must be constructed; see Gutierrez, Carter, and Drukker (2001). For this example, the output shows $LR = 0.43$ with a $p$-value of 0.256 for the half-normal model and $LR = 1.21$ with a $p$-value of 0.135 for the exponential model. There are several possible reasons for the failure to reject the null hypothesis, but the fact that the test is based on an asymptotic distribution and the sample size was 25 is certainly a leading candidate among those possibilities.

Technical note

`frontier` maximizes the log-likelihood function of a stochastic frontier model by using the Newton–Raphson method, and the estimated variance–covariance matrix is calculated as the inverse of the negative Hessian (matrix of second partial derivatives); see [R] `ml`. When comparing the results with those published using other software, be aware of the difference in the optimization methods, which may result in different, yet asymptotically equivalent, variance estimates.

Example 2: Models with heteroskedasticity

Often the error terms may not have constant variance. `frontier` allows you to model heteroskedasticity in either error term as a linear function of a set of covariates. The variance of either the technical inefficiency or the idiosyncratic component may be modeled as

$$\sigma_i^2 = \exp(w_i\delta)$$

The default constant included in $w_i$ may be suppressed by appending a `noconstant` option to the list of covariates. Also, you can simultaneously specify covariates for both $\sigma_{ui}$ and $\sigma_{vi}$.

In this example, we use a sample of 756 observations of fictional firms producing a manufactured good by using capital and labor. The firms are hypothesized to use a constant returns-to-scale technology, but the sizes of the firms differ. Believing that this size variation will introduce heteroskedasticity into the idiosyncratic error term, we estimate the parameters of a Cobb–Douglas production function. To do this, we use a conditional heteroskedastic half-normal model, with the size of the firm as an explanatory variable in the variance function for the idiosyncratic error. We also perform a test of the hypothesis that the firms use a constant returns-to-scale technology.
. use http://www.stata-press.com/data/r13/frontier1, clear

Iteration 4:  log likelihood =  -1500.3794
Stoc. frontier normal/half-normal model                 Number of obs =       756
                                      Wald chi2(2) =    9.68
Log likelihood =  -1500.3794  Prob > chi2 =  0.0079

|                | Coef.     | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|----------------|-----------|-----------|-------|------|----------------------|
| lnsig2v        |           |           |       |      |                      |
| _cons          | 3.156091  | .9265826  | 3.41  | 0.001| 1.340023 4.97216   |
| lnsig2v        | 1.947487  | .1017653  | 19.14 | 0.000| 1.748031 2.146943  |
| sigma_u        | 2.647838  | .134729   | 2.396514 | 2.925518

. test _b[lnlabor] + _b[lncapital] = 1
( 1)  [lnoutput]lnlabor + [lnoutput]lncapital = 1
         chi2( 1) =  0.03
         Prob > chi2 =  0.8622

The output above indicates that the variance of the idiosyncratic error term is a function of firm size. Also, we failed to reject the hypothesis that the firms use a constant returns-to-scale technology.

Technical note

In small samples, the conditional heteroskedastic estimators will lack precision for the variance parameters and may fail to converge altogether.

Example 3: The truncated-normal model

Let’s turn our attention to the truncated-normal model. Once again, we will use fictional data. For this example, we have 1,231 observations on the quantity of output, the total cost of production for each firm, the prices that each firm paid for labor and capital services, and a categorical variable measuring the quality of each firm’s management. After taking the natural logarithm of the costs (lncost), prices (lnp_k and lnp_l), and output (lnout), we fit a stochastic cost frontier model and specify the distribution for the inefficiency term to be truncated normal.
. use http://www.stata-press.com/data/r13/frontier2

. frontier incost lnp_k lnp_l lnout, distribution(tnormal) cost

H0: No inefficiency component:  z = 5.595  Prob>=z = 0.000

In addition to the coefficients, the output reports estimates for several parameters. sigma_v2 is the estimate of \( \sigma_v^2 \). sigma_u2 is the estimate of \( \sigma_u^2 \). gamma is the estimate of \( \gamma = \sigma_u^2 / \sigma_S^2 \). sigma2 is the estimate of \( \sigma_S^2 = \sigma_v^2 + \sigma_u^2 \). Because \( \gamma \) must be between 0 and 1, the optimization is parameterized in terms of the inverse logit of \( \gamma \), and this estimate is reported as ilgtgamma. Because \( \sigma_S^2 \) must be positive, the optimization is parameterized in terms of \( \ln(\sigma_S^2) \), whose estimate is reported as lnsigma2. Finally, mu is the estimate of \( \mu \), the mean of the truncated-normal distribution.

In the output above, the generalized log-likelihood test for the presence of the inefficiency term has been replaced with a test based on the third moment of the OLS residuals. When \( \mu = 0 \) and \( \sigma_u = 0 \), the truncated-normal model reduces to a linear regression model with normally distributed errors. However, the distribution of the test statistic under the null hypothesis is not well established, because it becomes impossible to evaluate the log likelihood as \( \sigma_u \) approaches zero, prohibiting the use of the likelihood-ratio test.

However, Coelli (1995) noted that the presence of an inefficiency term would negatively skew the residuals from an OLS regression. By identifying negative skewness in the residuals with the presence of an inefficiency term, Coelli derived a one-sided test for the presence of the inefficiency term. The results of this test are given at the bottom of the output. For this example, the null hypothesis of no inefficiency component is rejected.

In the example below, we fit a truncated model and detect a statistically significant inefficiency term in the model. We might question whether the inefficiency term is identically distributed over all firms or whether there might be heterogeneity across firms. frontier provides an extension to the truncated normal model by allowing the mean of the inefficiency term to be modeled as a linear function of a set of covariates. In our dataset, we have a categorical variable that measures the quality of a firm’s management. We refit the model, including the cm( ) option, specifying a set of
binary indicator variables representing the different categories of the quality-measurement variable as covariates.

```

The conditional mean model was developed in the context of panel-data estimators, and we can apply frontier's conditional mean model to panel data.
Stored results

frontier stores the following in \( e() \):

Scalars

- \( e(N) \) number of observations
- \( e(df_m) \) model degrees of freedom
- \( e(k) \) number of parameters
- \( e(k_{eq}) \) number of equations in \( e(b) \)
- \( e(k_{eq_model}) \) number of equations in overall model test
- \( e(k_{dv}) \) number of dependent variables
- \( e(chi2) \) \( \chi^2 \)
- \( e(ll) \) log likelihood
- \( e(ll_c) \) log likelihood for \( H_0: \sigma_u=0 \)
- \( e(z) \) test for negative skewness of OLS residuals
- \( e(sigma_u) \) standard deviation of technical inefficiency
- \( e(sigma_v) \) standard deviation of \( v_i \)
- \( e(p) \) significance
- \( e(chi2_c) \) LR test statistic
- \( e(p_z) \) \( p \)-value for \( z \)
- \( e(rank) \) rank of \( e(V) \)
- \( e(ic) \) number of iterations
- \( e(rc) \) return code
- \( e(converged) \) 1 if converged, 0 otherwise

Macros

- \( e(asobserved) \) factor variables \texttt{fvset} as \texttt{asobserved}
Methods and formulas

Consider an equation of the form

\[ y_i = x_i \beta + v_i - su_i \]

where \( y_i \) is the dependent variable, \( x_i \) is a \( 1 \times k \) vector of observations on the independent variables included as indent covariates, \( \beta \) is a \( k \times 1 \) vector of coefficients, and

\[ s = \begin{cases} 
1, & \text{for production functions} \\
-1, & \text{for cost functions} 
\end{cases} \]

The log-likelihood functions are as follows.

**Normal/half-normal model:**

\[
\ln L = \sum_{i=1}^{N} \left\{ \frac{1}{2} \ln \left( \frac{2}{\pi} \right) - \ln \sigma_S + \ln \Phi \left( -\frac{s \epsilon_i \lambda}{\sigma_S} \right) - \frac{\epsilon_i^2}{2 \sigma_S^2} \right\}
\]

**Normal/exponential model:**

\[
\ln L = \sum_{i=1}^{N} \left\{ -\ln \sigma_u + \frac{\sigma_v^2}{2 \sigma_u^2} + \ln \Phi \left( \frac{-s \epsilon_i \sigma_s^2}{\sigma_v} \right) + \frac{s \epsilon_i}{\sigma_u} \right\}
\]

**Normal/truncated-normal model:**

\[
\ln L = \sum_{i=1}^{N} \left\{ -\frac{1}{2} \ln (2\pi) - \ln \sigma_S - \ln \Phi \left( \frac{\mu}{\sigma_S \sqrt{\gamma}} \right) \\
+ \ln \Phi \left[ \frac{(1 - \gamma) \mu - s \gamma \epsilon_i}{\{\sigma_S^2 \gamma (1 - \gamma)\}^{1/2}} \right] - \frac{1}{2} \left( \frac{\epsilon_i + s \mu}{\sigma_S} \right)^2 \right\}
\]
where $\sigma_S = (\sigma_u^2 + \sigma_v^2)^{1/2}$, $\lambda = \sigma_u / \sigma_v$, $\gamma = \sigma_u^2 / \sigma_S^2$, $\epsilon_i = y_i - x_i \beta$, and $\Phi()$ is the cumulative distribution function of the standard normal distribution.

To obtain estimation for $u_i$, you can use either the mean or the mode of the conditional distribution $f(u|\epsilon)$.

$$E(u_i | \epsilon_i) = \mu_{*i} + \sigma_* \left\{ \frac{\phi(-\mu_{*i}/\sigma_*)}{\Phi(\mu_{*i}/\sigma_*)} \right\}$$

$$M(u_i | \epsilon_i) = \begin{cases} \mu_{*i} & \text{if } \mu_{*i} \geq 0 \\ 0 & \text{otherwise} \end{cases}$$

Then the technical efficiency ($s = 1$) or cost efficiency ($s = -1$) will be estimated by

$$E_i = E\{\exp(-su_i) | \epsilon_i\} = \left\{ \frac{1 - \Phi(s\sigma_* - \mu_{*i}/\sigma_*)}{1 - \Phi(-\mu_{*i}/\sigma_*)} \right\} \exp\left(-s\mu_{*i} + \frac{1}{2}\sigma_*^2\right)$$

where $\mu_{*i}$ and $\sigma_*$ are defined for the normal/half-normal model as

$$\mu_{*i} = -s\epsilon_i \sigma_u^2 / \sigma_S^2$$

$$\sigma_* = \sigma_u \sigma_v / \sigma_S$$

for the normal/exponential model as

$$\mu_{*i} = -s\epsilon_i - \sigma_v^2 / \sigma_u$$

$$\sigma_* = \sigma_v$$

and for the normal/truncated-normal model as

$$\mu_{*i} = -s\epsilon_i \sigma_u^2 + \mu \sigma_v^2 / \sigma_S^2$$

$$\sigma_* = \sigma_u \sigma_v / \sigma_S$$

In the half-normal and exponential models, when heteroskedasticity is assumed, the standard deviations, $\sigma_u$ or $\sigma_v$, will be replaced in the above equations by

$$\sigma_i^2 = \exp(w_i \delta)$$

where $w$ is the vector of explanatory variables in the variance function.

In the conditional mean model, the mean parameter of the truncated normal distribution, $\mu$, is modeled as a linear combination of the set of covariates, $w$.

$$\mu = w_i \delta$$
Therefore, the log-likelihood function can be rewritten as

\[
\ln L = \sum_{i=1}^{N} \left[ -\frac{1}{2} \ln (2\pi) - \ln \sigma_S - \ln \Phi \left( \frac{w_i \delta}{\sqrt{\sigma_S \gamma}} \right) \right. \\
+ \ln \Phi \left\{ \frac{(1 - \gamma) w_i \delta - s \gamma \epsilon_i}{\sqrt{\sigma_S \gamma (1 - \gamma)}} \right\} - \frac{1}{2} \left( \frac{\epsilon_i + s w_i \delta}{\sigma_S} \right)^2 \]
\]

The \( z \) test reported in the output of the truncated-normal model is a third-moment test developed by Coelli (1995) as an extension of a test previously developed by Pagan and Hall (1983). Coelli shows that under the null of normally distributed errors, the statistic

\[
z = \frac{m_3}{\left( \frac{6m_3^2}{N} \right)^{1/2}}
\]

has a standard normal distribution, where \( m_3 \) is the third moment from the OLS regression. Because the residuals are either negatively skewed (production function) or positively skewed (cost function), a one-sided \( p \)-value is used.

</tbody>
</table>

$s = \left\{ \begin{array}{ll} 1, & \text{for production functions} \\ -1, & \text{for cost functions} \end{array} \right.$

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

### Menu for predict

Statistics $>$ Postestimation $>$ Predictions, residuals, etc.

### Options for predict

- **xb**, the default, calculates the linear prediction.
- **stdp** calculates the standard error of the linear prediction.
- **u** produces estimates of minus the natural log of the technical efficiency via $E(u_i | \epsilon_i)$.
- **m** produces estimates of minus the natural log of the technical efficiency via $M(u_i | \epsilon_i)$.
- **te** produces estimates of the technical efficiency via $E\{\exp(-su_i) | \epsilon_i\}$.
- **scores** calculates equation-level score variables.

The first new variable will contain $\partial \ln L / \partial (x_i \beta)$.

The second new variable will contain $\partial \ln L / \partial (\ln \sigma^2 v)$.

The third new variable will contain $\partial \ln L / \partial (\ln \sigma^2 u)$.

### Remarks and examples

#### Example 1

In example 2 of [R] frontier, we modeled heteroskedasticity by specifying the `vhet()` option. We would like to compare the predicted efficiency in that case with respect to a model specification without accounting for the presence of heteroskedasticity in the error term. Kumbhakar and Lovell (2000, 117) show that failing to account for heteroskedasticity associated with firm size may lead to bias in the estimation of the technical efficiency. By incorrectly assuming homoskedasticity, the estimates for relatively small firms would be biased upward, while the estimates for relatively large firms would be biased downward. Let’s refit the model and use the `te` option of `predict`: 
. use http://www.stata-press.com/data/r13/frontier1
. frontier lnoutput lnlabor lncapital, vhet(size)
    (output omitted)
. predict te_vhet, te

Next we fit the model assuming homoskedasticity and then again predict the technical efficiency with the te option of predict:

. frontier lnoutput lnlabor lncapital
    (output omitted)
. predict te, te

The graph below shows the estimates for technical efficiency for the smaller and larger firms. The technical efficiency tends to be smaller for smaller firms when the model specification accounts for the presence of heteroskedasticity, whereas the predictions for the technical efficiency tends to be smaller for larger firms assuming homoskedasticity. These results agree with the theoretical statement in Kumbhakar and Lovell (2000) because the firm size was actually relevant to model heteroskedasticity in the idiosyncratic component of the error term.

Example 2

We also test in example 2 of [R] frontier whether the firms use constant returns to scale. We can use lincom as an alternative to perform an equivalent test based on the normal distribution.

. use http://www.stata-press.com/data/r13/frontier1, clear
. frontier lnoutput lnlabor lncapital, vhet(size)
    (output omitted)
. lincom _b[lnlabor] + _b[lncapital]-1
    ( 1)  [lnoutput]lnlabor + [lnoutput]lncapital = 1

| lnoutput  | Coef. | Std. Err. | z    | P>|z|   | [95% Conf. Interval] |
|-----------|-------|-----------|------|-------|----------------------|
| (1)       | .1022278 | .5888511 | 0.17 | 0.862 | -1.051899  1.256355 |
The \( p \)-value is exactly the same as the one we obtained with the `test` command in example 2 of \texttt{R frontier}. However, notice that by using \texttt{lincom}, we obtained an estimate of the deviation from the constant returns-to-scale assumption, which is not significantly different from zero in this case.

\texttt{R frontier} — Stochastic frontier models

\texttt{U 20 Estimation and postestimation commands}
Title

fvrevar — Factor-variables operator programming command

Syntax Description Options Remarks and examples
Stored results Also see

Syntax

fvrevar [varlist] [if] [in] [, substitute tsonly list stub(stub)]

You must tsset your data before using fvrevar if varlist contains time-series operators; see [TS] tsset.

Description

fvrevar creates an equivalent, temporary variable list for a varlist that might contain factor variables, interactions, or time-series–operated variables so that the resulting variable list can be used by commands that do not otherwise support factor variables or time-series–operated variables. The resulting list also could be used in a program to speed execution at the cost of using more memory.

Options

substitute specifies that equivalent, temporary variables be substituted for any factor variables, interactions, or time-series–operated variables in varlist. substitute is the default action taken by fvrevar; you do not need to specify the option.

tsonly specifies that equivalent, temporary variables be substituted for only the time-series–operated variables in varlist.

list specifies that all factor-variable operators and time-series operators be removed from varlist and the resulting list of base variables be returned in r(varlist). No new variables are created with this option.

stub(stub) specifies that fvrevar generate named variables instead of temporary variables. The new variables will be named stub#.

Remarks and examples

fvrevar might create no new variables, one new variable, or many new variables, depending on the number of factor variables, interactions, and time-series operators appearing in varlist. Any new variables created are temporary. The new, equivalent varlist is returned in r(varlist). The new varlist corresponds one to one with the original varlist.

Example 1

Typing

. use http://www.stata-press.com/data/r13/auto2
. fvrevar i.rep78 mpg turn
creates five temporary variables corresponding to the levels of rep78. No new variables are created for variables mpg and turn because they do not contain factor-variable or time-series operators.

The resulting variable list is

```
. display "'r(varlist)'"
   __000000 __000001 __000002 __000003 __000004  mpg turn
```

(Your temporary variable names may be different, but that is of no consequence.)

Temporary variables automatically vanish when the program concludes.

### Example 2

Suppose we want to create temporary variables for specific levels of a factor variable. To do this, we can use the parenthesis notation of factor-variable syntax.

```
. fvrevar i(2,3)bn.rep78 mpg
```

creates two temporary variables corresponding to levels 2 and 3 of rep78. Notice that we specified that neither level 2 nor 3 be set as the base level by using the bn notation. If we did not specify bn, level 2 would have been treated as the base level.

The resulting variable list is

```
. display "'r(varlist)'"
   __000005 __000002  mpg
```

We can see the results by listing the new variables alongside the original value of rep78.

```
. list rep78 'r(varlist)' in 1/5

</tr>
</tbody>
</table>
```

If we had needed only the base-variable names, we could have specified

```
. fvrevar i(2,3)bn.rep78 mpg, list
. display "'r(varlist)'"
   mpg rep78
```

The order of the list will probably differ from that of the original list; base variables are listed only once.

### Example 3

Now let’s assume we have a varlist containing both an interaction and time-series–operated variables. If we want to create temporary variables for the entire equivalent varlist, we can specify fvrevar with no options.
. generate t = _n
. tsset t
    time variable: t, 1 to 74
delta: 1 unit
. fvrevar c.turn#i(2,3).rep78 L.mpg

The resulting variable list is
. display "'r(varlist)'"
  __000006 __000007 __000008

If we want to create temporary variables only for the time-series–operated variables, we can specify
the `tsonly` option.
. fvrevar c.turn#i(2,3).rep78 L.mpg, tsonly

The resulting variable list is
. display "'r(varlist)'"
  c.turn#2b.rep78 c.turn#3.rep78 __000008

Notice that `fvrevar` returned the expanded factor-variable list with the `tsonly` option.

Technical note

`fvrevar`, substitute avoids creating duplicate variables. Consider
. fvrevar i.rep78 turn mpg i.rep78

`i.rep78` appears twice in the varlist. `fvrevar` will create only one set of new variables for the
five levels of `rep78` and will use these new variables once in the resulting `r(varlist)`. Moreover,
`fvrevar` will do this even across multiple calls:
. fvrevar i.rep78 turn mpg
. fvrevar i.rep78

`i.rep78` appears in two separate calls. At the first call, `fvrevar` creates five temporary variables
corresponding to the five levels of `rep78`. At the second call, `fvrevar` remembers what it has done
and uses the same temporary variables for `i.rep78`.

Stored results

`fvrevar` stores the following in `r()`:
Macros
  r(varlist) the modified variable list or list of base-variable names

</tr>
</tbody>
</table>

Description

fvset declares factor-variable settings. Factor-variable settings identify the base level and how to accumulate statistics over levels.

fvset base specifies the base level for each variable in varlist. The default for factor variables without a declared base level is first.
fvset design specifies how to accumulate over the levels of a factor variable. The margins command is the only command aware of this setting; see [R] margins. By default, margins assumes that factor variables are asobserved, meaning that they are accumulated by weighting by the number of observations or the sum of the weights if weights have been specified.

fvset clear removes factor-variable settings for each variable in varlist. fvset clear _all removes all factor-variable settings from all variables.

fvset report reports the current factor-variable settings for each variable in varlist. fvset without arguments is a synonym for fvset report.

Options

gbase(base_spec) restricts fvset report to report only the factor-variable settings for variables with the specified base_spec.

gdesign(design_spec) restricts fvset report to report only the factor-variable settings for variables with the specified design_spec.

Remarks and examples

Example 1

Using auto2.dta, we include factor variable i.rep78 in a regression:

```
. use http://www.stata-press.com/data/r13/auto2
(1978 Automobile Data)
. regress mpg i.rep78, baselevels
```

```
Source | SS df MS
-------+--------------------------------------------------
Model | 549.415777 4 137.353944
Residual | 1790.78712 64 27.9810488
Total | 2340.2029 68 34.4147485

Number of obs = 69
F( 4, 64) = 4.91
Prob > F = 0.0016
R-squared = 0.2348
Adj R-squared = 0.1869
Root MSE = 5.2897

mpg | Coef. Std. Err. t P>|t| [95% Conf. Interval]
-------+--------------------------------------------------
rep78 | 
Poor | -1.875 4.181884 -0.45 0.655 -10.22927 6.479274
Fair | -1.566667 3.863059 -0.41 0.686 -9.284014 6.150681
Average | .6666667 3.942718 0.17 0.866 -7.209818 8.543152
Good | 6.363636 4.066234 1.56 0.123 -1.759599 14.48687
Excellent | 
_cons | 21 3.740391 5.61 0.000 13.52771 28.47229
```

We specified the baselevels option so that the base level would be included in the output. By default, the first level is the base level. We can change the base level to 2:
. fvset base 2 rep78
. regress mpg i.rep78, baselevels

<table>
<thead>
<tr>

<td></td>
</tr>
</tbody>
</table>

Let's set `foreign` to always accumulate using equal relative frequencies:

```
.fvset design asbalanced foreign
.regress mpg i.foreign
```

Source | SS  | df | MS   | Number of obs = 74
Model  | 378.153515 | 1  | 378.153515 | F( 1, 72) = 13.18
Residual | 2065.30594 | 72 | 28.6848048 | Prob > F = 0.0005
Total   | 2443.45946 | 73 | 33.4720474 | R-squared = 0.1548

Adj R-squared = 0.1430

Root MSE = 5.3558

mpg Coef. Std. Err. t P>|t| [95% Conf. Interval]
foreign | 4.945804 | 1.362162 | 3.63 | 0.001 | 2.230384 7.661225
Foreign | 19.82692 | .7427186 | 26.70 | 0.000 | 18.34634 21.30751

Adjusted predictions Number of obs = 74
Model VCE : OLS
Expression : Linear prediction, predict()
at : foreign (asbalanced)

<table>
<thead>
<tr>
<th></th>
<th>Delta-method</th>
<th></th>
<th></th>
<th></th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Margin Std. Err. t P&gt;</td>
<td>t</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>_cons</td>
<td>22.29983 .6810811 32.74 0.000 20.94211 23.65754</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Suppose that we issued the `fvset design` command earlier in our session and that we cannot remember which variables we set as `asbalanced`. We can retrieve this information by using the `fvset report` command:

```
.fvset report, design(asbalanced)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Base</th>
<th>Design</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td></td>
<td>asbalanced</td>
</tr>
</tbody>
</table>

⚠️ Technical note

`margins` is aware of a factor variable’s design setting only through the estimation results it is working with. The design setting is stored by the estimation command; thus changing the design setting between the estimation command and `margins` will have no effect. For example, the output from the following two calls to `margins` yields the same results:
. fvset clear foreign  
. regress mpg i.foreign

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>

r(designlist) design setting for each variable in varlist
gllamm — Generalized linear and latent mixed models

Description

GLLAMM stands for generalized linear latent and mixed models, and gllamm is a Stata command for fitting such models written by Sophia Rabe-Hesketh (University of California–Berkeley) as part of joint work with Anders Skrondal (Norwegian Institute of Public Health) and Andrew Pickles (King’s College London).

Remarks and examples

Generalized linear latent and mixed models are a class of multilevel latent variable models, where a latent variable is a factor or a random effect (intercept or coefficient), or a disturbance (residual). The gllamm command for fitting such models is not an official command of Stata; it has been independently developed by highly regarded authors and is itself highly regarded. You can learn more about gllamm by visiting http://www.gllamm.org.

gllamm is available from the Statistical Software Components (SSC) archive. To install, type

```
.ssc describe gllamm
.ssc install gllamm
```

If you later wish to uninstall gllamm, type ado uninstall gllamm.

References

The references above are restricted to works by the primary authors of gllamm. There are many other books and articles that use or discuss gllamm; see http://www.gllamm.org/pub.html for a list.

Syntax

```
glm depvar [ indepvars ] [ if ] [ in ] [ weight ] [ , options ]
```

```
options                       Description

Model

family(familyname)            distribution of depvar; default is family(gaussian)
link(linkname)                link function; default is canonical link for family() specified

Model 2

noconstant                   suppress constant term
exposure(varname)             include ln(varname) in model with coefficient constrained to 1
offset(varname)               include varname in model with coefficient constrained to 1
constraints(constraints)      apply specified linear constraints
collinear                     keep collinear variables
asis                          retain perfect predictor variables
mu(varname)                   use varname as the initial estimate for the mean of depvar
init(varname)                 synonym for mu(varname)

SE/Robust

vce(vcetype)                  vcetype may be oim, robust, cluster clustvar, eim, opg,
                               bootstrap, jackknife, hac kernel, jackknife1, or unbiased
vfactor(#)                    multiply variance matrix by scalar #
disp(#)                       quasilikelihood multiplier
scale(x2 | dev | #)            set the scale parameter

Reporting

level(#)                      set confidence level; default is level(95)
eform                         report exponentiated coefficients
nocnsreport                   do not display constraints
display_options

Maximization

ml                            use maximum likelihood optimization; the default
irls                          use iterated, reweighted least-squares optimization of the deviance
maximize_options              control the maximization process; seldom used
fisher(#)                    use the Fisher scoring Hessian or expected information matrix (EIM)
search                        search for good starting values
noheader          suppress header table from above coefficient table  
notable           suppress coefficient table                           
nodisplay         suppress the output; iteration log is still displayed 
coeflegend       display legend instead of statistics

*indevars* may contain factor variables; see [U] 11.4.3 Factor variables.

*depvars* and *indevars* may contain time-series operators; see [U] 11.4.4 Time-series varlists.

*bootstrap*, *by*, *fp*, *jackknife*, *mfp*, *mi estimate*, *nestreg*, *rolling*, *statsby*, *stepwise*, and *svy* are allowed; see [U] 11.1.10 Prefix commands.

vce(bootstrap), vce(jackknife), and vce(jackknife1) are not allowed with the *mi estimate* prefix; see [MI] mi estimate.

Weights are not allowed with the *bootstrap* prefix; see [R] bootstrap.

aweights are not allowed with the *jackknife* prefix; see [R] jackknife.

vce(), vfactor(), disp(), scale(), irls, fisher(), noheader, notable, nodisplay, and weights are not allowed with the *svy* prefix; see [SVY] svy.

fweights, aweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.

noheader, notable, nodisplay, and coeflegend do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Menu**

*Statistics > Generalized linear models > Generalized linear models (GLM)*

**Description**

glm fits generalized linear models. It can fit models by using either IRLS (maximum quasilikelihood) or Newton–Raphson (maximum likelihood) optimization, which is the default.
See [U] 26 Overview of Stata estimation commands for a description of all of Stata’s estimation commands, several of which fit models that can also be fit using glm.

Options

**Model**

family(familyname) specifies the distribution of depvar; family(gaussian) is the default.

link(linkname) specifies the link function; the default is the canonical link for the family() specified (except for family(nbinomial)).

**Model 2**

noconstant, exposure(varname), offset(varname), constraints(constraints), collinear; see [R] estimation options. constraints(constraints) and collinear are not allowed with irls.

asis forces retention of perfect predictor variables and their associated, perfectly predicted observations and may produce instabilities in maximization; see [R] probit. This option is only allowed with option family(binomial) with a denominator of 1.

mu(varname) specifies varname as the initial estimate for the mean of depvar. This option can be useful with models that experience convergence difficulties, such as family(binomial) models with power or odds-power links. init(varname) is a synonym.

**SE/Robust**

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce option.

In addition to the standard vcetypes, glm allows the following alternatives:

vce(eim) specifies that the EIM estimate of variance be used.

vce(jackknife1) specifies that the one-step jackknife estimate of variance be used.

vce(hac kernel [#]) specifies that a heteroskedasticity- and autocorrelation-consistent (HAC) variance estimate be used. HAC refers to the general form for combining weighted matrices to form the variance estimate. There are three kernels built into glm. kernel is a user-written program or one of

   nwest | gallant | anderson

# specifies the number of lags. If # is not specified, $N - 2$ is assumed. If you wish to specify vce(hac ...), you must tsset your data before calling glm.

vce(unbiased) specifies that the unbiased sandwich estimate of variance be used.

vfactor(#) specifies a scalar by which to multiply the resulting variance matrix. This option allows you to match output with other packages, which may apply degrees of freedom or other small-sample corrections to estimates of variance.

disp(#) multiplies the variance of depvar by # and divides the deviance by #. The resulting distributions are members of the quasilikelihood family.

scale(x2 | dev | #) overrides the default scale parameter. This option is allowed only with Hessian (information matrix) variance estimates.
By default, \texttt{scale(1)} is assumed for the discrete distributions (binomial, Poisson, and negative binomial), and \texttt{scale(x2)} is assumed for the continuous distributions (Gaussian, gamma, and inverse Gaussian).

\texttt{scale(x2)} specifies that the scale parameter be set to the Pearson chi-squared (or generalized chi-squared) statistic divided by the residual degrees of freedom, which is recommended by McCullagh and Nelder (1989) as a good general choice for continuous distributions.

\texttt{scale(dev)} sets the scale parameter to the deviance divided by the residual degrees of freedom. This option provides an alternative to \texttt{scale(x2)} for continuous distributions and overdispersed or underdispersed discrete distributions.

\texttt{scale(#)} sets the scale parameter to \#. For example, using \texttt{scale(1)} in \texttt{family(gamma)} models results in exponential-errors regression. Additional use of \texttt{link(log)} rather than the default \texttt{link(power -1)} for \texttt{family(gamma)} essentially reproduces Stata's \texttt{streg, dist(exp) nohr} command (see \texttt{[ST] streg}) if all the observations are uncensored.

\texttt{Reporting level(#)}; see \texttt{[R] estimation options}.

\texttt{eform} displays the exponentiated coefficients and corresponding standard errors and confidence intervals. For \texttt{family(binomial) link(logit)} (that is, logistic regression), exponentiation results are odds ratios; for \texttt{family(nbinomial) link(log)} (that is, negative binomial regression) and for \texttt{family(poisson) link(log)} (that is, Poisson regression), exponentiated coefficients are incidence-rate ratios.

\texttt{nocnsreport}; see \texttt{[R] estimation options}.

\texttt{display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch}; see \texttt{[R] estimation options}.

\texttt{Maximization ml} requests that optimization be carried out using Stata's \texttt{ml} commands and is the default.

\texttt{irls} requests iterated, reweighted least-squares (IRLS) optimization of the deviance instead of Newton–Raphson optimization of the log likelihood. If the \texttt{irls} option is not specified, the optimization is carried out using Stata's \texttt{ml} commands, in which case all options of \texttt{ml maximize} are also available.

\texttt{maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs)}; see \texttt{[R] maximize}. These options are seldom used.

Setting the optimization type to \texttt{technique(bhhh)} resets the default \texttt{vcetype} to \texttt{vce(opg)}.

\texttt{fisher(#)} specifies the number of Newton–Raphson steps that should use the Fisher scoring Hessian or EIM before switching to the observed information matrix (OIM). This option is useful only for Newton–Raphson optimization (and not when using \texttt{irls}).

\texttt{search} specifies that the command search for good starting values. This option is useful only for Newton–Raphson optimization (and not when using \texttt{irls}).

The following options are available with \texttt{glm} but are not shown in the dialog box:

\texttt{noheader} suppresses the header information from the output. The coefficient table is still displayed.
notable suppresses the table of coefficients from the output. The header information is still displayed.
nodisplay suppresses the output. The iteration log is still displayed.
coeflegend; see [R] estimation options.

Remarks and examples

Remarks are presented under the following headings:

- General use
- Variance estimators
- User-defined functions

General use

 glm fits generalized linear models of \( y \) with covariates \( x \):

\[
g\{E(y)\} = x\beta, \quad y \sim F
\]

\( g() \) is called the link function, and \( F \) is the distributional family. Substituting various definitions for \( g() \) and \( F \) results in a surprising array of models. For instance, if \( y \) is distributed as Gaussian (normal) and \( g() \) is the identity function, we have

\[
E(y) = x\beta, \quad y \sim \text{Normal}
\]

or linear regression. If \( g() \) is the logit function and \( y \) is distributed as Bernoulli, we have

\[
\text{logit}\{E(y)\} = x\beta, \quad y \sim \text{Bernoulli}
\]

or logistic regression. If \( g() \) is the natural log function and \( y \) is distributed as Poisson, we have

\[
\ln\{E(y)\} = x\beta, \quad y \sim \text{Poisson}
\]

or Poisson regression, also known as the log-linear model. Other combinations are possible.

Although glm can be used to perform linear regression (and, in fact, does so by default), this regression should be viewed as an instructional feature; regress produces such estimates more quickly, and many postestimation commands are available to explore the adequacy of the fit; see [R] regress and [R] regress postestimation.

In any case, you specify the link function by using the \texttt{link()} option and specify the distributional family by using \texttt{family()}. The available link functions are

<table>
<thead>
<tr>
<th>Link function</th>
<th>glm option</th>
</tr>
</thead>
<tbody>
<tr>
<td>identity</td>
<td>link(identity)</td>
</tr>
<tr>
<td>log</td>
<td>link(log)</td>
</tr>
<tr>
<td>logit</td>
<td>link(logit)</td>
</tr>
<tr>
<td>probit</td>
<td>link(probit)</td>
</tr>
<tr>
<td>complementary log-log</td>
<td>link(cloglog)</td>
</tr>
<tr>
<td>odds power</td>
<td>link(opower #)</td>
</tr>
<tr>
<td>power</td>

<td>link(logc)</td>
</tr>
</tbody>
</table>

Define \( \mu = E(y) \) and \( \eta = g(\mu) \), meaning that \( g(\cdot) \) maps \( E(y) \) to \( \eta = x\beta + \text{offset} \).
Link functions are defined as follows:

- **identity**: defined as \( \eta = g(\mu) = \mu \).
- **log**: defined as \( \eta = \ln(\mu) \).
- **logit**: defined as \( \eta = \ln\{\mu/(1 - \mu)\} \), the natural log of the odds.
- **probit**: defined as \( \eta = \Phi^{-1}(\mu) \), where \( \Phi^{-1}(\cdot) \) is the inverse Gaussian cumulative.
- **cloglog**: defined as \( \eta = \ln\{-\ln\{1 - \mu\}\} \).
- **opower**: defined as \( \eta = [\{\mu/(1 - \mu)\}^n - 1]/n \), the power of the odds. The function is generalized so that \( \text{link(opower 0)} \) is equivalent to \( \text{link(logit)} \), the natural log of the odds.
- **power**: defined as \( \eta = \mu^n \). Specifying \( \text{link(power 1)} \) is equivalent to specifying \( \text{link(identity)} \). The power function is generalized so that \( \mu^0 \equiv \ln(\mu) \). Thus \( \text{link(power 0)} \) is equivalent to \( \text{link(log)} \). Negative powers are, of course, allowed.
- **nbinomial**: defined as \( \eta = \ln\{\mu/(\mu + k)\} \), where \( k = 1 \) if \( \text{family(nbinomial)} \) is specified, \( k = \#_k \) if \( \text{family(nbinomial \#}_k) \) is specified, and \( k \) is estimated via maximum likelihood if \( \text{family(nbinomial ml)} \) is specified.
- **loglog**: defined as \( \eta = -\ln\{-\ln(\mu)\} \).
- **logc**: defined as \( \eta = \ln(1 - \mu) \).

The available distributional families are

<table>
<thead>
<tr>
<th>Family</th>
<th>glm option</th>
</tr>
</thead>
<tbody>
<tr>
<td>Gaussian (normal)</td>
<td>family(gaussian)</td>
</tr>
<tr>
<td>inverse Gaussian</td>
<td>family(igaussian)</td>
</tr>
<tr>
<td>Bernoulli/binomial</td>
<td>family(binomial)</td>
</tr>
<tr>
<td>Poisson</td>
<td>family(poisson)</td>
</tr>
<tr>
<td>negative binomial</td>
<td>family(nbinomial)</td>
</tr>
<tr>
<td>gamma</td>
<td>family(gamma)</td>
</tr>
</tbody>
</table>

\( \text{family(normal)} \) is a synonym for \( \text{family(gaussian)} \).

The binomial distribution can be specified as 1) \( \text{family(binomial)} \), 2) \( \text{family(binomial \#}_N) \), or 3) \( \text{family(binomial varname}_N) \). In case 2, \( \#_N \) is the value of the binomial denominator \( N \), the number of trials. Specifying \( \text{family(binomial 1)} \) is the same as specifying \( \text{family(binomial)} \). In case 3, \( \text{varname}_N \) is the variable containing the binomial denominator, allowing the number of trials to vary across observations.

The negative binomial distribution can be specified as 1) \( \text{family(nbinomial)} \), 2) \( \text{family(nbinomial \#}_k) \), or 3) \( \text{family(nbinomial ml)} \). Omitting \( \#_k \) is equivalent to specifying \( \text{family(nbinomial 1)} \). In case 3, the value of \( \#_k \) is estimated via maximum likelihood. The value \( \#_k \) enters the variance and deviance functions. Typical values range between 0.01 and 2; see the technical note below.

You do not have to specify both \text{family()} and \text{link()}; the default \text{link()} is the canonical link for the specified \text{family()} (except for \text{nbinomial}):
GLM — Generalized linear models

<table>
<thead>
<tr>
<th>Family</th>
<th>Default link</th>
</tr>
</thead>
<tbody>
<tr>
<td>family(gaussian)</td>
<td>link(identity)</td>
</tr>
<tr>
<td>family(igaussian)</td>
<td>link(power -2)</td>
</tr>
<tr>
<td>family(binomial)</td>
<td>link(logit)</td>
</tr>
<tr>
<td>family(poisson)</td>
<td>link(log)</td>
</tr>
<tr>
<td>family(nbinomial)</td>
<td>link(log)</td>
</tr>
<tr>
<td>family(gamma)</td>
<td>link(power -1)</td>
</tr>
</tbody>
</table>

If you specify both `family()` and `link()`, not all combinations make sense. You may choose from the following combinations:

<table>
<thead>
<tr>
<th>identity</th>
<th>log</th>
<th>logit</th>
<th>probit</th>
<th>cloglog</th>
<th>power</th>
<th>opower</th>
<th>nbinomial</th>
<th>loglog</th>

</tbody>
</table>

Notes:

1. The variance factor $\#_v$ should be set to $n/(n - k)$, where $n$ is the number of observations and $k$ the number of regressors. If the number of regressors is not specified, the estimated standard errors will, as a result, differ by this factor.

2. Because the link is not the canonical link for the binomial family, you must specify the `vce(oim)` option if using `irls` to get equivalent standard errors. If `irls` is used without `vce(oim)`, the regression coefficients will be the same but the standard errors will be only asymptotically equivalent. If no options are specified (`nothing`), `glm` will optimize using Newton–Raphson, making it equivalent to the other Stata command.

   See [R] `cloglog` and [R] `probit` for more details about these commands.

3. Because the canonical link is being used, the standard errors will be equivalent whether the EIM or the OIM estimator of variance is used.
4. Family negative binomial, log-link models—also known as negative binomial regression models—are used for data with an overdispersed Poisson distribution. Although glm can be used to fit such models, using Stata’s maximum likelihood nbreg command is probably better. In the GLM approach, you specify `family(nbinomial #k)` and then search for a #k that results in the deviance-based dispersion being 1. You can also specify `family(nbinomial ml)` to estimate #k via maximum likelihood, which will report the same value returned from nbreg. However, nbreg also reports a confidence interval for it; see [R] nbreg and Rogers (1993). Of course, glm allows links other than log, and for those links, including the canonical nbinomial link, you will need to use glm.

5. `glm` can be used to estimate parameters from exponential regressions, but this method requires specifying `scale(1)`. However, censoring is not available. Censored exponential regression may be modeled using `glm` with `family(poisson)`. The log of the original response is entered into a Poisson model as an offset, whereas the new response is the censor variable. The result of such modeling is identical to the log relative hazard parameterization of `streg, dist(exp) nohr`. See [ST] `streg` for details about the `streg` command.

In general, where there is overlap between a capability of glm and that of some other Stata command, we recommend using the other Stata command. Our recommendation is not because of some inferiority of the GLM approach. Rather, those other commands, by being specialized, provide options and ancillary commands that are missing in the broader glm framework. Nevertheless, glm does produce the same answers where it should.

**Special note.** When equivalence is expected, for some datasets, you may still see very slight differences in the results, most often only in the later digits of the standard errors. When you compare glm output to an equivalent Stata command, these tiny discrepancies arise for many reasons:

a. `glm` uses a general methodology for starting values, whereas the equivalent Stata command may be more specialized in its treatment of starting values.

b. When using a canonical link, glm, irls should be equivalent to the maximum likelihood method of the equivalent Stata command, yet the convergence criterion is different (one is for deviance, the other for log likelihood). These discrepancies are easily resolved by adjusting one convergence criterion to correspond to the other.

c. When both glm and the equivalent Stata command use Newton–Raphson, small differences may still occur if the Stata command has a different default convergence criterion from that of glm. Adjusting the convergence criterion will resolve the difference. See [R] `ml` and [R] `maximize` for more details.

### Example 1

In example 1 of [R] `logistic`, we fit a model based on data from a study of risk factors associated with low birthweight (Hosmer, Lemeshow, and Sturdivant 2013, 24). We can replicate the estimation by using glm:
. use http://www.stata-press.com/data/r13/lbw
   (Hosmer & Lemeshow data)
. glm low age lwt i.race smoke ptl ht ui, family(binomial) link(logit)
Iteration 0: log likelihood = -101.0213
Iteration 1: log likelihood = -100.72519
Iteration 2: log likelihood = -100.724
Iteration 3: log likelihood = -100.724

These results are the same as those reported in example 1 of [R] logistic.

Included in the output header are values for the Akaike (1973) information criterion (AIC) and the Bayesian information criterion (BIC) (Raftery 1995). Both are measures of model fit adjusted for the number of parameters that can be compared across models. In both cases, a smaller value generally indicates a better model fit. AIC is based on the log likelihood and thus is available only when Newton–Raphson optimization is used. BIC is based on the deviance and thus is always available.

Technical note

The values for AIC and BIC reported in the output after glm are different from those reported by estat ic:

. estat ic

Akaike's information criterion and Bayesian information criterion

<table>
<thead>
<tr>
<th>Model</th>
<th>Obs</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>.</td>
<td>189</td>
<td>-100.724</td>
<td>9</td>
<td>219.448</td>
<td>248.6237</td>
<td></td>
</tr>
</tbody>
</table>

Note: N=Obs used in calculating BIC; see [R] BIC note

There are various definitions of these information criteria (IC) in the literature; glm and estat ic use different definitions. glm bases its computation of the BIC on deviance, whereas estat ic uses the likelihood. Both glm and estat ic use the likelihood to compute the AIC; however, the AIC from estat ic is equal to N, the number of observations, times the AIC from glm. Refer to Methods and formulas in this entry and [R] estat ic for the references and formulas used by glm and estat ic, respectively, to compute AIC and BIC. Inferences based on comparison of IC values reported by glm.
for different GLM models will be equivalent to those based on comparison of IC values reported by estat ic after glm.

Example 2

We use data from an early insecticide experiment, given in Pregibon (1980). The variables are ldose, the log dose of insecticide; n, the number of flour beetles subjected to each dose; and r, the number killed.

```
. use http://www.stata-press.com/data/r13/ldose
. list, sep(4)

<table>
<thead>
<tr>
<th>ldose</th>
<th>n</th>
<th>r</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.6907</td>
<td>59</td>
<td>6</td>
</tr>
<tr>
<td>1.7242</td>
<td>60</td>
<td>13</td>
</tr>
<tr>
<td>1.7552</td>
<td>62</td>
<td>18</td>
</tr>
<tr>
<td>1.7842</td>
<td>56</td>
<td>28</td>
</tr>
<tr>
<td>1.8113</td>
<td>63</td>
<td>52</td>
</tr>
<tr>
<td>1.8369</td>
<td>59</td>
<td>53</td>
</tr>
<tr>
<td>1.861</td>
<td>62</td>
<td>61</td>
</tr>
<tr>
<td>1.8839</td>
<td>60</td>
<td>60</td>
</tr>
</tbody>
</table>
```

The aim of the analysis is to estimate a dose–response relationship between \( p \), the proportion killed, and \( X \), the log dose.

As a first attempt, we will formulate the model as a linear logistic regression of \( p \) on ldose; that is, we will take the logit of \( p \) and represent the dose–response curve as a straight line in \( X \):

\[
\ln \left\{ \frac{p}{(1 - p)} \right\} = \beta_0 + \beta_1 X
\]

Because the data are grouped, we cannot use Stata’s logistic command to fit the model. Stata does, however, already have a command for performing logistic regression on data organized in this way, so we could type

```
. blogit r n ldose
```
Instead, we will fit the model by using glm:

```stata
. glm r ldose, family(binomial n) link(logit)
```

Iteration 0:  log likelihood = -18.824848
Iteration 1:  log likelihood = -18.715271
Iteration 2:  log likelihood = -18.715123
Iteration 3:  log likelihood = -18.715123

The only difference between `blogit` and `glm` here is how they obtain the answer. `blogit` expands the data to contain 481 observations (the sum of `n`) so that it can run Stata’s standard, individual-level logistic command. `glm`, on the other hand, uses the information on the binomial denominator directly. We specified `family(binomial n)`, meaning that variable `n` contains the denominator. Parameter estimates and standard errors from the two approaches do not differ.

An alternative model, which gives asymmetric sigmoid curves for $p$, involves the complementary log-log, or cloglog, function:

$$
\ln\{-\ln(1-p)\} = \beta_0 + \beta_1 X
$$

We fit this model by using `glm`:

```stata
. glm r ldose, family(binomial n) link(cloglog)
```

Iteration 0:  log likelihood = -14.883594
Iteration 1:  log likelihood = -14.822264
Iteration 2:  log likelihood = -14.822228
Iteration 3:  log likelihood = -14.822228

Generalized linear models

</tbody>
</table>
The complementary log-log model is preferred; the deviance for the logistic model, 11.23, is much higher than the deviance for the cloglog model, 3.45. This change also is evident by comparing log likelihoods, or equivalently, AIC values.

This example also shows the advantage of the `glm` command—we can vary assumptions easily. Note the minor difference in what we typed to obtain the logistic and cloglog models:

```
. glm r ldose, family(binomial n) link(logit)
. glm r ldose, family(binomial n) link(cloglog)
```

If we were performing this work for ourselves, we would have typed the commands in a more abbreviated form:

```
. glm r ldose, f(b n) l(1)
. glm r ldose, f(b n) l(cl)
```

Technical note

Factor variables may be used with `glm`. Say that, in the example above, we had `ldose`, the log dose of insecticide; `n`, the number of flour beetles subjected to each dose; and `r`, the number killed—all as before—except that now we have results for three different kinds of beetles. Our hypothetical data include `beetle`, which contains the values 1 (“Destructive flour”), 2 (“Red flour”), and 3 (“Mealworm”).

```
. use http://www.stata-press.com/data/r13/beetle
. list, sep(0)
```

Let's assume that, at first, we wish merely to add a shift factor for the type of beetle. We could type

```
. glm r i.beetle ldose, family(bin n) link(cloglog)
```

```
Iteration 0: log likelihood = -79.012269
Iteration 1: log likelihood = -76.94951
Iteration 2: log likelihood = -76.945645
Iteration 3: log likelihood = -76.945645
```

```
Generalized linear models
No. of obs = 24
Residual df = 20
Scale parameter = 1
(1/df) Deviance = 3.688253
(1/df) Pearson = 3.594506
Variances function: V(u) = u*(1-u/n) [Binomial]
Link function : g(u) = ln(-ln(1-u/n)) [Complementary log-log]
AIC = 6.74547
BIC = 10.20398
```
We find strong evidence that the insecticide works differently on the mealworm. We now check whether the curve is merely shifted or also differently sloped:

```
. glm r beetle##c.ldose, family(bin n) link(cloglog)
```

We find that the (complementary log-log) dose–response curve for the mealworm has roughly half the slope of that for the destructive flour beetle.

See [U] 25 Working with categorical data and factor variables; what is said there concerning linear regression is applicable to any GLM model.
Variance estimators

`glm` offers many variance options and gives different types of standard errors when used in various combinations. We highlight some of them here, but for a full explanation, see Hardin and Hilbe (2012).

Example 3

Continuing with our flour beetle data, we rerun the most recently displayed model, this time requesting estimation via IRLS.

```
. use http://www.stata-press.com/data/r13/beetle
. glm r beetle##c.ldose, f(bin n) l(cloglog) ltol(1e-13) irls
   Iteration 1: deviance =  54.41414
   Iteration 2: deviance =  50.19424
   Iteration 3: deviance =  50.16973
   (output omitted)
Generalized linear models                     No. of obs =      24

```

Note our use of the `ltol()` option, which, although unrelated to our discussion on variance estimation, was used so that the regression coefficients would match those of the previous Newton–Raphson (NR) fit.

Because IRLS uses the EIM for optimization, the variance estimate is also based on EIM. If we want optimization via IRLS but the variance estimate based on OIM, we specify `glm, irls vce(oim)`:
This approach is identical to NR except for the convergence path. Because the cloglog link is not the canonical link for the binomial family, EIM and OIM produce different results. Both estimators, however, are asymptotically equivalent.

Going back to NR, we can also specify `vce(robust)` to get the Huber/White/sandwich estimator of variance:

```
. glm r beetle##c.ldose, f(b n) l(cl) vce(robust) noheader nolog
```

The sandwich estimator gets its name from the form of the calculation—it is the multiplication of three matrices, with the outer two matrices (the “bread”) set to the OIM variance matrix. When `irls` is used along with `vce(robust)`, the EIM variance matrix is instead used as the bread. Using a result from McCullagh and Nelder (1989), Newson (1999) points out that the EIM and OIM variance matrices are equivalent under the canonical link. Thus if `irls` is specified with the canonical link, the resulting variance is labeled “Robust”. When the noncanonical link for the family is used, which is the case in the example below, the EIM and OIM variance matrices differ, so the resulting variance is labeled “Semirobust”.

The outer product of the gradient (OPG) estimate of variance is one that avoids the calculation of second derivatives. It is equivalent to the “middle” part of the sandwich estimate of variance and can be specified by using `glm, vce(opg)`, regardless of whether NR or IRLS optimization is used.

## Example 4

The Newey–West (1987) estimator of variance is a sandwich estimator with the “middle” of the sandwich modified to take into account possible autocorrelation between the observations. These estimators are a generalization of those given by the Stata command `newey` for linear regression. See `[TS] newey` for more details.

For example, consider the dataset given in `[TS] newey`, which has time-series measurements on `usr` and `idle`. We want to perform a linear regression with Newey–West standard errors.
Examining *Methods and formulas* of [TS] *newey*, we see that the variance estimate is multiplied by a correction factor of \( \frac{n}{(n-k)} \), where \( k \) is the number of regressors. *glm*, vce(hac ...) does not make this correction, so to get the same standard errors, we must use the vfactor() option within *glm* to make the correction manually.

```
. display 30/28
 1.0714286
. tsset time
  time variable:  time, 1 to 30
     delta: 1 unit
. glm usr idle, vce(hac nwest 3) vfactor(1.0714286)

 glm also offers variance estimators based on the bootstrap (resampling your data with replacement) and the jackknife (refitting the model with each observation left out in succession). Also included is the one-step jackknife estimate, which, instead of performing full reestimation when each observation is omitted, calculates a one-step NR estimate, with the full data regression coefficients as starting values.

See Hardin and Hilbe (2012) for a full discussion of the variance options that go with glm and, in particular, of how the different variance estimators are modified when vce(cluster clustvar) is specified. Finally, not all variance options are supported with all types of weights. See help glm for a current table of the variance options that are supported with the different weights.
User-defined functions

`glm` may be called with a user-written link function, variance (family) function, Newey–West kernel-weight function, or any combination of the three.

Syntax of link functions

```stata
program proname
    version 13
    args todo eta mu return
    if 'todo' == -1 {
        /* Set global macros for output */
        global SGLM_lt "title for link function"
        global SGLM_lf "subtitle showing link definition"
        exit
    }
    if 'todo' == 0 {
        /* Intermediate calculations go here */
        generate double 'eta' = ...
        exit
    }
    if 'todo' == 1 {
        /* Intermediate calculations go here */
        generate double 'mu' = ...
        exit
    }
    if 'todo' == 2 {
        /* Intermediate calculations go here */
        generate double 'return' = ...
        exit
    }
    if 'todo' == 3 {
        /* Intermediate calculations go here */
        generate double 'return' = ...
        exit
    }
    display as error "Unknown call to glm link function"
exit 198
end
```
Syntax of variance functions

program proname
    version 13
    args todo eta mu return
    if 'todo' == -1 {
        /* Set global macros for output */
        /* Also check that depvar is in proper range */
        /* Note: For this call, eta contains indicator for whether each obs. is in est. sample */
        global SGLM_vt "title for variance function"
        global SGLM_vf "subtitle showing function definition"
        global SGLM_mu "program to call to enforce boundary conditions on μ"
        exit
    }
    if 'todo' == 0 {
        /* set η to initial value. */
        /* Intermediate calculations go here */
        generate double 'eta' = ...

Example 5

Suppose that we wish to perform Poisson regression with a log-link function. Although this regression is already possible with standard `glm`, we will write our own version for illustrative purposes.

Because we want a log link, \( \eta = g(\mu) = \ln(\mu) \), and for a Poisson family the variance function is \( V(\mu) = \mu \).

The Poisson density is given by

\[
f(y_i) = \frac{e^{-\exp(\mu_i)}e^{\mu_i y_i}}{y_i!}
\]

resulting in a log likelihood of

\[
L = \sum_{i=1}^{n} \left\{ -e^{\mu_i} + \mu_i y_i - \ln(y_i!) \right\}
\]

The squared deviance of the \( i \)th observation for the Poisson family is given by

\[
d_i^2 = \begin{cases} 
2\hat{\mu}_i & \text{if } y_i = 0 \\
2\{y_i\ln(y_i/\hat{\mu}_i) - (y_i - \hat{\mu}_i)\} & \text{otherwise}
\end{cases}
\]
We now have enough information to write our own Poisson-log glm module. We create the file mylog.ado, which contains

```stata
program mylog
    version 13
    args todo eta mu return
    if 'todo' == -1 {
        global SGLM_lt "My Log"          // Titles for output
        global SGLM_lf "ln(u)"
        exit
    }
    if 'todo' == 0 {
        gen double 'eta' = ln('mu')      // η = ln(µ)
        exit
    }
    if 'todo' == 1 {
        gen double 'mu' = exp('eta')     // µ = exp(η)
        exit
    }
    if 'todo' == 2 {
        gen double 'return' = 'mu'       // ∂µ/∂η = exp(η) = µ
        exit
    }
    if 'todo' == 3 {
        gen double 'return' = 'mu'       // ∂²µ/∂η² = exp(η) = µ
        exit
    }
    di as error "Unknown call to glm link function"
end
```

and we create the file mypois.ado, which contains

```stata
program mypois
    version 13
    args todo eta mu return
    if 'todo' == -1 {
        local y "$SGLM_y"
        local touse "'eta'"             // 'eta' marks estimation sample here
        capture assert 'y'>=0 if 'touse' // check range of y
        if _rc {
            di as error "dependent variable 'y' has negative values"
            exit 499
        }
        global SGLM_vt "My Poisson"     // Titles for output
        global SGLM_vf "u"
        global SGLM_mu "glim_mu 0 ."    // see note 1
        exit
    }
    if 'todo' == 0 {
        gen double 'eta' = ln('mu')     // Initialization of η; see note 2
        exit
    }
```

if 'todo' == 1 {
    gen double 'return' = 'mu' // V(\mu) = \mu
    exit
}
if 'todo' == 2 { // \partial V(\mu)/\partial \mu
    gen byte 'return' = 1
    exit
}
if 'todo' == 3 { // squared deviance, defined above
    local y "SGLM_y"
    if "y" == "" {
        local y "e(depvar)"
    }
    gen double 'return' = cond('y'==0, 2*'mu', /*
    */ 2*(y*ln(y/'mu')-(y-'mu')))
    exit
}
if 'todo' == 4 { // Anscombe residual; see note 3
    local y "$SGLM_y"
    if "y" == "" {
        local y "e(depvar)"
    }
    gen double 'return' = 1.5*(y^(2/3)-'mu'^(2/3)) / 'mu'^(1/6)
    exit
}
if 'todo' == 5 { // log likelihood; see note 4
    local y "$SGLM_y"
    if "y" == "" {
        local y "e(depvar)"
    }
    gen double 'return' = -'mu'+y*ln('mu')-lngamma('y'+1)
    exit
}
if 'todo' == 6 { // adjustment to residual; see note 5
    gen double 'return' = 1/(6*sqrt('mu'))
    exit
}
di as error "Unknown call to glm variance function"
error 198

end

Notes:

1. *glm_mu* is a Stata program that will, at each iteration, bring \( \hat{\mu} \) back into its plausible range, should it stray out of it. Here *glm_mu* is called with the arguments zero and missing, meaning that zero is the lower bound of \( \hat{\mu} \) and there exists no upper bound—such is the case for Poisson models.

2. Here the initial value of \( \eta \) is easy because we intend to fit this model with our user-defined log link. In general, however, the initialization may need to vary according to the link to obtain convergence. If so, the global macro SGLM_L is used to determine which link is being utilized.

3. The Anscombe formula is given here because we know it. If we were not interested in Anscombe residuals, we could merely set \( \text{return} \) to missing. Also, the local macro \( y \) is set either to SGLM_y if it is in current estimation or to \( e\text{\{depvar\}} \) if this function is being accessed by *predict*.

4. If we were not interested in ML estimation, we could omit this code entirely and just leave an exit statement in its place. Similarly, if we were not interested in deviance or IRLS optimization, we could set \( \text{return} \) in the deviance portion of the code (\( \text{\{todo\}}=3 \)) to missing.
5. This code defines the term to be added to the predicted residuals if the adjusted option is specified. Again, if we were not interested, we could set `return` to missing.

We can now test our Poisson-log module by running it on the airline data presented in [R] poisson.

```
. use http://www.stata-press.com/data/r13/airline
. list airline injuries n XYZowned

(Standard errors scaled using dispersion equal to square root of 1.)

These are precisely the results given in [R] poisson and are those that would have been given had we run `glm, family(poisson) link(log)` . The only minor adjustment we needed to make was to specify the `scale(1)` option. If `scale()` is left unspecified, `glm` assumes `scale(1)` for discrete distributions and `scale(x2)` for continuous ones. By default, `glm` assumes that any user-defined family is continuous because it has no way of checking. Thus we needed to specify `scale(1)` because our model is discrete.

Because we were careful in defining the squared deviance, we could have fit this model with IRLS. Because log is the canonical link for the Poisson family, we would not only get the same regression coefficients but also the same standard errors.
Example 6

Suppose now that we wish to use our log link (mylog.ado) with glm's binomial family. This task requires some modification because our current function is not equipped to deal with the binomial denominator, which we are allowed to specify. This denominator is accessible to our link function through the global macro SGLM_m. We now make the modifications and store them in mylog2.ado.

```stata
program mylog2 // <-- changed
version 13
args todo eta mu return
if 'todo' == -1 {
    global SGLM_lt "My Log, Version 2" // <-- changed
    if "$SGLM_m" == "1" { // <-- changed
        global SGLM lf "ln(u)" // <-- changed
    }
    else global SGLM lf "ln(u/$SGLM_m)" // <-- changed
    exit
}
if 'todo' == 0 {
    gen double 'eta' = ln('mu'/SGLM_m) // <-- changed
    exit
}
if 'todo' == 1 {
    gen double 'mu' = $SGLM_m*exp('eta') // <-- changed
    exit
}
if 'todo' == 2 {
    gen double 'return' = 'mu'
    exit
}
if 'todo' == 3 {
    gen double 'return' = 'mu'
    exit
}
di as error "Unknown call to glm link function"
exit 198
end
```

We can now run our new log link with glm's binomial family. Using the flour beetle data from earlier, we have
. use http://www.stata-press.com/data/r13/beetle, clear
. glm r ldose, f(bin n) l(mylog2) irls

Iteration 1:  deviance =  2212.108

For a more detailed discussion on user-defined functions, and for an example of a user-defined Newey–West kernel weight, see Hardin and Hilbe (2012).

John Ashworth Nelder (1924–2010) was born in Somerset, England. He studied mathematics and statistics at Cambridge and worked as a statistician at the National Vegetable Research Station and then Rothamsted Experimental Station. In retirement, he was actively affiliated with Imperial College London. Nelder was especially well known for his contributions to the theory of linear models and to statistical computing. He was the principal architect of generalized and hierarchical generalized linear models and of the programs GenStat and GLIM.

Robert William Maclagan Wedderburn (1947–1975) was born in Edinburgh and studied mathematics and statistics at Cambridge. At Rothamsted Experimental Station, he developed the theory of generalized linear models with Nelder and originated the concept of quasilikelihood. He died of anaphylactic shock from an insect bite on a canal holiday.

Methods and formulas

This discussion highlights the details of parameter estimation and predicted statistics. For a more detailed treatment, and for information on variance estimation, see Hardin and Hilbe (2012).

glm obtains results by IRLS, as described in McCullagh and Nelder (1989), or by maximum likelihood using Newton–Raphson. The implementation here, however, allows user-specified weights, which we denote as \( v_j \) for the \( j \)th observation. Let \( M \) be the number of “observations” ignoring weights. Define

\[
  w_j = \begin{cases} 
    1 & \text{if no weights are specified} \\
    v_j & \text{if fweights or iweights are specified} \\
    Mv_j/(\sum_k v_k) & \text{if aweights or pweights are specified}
  \end{cases}
\]

The number of observations is then \( N = \sum_j w_j \) if fweights are specified and \( N = M \) otherwise. Each IRLS step is performed by \texttt{regress} using \( w_j \) as the weights.

Let \( d_j^2 \) denote the squared deviance residual for the \( j \)th observation:

- For the Gaussian family, \( d_j^2 = (y_j - \hat{\mu}_j)^2 \).
- For the Bernoulli family (binomial with denominator 1),
  \[
  d_j^2 = \begin{cases} 
    -2\ln(1 - \hat{\mu}_j) & \text{if } y_j = 0 \\
    -2\ln(\hat{\mu}_j) & \text{otherwise}
  \end{cases}
\]
- For the binomial family with denominator \( m_j \),
  \[
  d_j^2 = \begin{cases} 
    2y_j\ln(y_j/\hat{\mu}_j) + 2(m_j - y_j)\ln\{(m_j - y_j)/(m_j - \hat{\mu}_j)\} & \text{if } 0 < y_j < m_j \\
    2m_j\ln\{m_j/(m_j - \hat{\mu}_j)\} & \text{if } y_j = 0 \\
    2y_j\ln(y_j/\hat{\mu}_j) & \text{if } y_j = m_j
  \end{cases}
\]
- For the Poisson family,
  \[
  d_j^2 = \begin{cases} 
    2\hat{\mu}_j & \text{if } y_j = 0 \\
    2\{y_j\ln(y_j/\hat{\mu}_j) - (y_j - \hat{\mu}_j)\} & \text{otherwise}
  \end{cases}
\]
- For the gamma family, \( d_j^2 = -2\{\ln(y_j/\hat{\mu}_j) - (y_j - \hat{\mu}_j)/\hat{\mu}_j\} \).
- For the inverse Gaussian, \( d_j^2 = (y_j - \hat{\mu}_j)^2/(\hat{\mu}_j^2y_j) \).
For the negative binomial,

\[ d_j^2 = \begin{cases} 
2 \ln(1 + k \hat{\mu}_j)/k & \text{if } y_j = 0 \\
2 y_j \ln(y_j/\hat{\mu}_j) - 2 \{(1 + ky_j)/k\ln\{(1 + ky_j)/(1 + k\hat{\mu}_j)\} & \text{otherwise}
\end{cases} \]

Let \( \phi = 1 \) if the scale parameter is set to one; otherwise, define \( \phi = \hat{\phi}_0(n - k)/n \), where \( \hat{\phi}_0 \) is the estimated scale parameter and \( k \) is the number of covariates in the model (including intercept).

Let \( \ln L_j \) denote the log likelihood for the \( j \)th observation:

For the Gaussian family,

\[
\ln L_j = -\frac{1}{2} \left[ \left( \frac{y_j - \hat{\mu}_j}{\phi} \right)^2 \right] + \ln(2\pi\phi)
\]

For the binomial family with denominator \( m_j \) (Bernoulli if all \( m_j = 1 \)),

\[
\ln L_j = \phi \times \begin{cases} 
\ln\{\Gamma(m_j + 1)\} - \ln\{\Gamma(y_j + 1)\} + \ln\{\Gamma(m_j - y_j + 1)\} & \text{if } 0 < y_j < m_j \\
(m_j - y_j) \ln(1 - \hat{\mu}_j/m_j) + y_j \ln(\hat{\mu}_j/m_j) & \text{if } y_j = 0 \\
m_j \ln(1 - \hat{\mu}_j/m_j) & \text{if } y_j = m_j
\end{cases}
\]

For the Poisson family,

\[
\ln L_j = \phi [y_j \ln(\hat{\mu}_j) - \hat{\mu}_j - \ln\{\Gamma(y_j + 1)\}]
\]

For the gamma family, \( \ln L_j = -y_j/\hat{\mu}_j + \ln(1/\hat{\mu}_j) \).

For the inverse Gaussian,

\[
\ln L_j = -\frac{1}{2} \left\{ \frac{(y_j - \hat{\mu}_j)^2}{y_j \hat{\mu}_j^2} + 3\ln(y_j) + \ln(2\pi) \right\}
\]

For the negative binomial (let \( m = 1/k \)),

\[
\ln L_j = \phi \left[ \ln\{\Gamma(m + y_j)\} - \ln\{\Gamma(y_j + 1)\} - \ln\{\Gamma(m)\} \\
- m \ln(1 + \hat{\mu}_j/m) + y_j \ln\{\hat{\mu}_j/(\hat{\mu}_j + m)\} \right]
\]

The overall deviance reported by \texttt{glm} is \( D^2 = \sum_j w_j d_j^2 \). The dispersion of the deviance is \( D^2 \) divided by the residual degrees of freedom.

The Akaike information criterion (AIC) and Bayesian information criterion (BIC) are given by

\[
\text{AIC} = \frac{-2 \ln L + 2k}{N}
\]
\[
\text{BIC} = D^2 - (N - k) \ln(N)
\]

where \( \ln L = \sum_j w_j \ln L_j \) is the overall log likelihood.
The Pearson deviance reported by \texttt{glm} is \(\sum_j w_j r_j^2\). The corresponding Pearson dispersion is the Pearson deviance divided by the residual degrees of freedom. \texttt{glm} also calculates the scaled versions of all these quantities by dividing by the estimated scale parameter.

\section*{Acknowledgments}

\texttt{glm} was written by James Hardin of the Arnold School of Public Health at the University of South Carolina and Joseph Hilbe of Arizona State University, the coauthors of the Stata Press book \textit{Generalized Linear Models and Extensions}. The previous version of this routine was written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book \textit{Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model}. The original version of this routine was published in Royston (1994). Royston’s work, in turn, was based on a prior implementation by Joseph Hilbe, first published in Hilbe (1993). Roger Newson wrote an early implementation (Newson 1999) of robust variance estimates for GLM. Parts of this entry are excerpts from Hardin and Hilbe (2012).

Description

The following postestimation commands are available after `glm`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>contrast</code></td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td><code>estat ic</code></td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td><code>estat summarize</code></td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>forecast</code>¹</td>
<td>dynamic forecasts and simulations</td>
</tr>
<tr>
<td><code>lincom</code></td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td><code>linktest</code></td>
<td>link test for model specification</td>
</tr>
<tr>
<td><code>lrtest²</code></td>
<td>likelihood-ratio test</td>
</tr>
<tr>
<td><code>margins</code></td>
<td>marginal means, predictive margins, marginal effects, and average marginal effects</td>
</tr>
<tr>
<td><code>marginsplot</code></td>
<td>graph the results from margins (profile plots, interaction plots, etc.)</td>
</tr>
<tr>
<td><code>nlcom</code></td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td><code>predict</code></td>
<td>predictions, residuals, influence statistics, and other diagnostic measures</td>
</tr>
<tr>
<td><code>predictnl</code></td>
<td>point estimates, standard errors, testing, and inference for generalized predictions</td>
</tr>
<tr>
<td><code>pwcompare</code></td>
<td>pairwise comparisons of estimates</td>
</tr>
<tr>
<td><code>suest</code></td>
<td>seemingly unrelated estimation</td>
</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

¹ `forecast` is not appropriate with `mi` or `svy` estimation results.
² `lrtest` is not appropriate with `svy` estimation results.
Syntax for predict

```
predict [ type ] newvar [ if ] [ in ] [ , statistic options ]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>mu</td>
<td>expected value of y; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction $\eta = \hat{x}\hat{\beta}$</td>
</tr>
<tr>
<td>eta</td>
<td>synonym of xb</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td>anscombe</td>
<td>Anscombe (1953) residuals</td>
</tr>
<tr>
<td>cooksd</td>
<td>Cook's distance</td>
</tr>
<tr>
<td>deviance</td>
<td>deviance residuals</td>
</tr>
<tr>
<td>hat</td>
<td>diagonals of the “hat” matrix</td>
</tr>
<tr>
<td>likelihood</td>
<td>a weighted average of standardized deviance and standardized Pearson residuals</td>
</tr>
<tr>
<td>pearson</td>
<td>Pearson residuals</td>
</tr>
<tr>
<td>response</td>
<td>differences between the observed and fitted outcomes</td>
</tr>
<tr>
<td>score</td>
<td>first derivative of the log likelihood with respect to $x_j\beta$</td>
</tr>
<tr>
<td>working</td>
<td>working residuals</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>nooffset</td>
<td>modify calculations to ignore offset variable</td>
</tr>
<tr>
<td>adjusted</td>
<td>adjust deviance residual to speed up convergence</td>
</tr>
<tr>
<td>standardized</td>
<td>multiply residual by the factor $(1 - h)^{-1/2}$</td>
</tr>
<tr>
<td>studentized</td>
<td>multiply residual by one over the square root of the estimated scale parameter</td>
</tr>
<tr>
<td>modified</td>
<td>modify denominator of residual to be a reasonable estimate of the variance of depvar</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ... if wanted only for the estimation sample.`

mu, xb, stdp, and score are the only statistics allowed with svy estimation results.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

```
Main
mu, the default, specifies that predict calculate the expected value of y, equal to $g^{-1}(x\hat{\beta})$ [$ng^{-1}(x\hat{\beta})$ for the binomial family].

xb calculates the linear prediction $\eta = x\hat{\beta}$.

eta is a synonym for xb.

stdp calculates the standard error of the linear prediction.

anscombe calculates the Anscombe (1953) residuals to produce residuals that closely follow a normal distribution.
```
**cooked** calculates Cook’s distance, which measures the aggregate change in the estimated coefficients when each observation is left out of the estimation.

**deviance** calculates the deviance residuals. Deviance residuals are recommended by McCullagh and Nelder (1989) and by others as having the best properties for examining the goodness of fit of a GLM. They are approximately normally distributed if the model is correct. They may be plotted against the fitted values or against a covariate to inspect the model’s fit. Also see the **pearson** option below.

**hat** calculates the diagonals of the “hat” matrix, analogous to linear regression.

**likelihood** calculates a weighted average of standardized deviance and standardized Pearson residuals.

**pearson** calculates the Pearson residuals. Pearson residuals often have markedly skewed distributions for nonnormal family distributions. Also see the **deviance** option above.

**response** calculates the differences between the observed and fitted outcomes.

**score** calculates the equation-level score, \( \partial \ln L / \partial (x_j \beta) \).

**working** calculates the working residuals, which are response residuals weighted according to the derivative of the link function.

### Options

- **nooffset** is relevant only if you specified `offset(varname)` for `glm`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as \( x_j \beta \) rather than as \( x_j \beta + \text{offset}_j \).

- **adjusted** adjusts the deviance residual to speed up the convergence to the limiting normal distribution. The adjustment deals with adding to the deviance residual a higher-order term that depends on the variance function family. This option is allowed only when `deviance` is specified.

- **standardized** requests that the residual be multiplied by the factor \( (1 - h)^{-1/2} \), where \( h \) is the diagonal of the hat matrix. This operation is done to account for the correlation between `depvar` and its predicted value.

- **studentized** requests that the residual be multiplied by one over the square root of the estimated scale parameter.

- **modified** requests that the denominator of the residual be modified to be a reasonable estimate of the variance of `depvar`. The base residual is multiplied by the factor \( (k/w)^{-1/2} \), where \( k \) is either one or the user-specified dispersion parameter and \( w \) is the specified weight (or one if left unspecified).

### Remarks and examples

Remarks are presented under the following headings:

- **Predictions**
- **Other postestimation commands**
Predictions

Example 1

After glm estimation, predict may be used to obtain various predictions based on the model. In example 2 of [R] glm, we mentioned that the complementary log-log link seemed to fit the data better than the logit link. Now we go back and obtain the fitted values and deviance residuals:

```
. use http://www.stata-press.com/data/r13/ldose
. glm r ldose, family(binomial n) link(logit)  
   (output omitted)
. predict mu_logit  
   (option mu assumed; predicted mean r)
. predict dr_logit, deviance
. quietly glm r ldose, f(binomial n) l(cloglog)
. predict mu_cl  
   (option mu assumed; predicted mean r)
. predict dr_cl, d
. format mu_logit dr_logit mu_cl dr_cl %9.5f
. list r mu_logit dr_logit mu_cl dr_cl, sep(4)
```

<table>
<thead>
<tr>
<th></th>
<th>r</th>
<th>mu_logit</th>
<th>dr_logit</th>
<th>mu_cl</th>
<th>dr_cl</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>6</td>
<td>3.45746</td>
<td>1.28368</td>
<td>5.58945</td>
<td>0.18057</td>
</tr>
<tr>
<td>2</td>
<td>13</td>
<td>9.84167</td>
<td>1.05969</td>
<td>11.28067</td>
<td>0.55773</td>
</tr>
<tr>
<td>3</td>
<td>18</td>
<td>22.45139</td>
<td>-1.19611</td>
<td>20.95422</td>
<td>-0.80330</td>
</tr>
<tr>
<td>4</td>
<td>28</td>
<td>33.89761</td>
<td>-1.59412</td>
<td>30.36942</td>
<td>-0.63439</td>
</tr>
<tr>
<td>5</td>
<td>52</td>
<td>50.09584</td>
<td>0.60614</td>
<td>47.77644</td>
<td>1.28883</td>
</tr>
<tr>
<td>6</td>
<td>53</td>
<td>53.29092</td>
<td>-0.12716</td>
<td>54.14273</td>
<td>-0.52366</td>
</tr>
<tr>
<td>7</td>
<td>61</td>
<td>59.22216</td>
<td>1.28107</td>
<td>61.11331</td>
<td>-0.11878</td>
</tr>
<tr>
<td>8</td>
<td>60</td>
<td>58.74297</td>
<td>1.59398</td>
<td>59.94723</td>
<td>0.32495</td>
</tr>
</tbody>
</table>

In six of the eight cases, \(|dr\_logit| > |dr\_cl|\). The above represents only one of the many available options for predict. See Hardin and Hilbe (2012) for a more in-depth examination.

Other postestimation commands

Technical note

After glm estimation, you may perform any of the postestimation commands that you would perform after any other kind of estimation in Stata; see [U] 20 Estimation and postestimation commands. Below we test the joint significance of all the interaction terms.
. use http://www.stata-press.com/data/r13/beetle, clear
. glm r beetle##c.ldose, family(binomial n) link(cloglog)
(output omitted)
. testparm i.beetle beetle#c.ldose
   ( 1) [r]2.beetle = 0
   ( 2) [r]3.beetle = 0
   ( 3) [r]2.beetle#c.ldose = 0
   ( 4) [r]3.beetle#c.ldose = 0
   chi2( 4) = 249.69
   Prob > chi2 = 0.0000

If you wanted to print the variance–covariance matrix of the estimators, you would type estat vce.

If you use the linktest postestimation command, you must also specify the family() and link() options; see [R] linktest.

Methods and formulas

We follow the terminology used in Methods and formulas of [R] glm.

The deviance residual calculated by predict following glm is
\[ r^D_j = \text{sign}(y_j - \hat{\mu}_j) \sqrt{d^2_j}. \]

The Pearson residual calculated by predict following glm is
\[ r^P_j = \frac{y_j - \hat{\mu}_j}{\sqrt{V(\hat{\mu}_j)}} \]

where \( V(\hat{\mu}_j) \) is the family-specific variance function.

\[
V(\hat{\mu}_j) = \begin{cases} 
\hat{\mu}_j(1 - \hat{\mu}_j/m_j) & \text{if binomial or Bernoulli } (m_j = 1) \\
\hat{\mu}_j^2 & \text{if gamma} \\
1 & \text{if Gaussian} \\
\hat{\mu}_j^3 & \text{if inverse Gaussian} \\
\hat{\mu}_j + k\hat{\mu}_j^2 & \text{if negative binomial} \\
\hat{\mu}_j & \text{if Poisson}
\end{cases}
\]

The response residuals are given by \( r^R_i = y_i - \mu_i \). The working residuals are
\[
r^W_i = (y_i - \hat{\mu}_i) \left( \frac{\partial \eta}{\partial \mu} \right)_i
\]
and the score residuals are
\[
r^S_i = \frac{y_i - \hat{\mu}_i}{V(\hat{\mu}_i)} \left( \frac{\partial \eta}{\partial \mu} \right)_i^{-1}
\]

Define \( \hat{W} = V(\hat{\mu}) \) and \( X \) to be the covariate matrix. \( h_i \), then, is the \( i \)th diagonal of the hat matrix given by
\[
\hat{H} = \hat{W}^{1/2}X(X^T\hat{W}X)^{-1}X^T\hat{W}^{1/2}
\]
As a result, the likelihood residuals are given by

$$r^L_i = \text{sign}(y_i - \hat{\mu}_i) \left\{ h_i (r_i^{P'})^2 + (1 - h_i) (r_i^{D'})^2 \right\}^{1/2}$$

where $r_i^{P'}$ and $r_i^{D'}$ are the standardized Pearson and standardized deviance residuals, respectively. By standardized, we mean that the residual is divided by $\{1 - h_i\}^{1/2}$.

Cook’s distance is an overall measure of the change in the regression coefficients caused by omitting the $i$th observation from the analysis. Computationally, Cook’s distance is obtained as

$$C_i = \frac{(r_i^{P'})^2 h_i}{k(1 - h_i)}$$

where $k$ is the number of regressors, including the constant.

Anscombe residuals are given by

$$r^A_i = \frac{A(y_i) - A(\hat{\mu}_i)}{A'(\hat{\mu}_i) \{V(\hat{\mu}_i)\}^{1/2}}$$

where

$$A(\cdot) = \int \frac{d\mu}{V^{1/3}(\mu)}$$

Deviance residuals may be adjusted (predict, adjusted) to make the following correction:

$$r^{Da}_i = r^D_i + \frac{1}{6} \rho_3(\theta)$$

where $\rho_3(\theta)$ is a family-specific correction. See Hardin and Hilbe (2012) for the exact forms of $\rho_3(\theta)$ for each family.

indepvars may contain factor variables; see [U] 11.4.3 Factor variables.

bootstrap, by, jackknife, rolling, and statsby are allowed; see [U] 11.1.10 Prefix commands. fp is allowed with blogit and bprobit.

nocoef and coeflegend do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Menu

blogit
Statistics > Binary outcomes > Grouped data > Logit regression for grouped data

bprobit
Statistics > Binary outcomes > Grouped data > Probit regression for grouped data

glogit
Statistics > Binary outcomes > Grouped data > Weighted least-squares logit regression

gprobit
Statistics > Binary outcomes > Grouped data > Weighted least-squares probit regression

Description

blogit and bprobit produce maximum-likelihood logit and probit estimates on grouped (“blocked”) data; glogit and gprobit produce weighted least-squares estimates. In the syntax diagrams above, pos_var and pop_var refer to variables containing the total number of positive responses and the total population.

See [R] logistic for a list of related estimation commands.

Options for blogit and bprobit

noconstant; see [R] estimation options.

asis forces retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see [R] probit.

offset(varname), constraints(constraints), collinear; see [R] estimation options.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#); see [R] estimation options.
or (blogit only) reports the estimated coefficients transformed to odds ratios, that is, $e^b$ rather than $b$.

Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. or may be specified at estimation or when replaying previously estimated results.

noconsreport; see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see [R] estimation options.

Options for glogit and gprobit

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (ols) and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

vce(ols), the default, uses the standard variance estimator for ordinary least-squares regression.

level(#) ; see [R] estimation options.

or (glogit only) reports the estimated coefficients transformed to odds ratios, that is, $e^b$ rather than $b$.

Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. or may be specified at estimation or when replaying previously estimated results.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see [R] estimation options.

The following option is available with blogit and bprobit but is not shown in the dialog box:

nocoef specifies that the coefficient table not be displayed. This option is sometimes used by program writers but is useless interactively.

coeflegend; see [R] estimation options.

Remarks and examples

Remarks are presented under the following headings:

Maximum likelihood estimates

Weighted least-squares estimates
Maximum likelihood estimates

`blogit` produces the same results as `logit` and `logistic`, and `bprobit` produces the same results as `probit`, but the “blocked” commands accept data in a slightly different “shape”. Consider the following two datasets:

```
. use http://www.stata-press.com/data/r13/xmpl1
. list, sepby(agecat)

<table>
<thead>
<tr>
<th>agecat</th>
<th>exposed</th>
<th>died</th>
<th>pop</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0</td>
<td>0</td>
<td>115</td>
</tr>
<tr>
<td>0</td>
<td>0</td>
<td>1</td>
<td>5</td>
</tr>
<tr>
<td>0</td>
<td>1</td>
<td>0</td>
<td>98</td>
</tr>
<tr>
<td>0</td>
<td>1</td>
<td>1</td>
<td>8</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
<td>0</td>
<td>69</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
<td>1</td>
<td>16</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
<td>0</td>
<td>76</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
<td>1</td>
<td>22</td>
</tr>
</tbody>
</table>
```

. use http://www.stata-press.com/data/r13/xmpl2
. list

<table>
<thead>
<tr>
<th>agecat</th>
<th>exposed</th>
<th>deaths</th>
<th>pop</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0</td>
<td>5</td>
<td>120</td>
</tr>
<tr>
<td>0</td>
<td>1</td>
<td>8</td>
<td>106</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
<td>16</td>
<td>85</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
<td>22</td>
<td>98</td>
</tr>
</tbody>
</table>
```

These two datasets contain the same information; observations 1 and 2 of `xmpl1` correspond to observation 1 of `xmpl2`, observations 3 and 4 of `xmpl1` correspond to observation 2 of `xmpl2`, and so on.

The first observation of `xmpl1` says that for `agecat==0` and `exposed==0`, 115 subjects did not die (`died==0`). The second observation says that for the same `agecat` and `exposed` groups, five subjects did die (`died==1`). In `xmpl2`, the first observation says that there were five deaths of a population of 120 in `agecat==0` and `exposed==0`. These are two different ways of saying the same thing. Both datasets are transcriptions from the following table, reprinted in Rothman, Greenland, and Lash (2008, 260), for age-specific deaths from all causes for tolbutamide and placebo treatment groups (University Group Diabetes Program 1970):

<table>
<thead>
<tr>
<th>Age through 54</th>
<th>55 and above</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tolbutamide</td>
<td>Placebo</td>
</tr>
<tr>
<td>Dead</td>
<td>8</td>
</tr>
<tr>
<td>Surviving</td>
<td>98</td>
</tr>
</tbody>
</table>

The data in `xmpl1` are said to be “fully relational”, which is computer jargon meaning that each observation corresponds to one cell of the table. Stata typically prefers data in this format. The second form of storing these data in `xmpl2` is said to be “folded”, which is computer jargon for something less than fully relational.

`blogit` and `bprobit` deal with “folded” data and produce the same results that `logit` and `probit` would have if the data had been stored in the “fully relational” representation.
Example 1

For the tolbutamide data, the fully relational representation is preferred. We could then use `logistic`, `logit`, and any of the epidemiological table commands; see [R] `logistic`, [R] `logit`, and [ST] `epitab`. Nevertheless, there are occasions when the folded representation seems more natural. With `blogit` and `bprobit`, we avoid the tedium of having to unfold the data:

```
. use http://www.stata-press.com/data/r13/xmpl2
. blogit deaths pop agecat exposed, or
```

| _outcome | Odds Ratio | Std. Err. | z | P>|z| | [95% Conf. Interval] |
|----------|-----------|-----------|---|-----|---------------------|
| agecat   | 4.216299  | 1.431519  | 4.24| 0.000 | 2.167361  8.202223 |
| exposed  | 1.404674  | .4374454  | 1.09| 0.275 | .7629451  2.586175 |
| _cons    | .0513818  | .0170762  | -8.93| 0.000 | .0267868  .0985593 |

If we had not specified the `or` option, results would have been presented as coefficients instead of as odds ratios. The estimated odds ratio of death for tolbutamide exposure is 1.40, although the 95% confidence interval includes 1. (By comparison, these data, in fully relational form and analyzed using the `cs` command [see [ST] `epitab`], produce a Mantel–Haenszel weighted odds ratio of 1.40 with a 95% confidence interval of 0.76 to 2.59.)

We can see the underlying coefficients by replaying the estimation results and not specifying the `or` option:

```
. blogit
```

| _outcome | Coef. | Std. Err. | z | P>|z| | [95% Conf. Interval] |
|----------|-------|-----------|---|-----|---------------------|
| agecat   | 1.438958 | .3395203  | 4.24| 0.000 | .7735101  2.104405 |
| exposed  | .3398053 | .3114213  | 1.09| 0.275 | -.2705692  .9501798 |
| _cons    | -2.968471 | .33234  | -8.93| 0.000 | -.619846  -2.317097 |
Example 2

bprobit works like blogit, substituting the probit for the logit-likelihood function.

```
bprobit deaths pop agecat exposed
```

Probit regression for grouped data

```
Number of obs = 409
LR chi2(2) = 22.58
Prob > chi2 = 0.0000
Log likelihood = -142.56478 Pseudo R2 = 0.0734
```

| _outcome | Coef.  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|----------|--------|-----------|-------|------|----------------------|
| agecat   | 0.7542 | 0.1709    | 4.41  | 0.000| 0.4191 1.0893 |
| exposed  | 0.1906 | 0.1666    | 1.14  | 0.253| -0.136 0.517   |
| _cons    | -1.674 | 0.162     | -10.34| 0.000| -1.991 -1.357  |

Weighted least-squares estimates

Example 3

We have state data for the United States on the number of marriages (marriage), the total population aged 18 years or more (pop18p), and the median age (medage). The dataset excludes Nevada, so it has 49 observations. We now wish to estimate a logit equation for the marriage rate. We will include age squared by specifying the term c.medage#c.medage:

```
. use http://www.stata-press.com/data/r13/census7
(1980 Census data by state)
. glogit marriage pop18p medage c.medage#c.medage
```

Weighted LS logistic regression for grouped data

```
Number of obs = 49
F( 2, 46) = 12.89
Prob > F = 0.0000
R-squared = 0.3591
Adj R-squared = 0.3313
Root MSE = .1666
```

| Source   | SS     | df | MS   | | Number of obs = 49 |
|----------|--------|----|------||--|-------------------|
| Model    | .7159  | 2  | .3579| | F( 2, 46) = 12.89  |
| Residual | 1.2777 | 46 | .0278| | Prob > F = 0.0000  |
| Total    | 1.9937 | 48 | .0415| | R-squared = 0.3591 |

| Coef.     | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|-----------|-----------|-------|------|----------------------|
| medage    | -.6459    | .2828| -2.28| 0.027    | -1.215  -.076    |
| c.medage# | .0095     | .0046| 2.05 | 0.046    | .0001  .018     |
| c.medage  | .0095     | .0046| 2.05 | 0.046    | .0001  .018     |
| _cons     | 6.5039    | 4.289| 1.52 | 0.136    | -2.129  15.137  |
Example 4

We could just as easily have fit a grouped-probit model by typing `gprobit` rather than `glogit`:

```
   . gprobit marriage pop18p medage c.medage#c.medage
```

Weighted LS probit regression for grouped data

```
Source | SS       | df | MS       | Number of obs =  49
------|----------|----|----------|---------------------
Model  | .108222962 | 2  | .054111481 | F(  2,   46) =  12.94
Residual | .192322476 | 46 | .004180923 | Prob > F = 0.0000
          |           |    |           | R-squared = 0.3601
          |           |    |           | Adj R-squared = 0.3323
Total   | .300545438 | 48 | .006261363 | Root MSE = 0.06466
```

|          | Coef.   | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|----------|---------|-----------|-------|-----|----------------------|
| medage   | -.2755007 | .1121042  | -2.46 | 0.018 | -.5011548 -.0498466 |
| c.medage#c.medage | .0041082 | .0018422  | 2.23  | 0.031 | .0004001 .0078163 |
| _cons    | 2.357708  | 1.704446  | 1.38  | 0.173 | -1.073164 5.788579  |

Stored results

`blogit` and `bprobit` store the following in `e()`:

Scalars:
- `e(N)` number of observations
- `e(N_cds)` number of completely determined successes
- `e(N_pdf)` number of completely determined failures
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(r2_p)` pseudo-$R$-squared
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(N_clust)` number of clusters
- `e(chi2)` \(\chi^2\)
- `e(p)` significance of model test
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise
Macros

- **e(cmd)**: blogit or bprobit
- **e(cmdline)**: command as typed
- **e(depvar)**: variable containing number of positive responses and variable containing population size
- **e(wtype)**: weight type
- **e(wexp)**: weight expression
- **e(title)**: title in estimation output
- **e(clustvar)**: name of cluster variable
- **e(offset)**: linear offset variable
- **e(chi2type)**: Wald or LR; type of model $\chi^2$ test
- **e(vce)**: vcetype specified in vce()
- **e(vcetype)**: title used to label Std. Err.
- **e(opt)**: type of optimization
- **e(which)**: max or min; whether optimizer is to perform maximization or minimization
- **e(ml_method)**: type of ml method
- **e(user)**: name of likelihood-evaluator program
- **e(technique)**: maximization technique
- **e(properties)**: b V
- **e(predict)**: program used to implement predict
- **e(marginsok)**: predictions allowed by margins
- **e(asbalanced)**: factor variables fvset as asbalanced
- **e(asobserved)**: factor variables fvset as asobserved

Matrices

- **e(b)**: coefficient vector
- **e(Cns)**: constraints matrix
- **e(ilog)**: iteration log (up to 20 iterations)
- **e(gradient)**: gradient vector
- **e(mns)**: vector of means of the independent variables
- **e(rules)**: information about perfect predictors
- **e(V)**: variance-covariance matrix of the estimators
- **e(V_modelbased)**: model-based variance

Functions

- **e(sample)**: marks estimation sample

**glogit** and **gprobit** store the following in **e()**:

Scalars

- **e(N)**: number of observations
- **e(mss)**: model sum of squares
- **e(df_m)**: model degrees of freedom
- **e(rss)**: residual sum of squares
- **e(df_r)**: residual degrees of freedom
- **e(r2)**: $R$-squared
- **e(r2_a)**: adjusted $R$-squared
- **e(F)**: $F$ statistic
- **e(rmse)**: root mean squared error
- **e(rank)**: rank of e(V)

Macros

- **e(cmd)**: glogit or gprobit
- **e(cmdline)**: command as typed
- **e(depvar)**: variable containing number of positive responses and variable containing population size
- **e(model)**: ols
- **e(title)**: title in estimation output
- **e(vce)**: vcetype specified in vce()
- **e(vcetype)**: title used to label Std. Err.
- **e(properties)**: b V
- **e(predict)**: program used to implement predict
- **e(marginsok)**: predictions allowed by margins
- **e(asbalanced)**: factor variables fvset as asbalanced
- **e(asobserved)**: factor variables fvset as asobserved
Methods and formulas

Methods and formulas are presented under the following headings:

- **Maximum likelihood estimates**
- **Weighted least-squares estimates**

### Maximum likelihood estimates

The results reported by `blogit` and `bprobit` are obtained by maximizing a weighted logit- or probit-likelihood function. Let $F(\cdot)$ denote the normal- or logistic-likelihood function. The likelihood of observing each observation in the data is then

$$F(\beta x)^s \{1 - F(\beta x)\}^{t-s}$$

where $s$ is the number of successes and $t$ is the population. The term above is counted as contributing $s + (t - s) = t$ degrees of freedom. All of this follows directly from the definitions of logit and probit.

`blogit` and `bprobit` support the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] _robust_, particularly Maximum likelihood estimators and Methods and formulas.

### Weighted least-squares estimates

The logit function is defined as the log of the odds ratio. If there is one explanatory variable, the model can be written as

$$\log \left( \frac{p_j}{1 - p_j} \right) = \beta_0 + \beta_1 x_j + \epsilon_j$$  \hspace{1cm} (1)

where $p_j$ represents successes divided by population for the $j$th observation. (If there is more than one explanatory variable, we simply interpret $\beta_1$ as a row vector and $x_j$ as a column vector.) The large-sample expectation of $\epsilon_j$ is zero, and its variance is

$$\sigma_j^2 = \frac{1}{n_j p_j (1 - p_j)}$$

where $n_j$ represents the population for observation $j$. We can thus apply weighted least squares to the observations, with weights proportional to $n_j p_j (1 - p_j)$.

As in any feasible generalized least-squares problem, estimation proceeds in two steps. First, we fit (1) by OLS and compute the predicted probabilities as

$$\hat{p}_j = \frac{\exp(\hat{\beta}_0 + \hat{\beta}_1 x_j)}{1 + \exp(\hat{\beta}_0 + \hat{\beta}_1 x_j)}$$

In the second step, we fit (1) by using analytic weights equal to $n_j \hat{p}_j (1 - \hat{p}_j)$. 

---

Matrices
- $e(b)$: coefficient vector
- $e(V)$: variance–covariance matrix of the estimators

Functions
- $e(sample)$: marks estimation sample
For gprobit, write $\Phi(\cdot)$ for the cumulative normal distribution, and define $z_j$ implicitly by $\Phi(z_j) = p_j$, where $p_j$ is the fraction of successes for observation $j$. The probit model for one explanatory variable can be written as

$$\Phi^{-1}(p_j) = \beta_0 + \beta_1 x_j + \epsilon_j$$

(If there is more than one explanatory variable, we simply interpret $\beta_1$ as a row vector and $x_j$ as a column vector.)

The expectation of $\epsilon_j$ is zero, and its variance is given by

$$\sigma^2_j = \frac{p_j(1 - p_j)}{n_j \phi^2\{\Phi^{-1}(p_j)\}}$$

where $\phi(\cdot)$ represents the normal density (Amemiya 1981, 1498). We can thus apply weighted least squares to the observations with weights proportional to $1/\sigma^2_j$. As for grouped logit, we use a two-step estimator to obtain the weighted least-squares estimates.

</tr>
</tbody>
</table>

* `estat ic` and `lrtest` are not appropriate after `glogit` and `gprobit`.

**Syntax for predict**

```
predict [type] newvar [if] [in] [ , statistic ]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>n</td>
<td>predicted count; the default</td>
</tr>
<tr>
<td>pr</td>
<td>probability of a positive outcome</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ... if` wanted only for the estimation sample.
Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

- **n**, the default, calculates the expected count, that is, the estimated probability times \( pop_{\text{var}} \), which is the total population.
- **pr** calculates the predicted probability of a positive outcome.
- **xb** calculates the linear prediction.
- **stdp** calculates the standard error of the linear prediction.

Syntax

Interactive version

gmm ([eqname1:]<mexp1>) ([eqname2:]<mexp2>)...[if] [in] [weight] [ , options]

Moment-evaluator program version

gmm moment_prog [if] [in] [weight], {equations(namelist)|nequations(#)}
{parameters(namelist)|nparameters(#)} [options] [program_options]

where

mexp_j is the substitutable expression for the jth moment equation and
moment_prog is a moment-evaluator program.

options Description

Model

derivative(<dexp_mn>) specify derivative of mexp_m with respect to parameter n; can be
specified more than once (interactive version only)
* twostep use two-step GMM estimator; the default
* onestep use one-step GMM estimator
* igmm use iterative GMM estimator

Instruments

instruments([<eqlist>:]varlist[, noconstant])
specify instruments; can be specified more than once
xtinstruments([<eqlist>:]varlist, lags(#1/#2))
specify panel-style instruments; can be specified more than once

Weight matrix

wmatrix(wmtype[, independent])
specify weight matrix; wmtype may be robust, cluster clustvar, hac kernel [lags], or unadjusted
center center moments in weight-matrix computation
winitial(iwtype[, independent])
specify initial weight matrix; iwtype may be identity, unadjusted, xt xtspec, or the name of a Stata matrix
Options

- **variables(varlist)**: specify variables in model
- **nocommonesample**: do not restrict estimation sample to be the same for all equations

SE/Robust

- **vce(vcetype[, independent])**:
  - `vcetype` may be `robust`, `cluster clustvar`, `bootstrap`, `jackknife`, `hac kernel lags`, or `unadjusted`
- **quickderivatives**: use alternative method of computing numerical derivatives for VCE

Reporting

- **level(#)**: set confidence level; default is `level(95)`
- **title(string)**: display string as title above the table of parameter estimates
- **title2(string)**: display string as subtitle
- **display_options**: control column formats and line width

Optimization

- **from(initial_values)**: specify initial values for parameters
- **igmmiterate(#)**: specify maximum number of iterations for iterated GMM estimator
- **igmmeps(#)**: specify # for iterated GMM parameter convergence criterion; default is `igmmeps(1e-6)`
- **igmmweps(#)**: specify # for iterated GMM weight-matrix convergence criterion; default is `igmmweps(1e-6)`
- **optimization_options**: control the optimization process; seldom used
- **coeflegend**: display legend instead of statistics

* You can specify at most one of these options.
† These options may be specified only when `igmm` is specified.

**program_options**

<table>
<thead>
<tr>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>evaluator_options</strong></td>

</tr>
</tbody>
</table>

* You may not specify both `hasderivatives` and `hasldderivatives`.
† You must specify `equations(namelist)` or `nequations(#)`; you may specify both.
‡ You must specify `parameters(namelist)` or `nparameters(#)`; you may specify both.
bootstrap, by, jackknife, rolling, statsby, and xi are allowed; see [U] 11.1.10 Prefix commands.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
aweights are not allowed with the jackknife prefix; see [R] jackknife.
aweights, fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.
coeflegend does not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

\( <mexp_j> \) and \( <dexp_{mn}> \) are extensions of valid Stata expressions that also contain parameters to be estimated. The parameters are enclosed in curly braces and must otherwise satisfy the naming requirements for variables; \{beta\} is an example of a parameter. Also allowed is a notation of the form \( \{<eqname>:varlist\} \) for linear combinations of multiple covariates and their parameters. For example, \{xb: mpg price turn\} defines a linear combination of the variables mpg, price, and turn. See Substitutable expressions under Remarks and examples below.

### Menu

Statistics > Endogenous covariates > Generalized method of moments estimation

### Description

\texttt{gmm} performs generalized method of moments (GMM) estimation. With the interactive version of the command, you enter the moment equations directly into the dialog box or on the command line using substitutable expressions. The moment-evaluator program version gives you greater flexibility in exchange for increased complexity; with this version, you write a program in an ado-file that calculates the moments based on a vector of parameters passed to it.

\texttt{gmm} can fit both single- and multiple-equation models, and it allows moment conditions of the form \( E\{z_i u_i(\beta)\} = 0 \), where \( z_i \) is a vector of instruments and \( u_i(\beta) \) is often an additive regression error term, as well as more general moment conditions of the form \( E\{h_i(z_i; \beta)\} = 0 \). \texttt{gmm} works with cross-sectional, time-series, and longitudinal (panel) data.

### Options

- **Model**

  \texttt{derivative([eqname | #]/name = <dexp_{mn}>)} specifies the derivative of moment equation \texttt{eqname} or \# with respect to parameter \texttt{name}. If \texttt{eqname} or \# is not specified, \texttt{gmm} assumes that the derivative applies to the first moment equation.

  For a moment equation of the form \( E\{z_m u_m(\beta)\} = 0 \), \texttt{derivative(m/\beta_j = <dexp_{mn}>)} is to contain a substitutable expression for \( \partial u_m / \partial \beta_j \).

  For a moment equation of the form \( E\{h_m(z_i; \beta)\} = 0 \), \texttt{derivative(m/\beta_j = <dexp_{mn}>)} is to contain a substitutable expression for \( \partial h_m / \partial \beta_j \).

  \texttt{<dexp_{mn}>} uses the same substitutable expression syntax as is used to specify moment equations. If you declare a linear combination in a moment equation, you provide the derivative for the linear combination; \texttt{gmm} then applies the chain rule for you. See Specifying derivatives under Remarks and examples below for examples.

  If you do not specify the \texttt{derivative()} option, \texttt{gmm} calculates derivatives numerically. You must either specify no derivatives or specify all the derivatives that are not identically zero; you cannot specify some analytic derivatives and have \texttt{gmm} compute the rest numerically.
twostep, onestep, and igmm specify which estimator is to be used. You can specify at most one of these options. twostep is the default.

twostep requests the two-step GMM estimator. gmm obtains parameter estimates based on the initial weight matrix, computes a new weight matrix based on those estimates, and then reestimates the parameters based on that weight matrix.

onestep requests the one-step GMM estimator. The parameters are estimated based on an initial weight matrix, and no updating of the weight matrix is performed except when calculating the appropriate variance-covariance (VCE) matrix.

igmm requests the iterative GMM estimator. gmm obtains parameter estimates based on the initial weight matrix, computes a new weight matrix based on those estimates, reestimates the parameters based on that weight matrix, computes a new weight matrix, and so on, to convergence. Convergence is declared when the relative change in the parameter vector is less than igmmeps(), the relative change in the weight matrix is less than igmmweps(), or igmmiterate() iterations have been completed. Hall (2005, sec. 2.4 and 3.6) mentions that there may be gains to finite-sample efficiency from using the iterative estimator.

\[ \text{instruments(} [\text{eqlist}:] \text{varlist[, noconstant]} \text{)} \]

specifies a list of instrumental variables to be used. If you specify a single moment equation, then you do not need to specify the equations to which the instruments apply; you can omit the eqlist and simply specify instruments(varlist). By default, a constant term is included in varlist; to omit the constant term, use the noconstant suboption: instruments(varlist, noconstant).

If you specify a model with multiple moment conditions of the form

\[
E \begin{bmatrix} z_{11}u_{11}(\beta) \\ \vdots \\ z_{qi}u_{qi}(\beta) \end{bmatrix} = 0
\]

then you can specify the equations to indicate the moment equations for which the list of variables is to be used as instruments if you do not want that list applied to all the moment equations. For example, you might type

\[
gmm (\text{main:<mexp}_1>) (<mexp_2>) (<mexp_3>), \text{instruments(z1 z2) //} \text{instruments(2: z3) instruments(main 3: z4)}
\]

Variables z1 and z2 will be used as instruments for all three equations, z3 will be used as an instrument for the second equation, and z4 will be used as an instrument for the first and third equations. Notice that we chose to supply a name for the first moment equation but not the second two.

\text{varlist} may contain factor variables and time-series operators; see [U] 11.4.3 Factor variables and [U] 11.4.4 Time-series varlists, respectively.

\text{xtinstruments(} [\text{eqlist}:] \text{varlist, lags(#1/#2)}\text{)} is for use with panel-data models in which the set of available instruments depends on the time period. As with instruments(), you can prefix the list of variables with equation names or numbers to target instruments to specific equations. Unlike with instruments(), a constant term is not included in varlist. You must \text{xtset} your data before using this option; see [XT] xtset.

If you specify

\[
gmm \ldots, \text{xtinstruments(x, lags(1/.)}) \ldots
\]
then for panel \(i\) and period \(t\), \texttt{gmm} uses as instruments \(x_{i,t-1}, x_{i,t-2}, \ldots, x_{i1}\). More generally, specifying \texttt{xtinstruments(x, lags(#1, #2))} uses as instruments \(x_{i,t-#1}, \ldots, x_{i,t-#2}\); setting \#2 = . requests all available lags. \#1 and \#2 must be zero or positive integers.

\texttt{gmm} automatically excludes observations for which no valid instruments are available. It does, however, include observations for which only a subset of the lags is available. For example, if you request that lags one through three be used, then \texttt{gmm} will include the observations for the second and third time periods even though fewer than three lags are available as instruments.

---

### Weight matrix

\texttt{wmatrix(wmtype[, independent])} specifies the type of weight matrix to be used in conjunction with the two-step and iterated GMM estimators.

Specifying \texttt{wmatrix(robust)} requests a weight matrix that is appropriate when the errors are independent but not necessarily identically distributed. \texttt{wmatrix(robust)} is the default.

Specifying \texttt{wmatrix(cluster clustvar)} requests a weight matrix that accounts for arbitrary correlation among observations within clusters identified by \texttt{clustvar}.

Specifying \texttt{wmatrix(hac kernel #)} requests a heteroskedasticity- and autocorrelation-consistent (HAC) weight matrix using the specified kernel (see below) with # lags. The bandwidth of a kernel is equal to the number of lags plus one.

Specifying \texttt{wmatrix(hac kernel opt)} requests an HAC weight matrix using the specified kernel, and the lag order is selected using Newey and West’s (1994) optimal lag-selection algorithm.

Specifying \texttt{wmatrix(hac kernel)} requests an HAC weight matrix using the specified kernel and \(N - 2\) lags, where \(N\) is the sample size.

There are three kernels available for HAC weight matrices, and you may request each one by using the name used by statisticians or the name perhaps more familiar to economists:

- \texttt{bartlett} or \texttt{nw}est requests the Bartlett (Newey–West) kernel;
- \texttt{parzen} or \texttt{gallant} requests the Parzen (Gallant) kernel; and
- \texttt{quadraticspectral} or \texttt{andrews} requests the quadratic spectral (Andrews) kernel.

Specifying \texttt{wmatrix(unadjusted)} requests a weight matrix that is suitable when the errors are homoskedastic. In some applications, the GMM estimator so constructed is known as the (nonlinear) two-stage least-squares (2SLS) estimator.

Including the \texttt{independent} suboption creates a weight matrix that assumes moment equations are independent. This suboption is often used to replicate other models that can be motivated outside the GMM framework, such as the estimation of a system of equations by system-wide 2SLS. This suboption has no effect if only one moment equation is specified.

\texttt{wmatrix()} has no effect if \texttt{onestep} is also specified.

\texttt{center} requests that the sample moments be centered (demeaned) when computing GMM weight matrices. By default, centering is not done.

\texttt{winitial(wmtype[, independent])} specifies the weight matrix to use to obtain the first-step parameter estimates.

Specifying \texttt{winitial(unadjusted)} requests a weight matrix that assumes the moment equations are independent and identically distributed. This matrix is of the form \((Z'Z)^{-1}\), where \(Z\) represents all the instruments specified in the \texttt{instruments()} option. To avoid a singular weight matrix, you should specify at least \(q - 1\) moment equations of the form \(E\{z_{hi}u_{hi}(\beta)\} = 0\), where \(q\) is the number of moment equations, or you should specify the \texttt{independent} suboption.
Including the `independent` suboption creates a weight matrix that assumes moment equations are independent. Elements of the weight matrix corresponding to covariances between two moment equations are set equal to zero. This suboption has no effect if only one moment equation is specified.

`winitial(unadjusted)` is the default.

`winitial(xt xtspec)` is for use with dynamic panel-data models in which one of the moment equations is specified in first-differences form. `xtspec` is a string consisting of the letters “L” and “D”, the length of which is equal to the number of moment equations in the model. You specify “L” for a moment equation if that moment equation is written in levels, and you specify “D” for a moment equation if it is written in first-differences; `xtspec` is not case sensitive. When you specify this option, you can specify at most one moment equation in levels and one moment equation in first-differences. See the examples listed in *Dynamic panel-data models* under Remarks and examples below.

`winitial(identity)` requests that the identity matrix be used.

`winitial(matname)` requests that Stata matrix `matname` be used. You cannot specify the independent suboption if you specify `winitial(matname)`.

---

**Options**

`variables(varlist)` specifies the variables in the model. `gmm` ignores observations for which any of these variables has a missing value. If you do not specify `variables()`, then `gmm` assumes all the observations are valid and issues an error message with return code 480 if any moment equations evaluate to missing for any observations at the initial value of the parameter vector.

`nocommonesample` requests that `gmm` not restrict the estimation sample to be the same for all equations. By default, `gmm` will restrict the estimation sample to observations that are available for all equations in the model, mirroring the behavior of other multiple-equation estimators such as `nlsur`, `sureg`, or `reg3`. For certain models, however, different equations can have different numbers of observations. For these models, you should specify `nocommonesample`. See *Dynamic panel-data models* below for one application of this option. You cannot specify weights if you specify `nocommonesample`.

---

**SE/Robust**

`vce(vcetype[, independent])` specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster `clustvar`), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] *vce_option*.

`vce(unadjusted)` specifies that an unadjusted (nonrobust) VCE matrix be used; this, along with the `twostep` option, results in the “optimal two-step GMM” estimates often discussed in textbooks.

The default `vcetype` is based on the `wmtype` specified in the `wmatrix()` option. If `wmatrix()` is specified but `vce()` is not, then `vcetype` is set equal to `wmtype`. To override this behavior and obtain an unadjusted (nonrobust) VCE matrix, specify `vce(unadjusted)`.

Specifying `vce(bootstrap)` or `vce(jackknife)` results in standard errors based on the bootstrap or jackknife, respectively. See [R] *vce_option*, [R] *bootstrap*, and [R] *jackknife* for more information on these VCEs.

The syntax for `vcetypes` other than `bootstrap` and `jackknife` is identical to those for `wmatrix()`.
quickderivatives requests that an alternative method be used to compute the numerical derivatives for the VCE. This option has no effect if you specify the derivatives(), hasderivatives, or haslfderivatives option.

The VCE depends on a matrix of partial derivatives that \texttt{gmm} must compute numerically unless you supply analytic derivatives. This Jacobian matrix will be especially large if your model has many instruments, moment equations, or parameters.

By default, \texttt{gmm} computes each element of the Jacobian matrix individually, searching for an optimal step size each time. Although this procedure results in accurate derivatives, it is computationally taxing: \texttt{gmm} may have to evaluate the moments of your model five or more times for each element of the Jacobian matrix.

When you specify the quickderivatives option, \texttt{gmm} computes all derivatives corresponding to a parameter at once, using a fixed step size proportional to the parameter’s value. This method requires just two evaluations of the model’s moments to compute an entire column of the Jacobian matrix and therefore has the most impact when you specify many instruments or moment equations.

Most of the time, the two methods produce virtually identical results, but the quickderivatives method may fail if a moment equation is highly nonlinear or if instruments differ by orders of magnitude. In the rare case where you specify quickderivatives and obtain suspiciously large or small standard errors, try refitting your model without this option.

Reporting

\texttt{level(\#)}; see \texttt{[R] estimation options}.

\texttt{title(string)} specifies an optional title that will be displayed just above the table of parameter estimates.

\texttt{title2(string)} specifies an optional subtitle that will be displayed between the title specified in \texttt{title()} and the table of parameter estimates. If \texttt{title2()} is specified but \texttt{title()} is not, \texttt{title2()} has the same effect as \texttt{title()}.

display_options: \texttt{cformat(\%fmt)}, \texttt{pformat(\%fmt)}, \texttt{sformat(\%fmt)}, and \texttt{nolstretch}; see \texttt{[R] estimation options}.

Optimization

\texttt{from(initial_values)} specifies the initial values to begin the estimation. You can specify a $1 \times k$ matrix, where $k$ is the number of parameters in the model, or you can specify a parameter name, its initial value, another parameter name, its initial value, and so on. For example, to initialize alpha to 1.23 and delta to 4.57, you would type

\begin{verbatim}
gmm ..., from(alpha 1.23 delta 4.57) ...
\end{verbatim}

Initial values declared using this option override any that are declared within substitutable expressions. If you specify a parameter that does not appear in your model, \texttt{gmm} exits with error code 480. If you specify a matrix, the values must be in the same order in which the parameters are declared in your model. \texttt{gmm} ignores the row and column names of the matrix.

\texttt{igmmiterate(\#)}, \texttt{igmmeps(\#)}, and \texttt{igmmweps(\#)} control the iterative process for the iterative GMM estimator. These options can be specified only if you also specify \texttt{igmm}.

\texttt{igmmiterate(\#)} specifies the maximum number of iterations to perform with the iterative GMM estimator. The default is the number set using \texttt{set maxiter (set [R] maximize)}, which is 16,000 by default.
igmmeps(#) specifies the convergence criterion used for successive parameter estimates when the iterative GMM estimator is used. The default is igmmeps(1e-6). Convergence is declared when the relative difference between successive parameter estimates is less than igmmeps() and the relative difference between successive estimates of the weight matrix is less than igmwmeps().

igmwmeps(#) specifies the convergence criterion used for successive estimates of the weight matrix when the iterative GMM estimator is used. The default is igmwmeps(1e-6). Convergence is declared when the relative difference between successive parameter estimates is less than igmmeps() and the relative difference between successive estimates of the weight matrix is less than igmwmeps().

**optimization options:** technique(), conv_maxiter(), conv_ptol(), conv_vtol(), conv_nrtol(), tracelevel(). technique() specifies the optimization technique to use; gn (the default), nr, dfp, and bfgs are allowed. conv_maxiter() specifies the maximum number of iterations; conv_ptol(), conv_vtol(), and conv_nrtol() specify the convergence criteria for the parameters, gradient, and scaled Hessian, respectively. tracelevel() allows you to obtain additional details during the iterative process. See [M-5] optimize().

The following options pertain only to the moment-evaluator program version of gmm.

---

**Evaluator options** refer to any options allowed by your moment_prog.

hasderivatives and haslfderivatives indicate that you have written your moment-evaluator program to compute derivatives. You may specify one or the other but not both. If you do not specify either of these options, gmm computes the derivatives numerically.

hasderivatives indicates that your moment-evaluator program computes parameter-level derivatives.

haslfderivatives indicates that your moment-evaluator program computes equation-level derivatives and is useful only when you specify the parameters of your model using the <eqname>:<varname> syntax of the parameters() option.

See Details of moment-evaluator programs below for more information.

equations(namelist) specifies the names of the moment equations in the model. If you specify both equations() and nequations(), the number of names in the former must match the number specified in the latter.

nequations(#) specifies the number of moment equations in the model. If you do not specify names with the equations() option, gmm numbers the moment equations 1, 2, 3, ... . If you specify both equations() and nequations(), the number of names in the former must match the number specified in the latter.

parameters(namelist) specifies the names of the parameters in the model. The names of the parameters must adhere to the naming conventions of Stata’s variables; see [U] 11.3 Naming conventions.

Alternatively, you may specify a list of names in which each item in the list is of the form <eqname>:<varname>, where eqname is an equation name used to group parameters, and varname is the name of an existing variable or _cons to indicate a constant term. When you use this syntax, gmm adorns the parameter vector passed to your evaluator program with these names so that you can use matrix score (see [P] matrix score) to compute linear combinations of parameters. These equation names are not related to the names you may give to the moment equations.
If you specify both `parameters()` and `nparameters()`, the number of names in the former must match the number specified in the latter.

`nparameters(#)` specifies the number of parameters in the model. If you do not specify names with the `parameters()` option, `gmm` names them `b1, b2, ..., b#`. If you specify both `parameters()` and `nparameters()`, the number of names in the former must match the number specified in the latter.

The following option is available with `gmm` but is not shown in the dialog box: `coeflegend`; see [R] estimation options.

**Remarks and examples**

Remarks are presented under the following headings:

- Introduction
- Substitutable expressions
- The weight matrix and two-step estimation
- Obtaining standard errors
- Exponential (Poisson) regression models
- Specifying derivatives
- Exponential regression models with panel data
- Rational-expectations models
- System estimators
- Dynamic panel-data models
- Details of moment-evaluator programs

**Introduction**

The generalized method of moments (GMM) estimator is a workhorse of modern econometrics and is discussed in all the leading textbooks, including Cameron and Trivedi (2005, 2010), Davidson and MacKinnon (1993, 2004), Greene (2012, 468–506), Ruud (2000), Hayashi (2000), Wooldridge (2010), Hamilton (1994), and Baum (2006). An excellent treatise on GMM with a focus on time-series applications is Hall (2005). The collection of papers by Mátayás (1999) provides both theoretical and applied aspects of GMM. Here we give a brief introduction to the methodology and emphasize how the various options of `gmm` are used.

The starting point for the generalized method of moments (GMM) estimator is the analogy principle, which says we can estimate a parameter by replacing a population moment condition with its sample analogue. For example, the mean of an independent and identically distributed (i.i.d.) population is defined as the value \( \mu \) such that the first (central) population moment is zero; that is, \( \mu \) solves \( E(y - \mu) = 0 \) where \( y \) is a random draw from the population. The analogy principle tells us that to obtain an estimate, \( \hat{\mu} \), of \( \mu \), we replace the population-expectations operator with its sample analogue (Manski 1988; Wooldridge 2010):

\[
E(y - \mu) = 0 \rightarrow \frac{1}{N} \sum_{i=1}^{N} (y_i - \hat{\mu}) = 0 \rightarrow \hat{\mu} = \frac{1}{N} \sum_{i=1}^{N} y_i
\]

where \( N \) denotes sample size and \( y_i \) represents the \( i \)th observation of \( y \) in our dataset. The estimator \( \hat{\mu} \) is known as the method of moments (MM) estimator, because we started with a population moment condition and then applied the analogy principle to obtain an estimator that depends on the observed data.
Ordinary least-squares (OLS) regression can also be viewed as an MM estimator. In the model

\[ y = \mathbf{x}' \beta + u \]

we assume that \( u \) has mean zero conditional on \( \mathbf{x} \): \( E(u | \mathbf{x}) = 0 \). This conditional expectation implies the unconditional expectation \( E(\mathbf{x}u) = 0 \) because, using the law of iterated expectations,

\[ E(\mathbf{x}u) = E_x \{ E(\mathbf{x}u | \mathbf{x}) \} = E_x \{ \mathbf{x} E(u | \mathbf{x}) \} = 0 \]

(Using the law of iterated expectations to derive unconditional expectations based on conditional expectations, perhaps motivated by subject theory, is extremely common in GMM estimation.) Continuing,

\[ E(\mathbf{x}u) = E \{ \mathbf{x}(y - \mathbf{x}' \beta) \} = 0 \]

Applying the analogy principle,

\[ E \{ \mathbf{x}(y - \mathbf{x}' \beta) \} \longrightarrow \frac{1}{N} \sum_{i=1}^{N} \mathbf{x}_i(y_i - \mathbf{x}_i' \beta) = 0 \]

so that

\[ \hat{\beta} = \left( \sum_{i} \mathbf{x}_i \mathbf{x}_i' \right)^{-1} \sum_{i} \mathbf{x}_i y_i \]

which is just the more familiar formula \( \hat{\beta} = (\mathbf{X}' \mathbf{X})^{-1} \mathbf{X}' \mathbf{y} \) written using summation notation.

In both the previous examples, the number of parameters we were estimating equaled the number of moment conditions. In the first example, we estimated one parameter, \( \mu \), and had one moment condition \( E(y - \mu) = 0 \). In the second example, the parameter vector \( \beta \) had \( k \) elements, as did the vector of regressors \( \mathbf{x} \), yielding \( k \) moment conditions. Ignoring peculiar cases, a model of \( m \) equations in \( m \) unknowns has a unique solution, and because the moment equations in these examples were linear, we were able to solve for the parameters analytically. Had the moment conditions been nonlinear, we would have had to use numerical techniques to solve for the parameters, but that is not a significant limitation with modern computers.

What if we have more moment conditions than parameters? Say we have \( l \) moment conditions and \( k \) parameters. A model of \( l > k \) equations in \( k \) unknowns does not have a unique solution. Any size-\( k \) subset of the moment conditions would yield a consistent parameter estimate, though the parameter estimate so obtained would in general be different based on which \( k \) moment conditions we used.

For concreteness, let’s return to our regression model,

\[ y = \mathbf{x}' \beta + u \]

but we no longer wish to assume that \( E(\mathbf{x}u) = 0 \); we suspect that the error term \( u \) affects one or more elements of \( \mathbf{x} \). As a result, we can no longer use the OLS estimator. Suppose we have a vector \( \mathbf{z} \) with the properties that \( E(\mathbf{z}u) = 0 \), that the rank of \( E(\mathbf{z}' \mathbf{z}) \) equals \( l \), and that the rank of \( E(\mathbf{z}' \mathbf{x}) = k \). The first assumption simply states that \( \mathbf{z} \) is not correlated with the error term. The second assumption rules out perfect collinearity among the elements of \( \mathbf{z} \). The third assumption, known as the rank condition in econometrics, ensures that \( \mathbf{z} \) is sufficiently correlated with \( \mathbf{x} \) and that the estimator is feasible. If some elements of \( \mathbf{x} \) are not correlated with \( u \), then they should also appear in \( \mathbf{z} \).

If \( l < k \), then the rank of \( E(\mathbf{z}' \mathbf{x}) < k \), violating the rank condition.
If \( l = k \), then we can use the simpler MM estimator we already discussed; we would obtain what is sometimes called the simple instrumental-variables estimator \( \hat{\beta} = \left( \sum_i z_i x_i' \right)^{-1} \sum_i z_i y_i \). The rank condition ensures that \( \sum_i z_i x_i' \) is invertible, at least in the population.

If \( l > k \), the GMM estimator chooses the value, \( \hat{\beta} \), that minimizes a quadratic function of the moment conditions. We could define

\[
\hat{\beta} \equiv \arg \min_{\beta} \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\} \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\}
\]

where for our linear regression example \( u_i(\beta) = y_i - x_i' \beta \). This estimator tries to make the moment conditions as close to zero as possible. This simple estimator, however, applies equal weight to each of the moment conditions; and as we shall see later, we can obtain more efficient estimators by choosing to weight some moment conditions more highly than others.

Consider the quadratic function

\[
Q(\beta) = \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\} \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\} \]

where \( W \) is a symmetric positive-definite matrix known as a weight matrix. Then we define the GMM estimator as

\[
\hat{\beta} \equiv \arg \min_{\beta} Q(\beta)
\]

Continuing with our regression model example, if we choose

\[
W = \left( \frac{1}{N} \sum_i z_i z_i' \right)^{-1}
\]

then we obtain

\[
\hat{\beta} = \left\{ \left( \frac{1}{N} \sum_i x_i z_i' \right) \left( \frac{1}{N} \sum_i z_i z_i' \right)^{-1} \left( \frac{1}{N} \sum_i z_i x_i' \right) \right\}^{-1} \times \\
\left\{ \left( \frac{1}{N} \sum_i x_i z_i' \right) \left( \frac{1}{N} \sum_i z_i z_i' \right)^{-1} \left( \frac{1}{N} \sum_i z_i y_i \right) \right\}
\]

which is the well-known two-stage least-squares (2SLS) estimator. Our choice of weight matrix here was based on the assumption that \( u \) was homoskedastic. A feature of GMM estimation is that by selecting different weight matrices, we can obtain estimators that can tolerate heteroskedasticity, clustering, autocorrelation, and other features of \( u \). See \[R\] \texttt{ivregress} for more information about the 2SLS and linear GMM estimators.

Returning to the case where the model is “just identified”, meaning that \( l = k \), if we apply the GMM estimator, we will obtain the same estimate, \( \hat{\beta} \), regardless of our choice of \( W \). Because \( l = k \), if a unique solution exists, it will set all the sample moment conditions to zero jointly, so \( W \) has no impact on the value of \( \beta \) that minimizes the objective function.

We will highlight other features of the GMM estimator and the \texttt{gmm} command as we proceed through examples. First, though, we discuss how to specify moment equations by using substitutable expressions.
Substitutable expressions

To use the interactive version of \texttt{gmm}, you define the moment equations by using substitutable expressions. In most applications, your moment conditions are of the form $E\{z'_i u_i(\beta)\}$, where $u_i(\beta)$ is a residual term that depends on the parameter vector $\beta$ as well as variables in your dataset, though we suppress expressing the variables for notational simplicity; we refer to $u_i(\beta)$ as the moment equation to differentiate it from the moment conditions $E\{z'_i u_i(\beta)\} = 0$.

Substitutable expressions in \texttt{gmm} work much like those used in \texttt{nl} and \texttt{nlsur}, though with one important difference. For the latter two commands, you type the name of the dependent variable, an equal sign, and then the regression function. For example, in \texttt{nl}, if you want to fit the function $y = f(x; \beta) + u$, you would type
\begin{verbatim}
nl (y = <expression for f(x; \beta)>, ...)
\end{verbatim}
On the other hand, \texttt{gmm} requires you to write a substitutable expression for $u$; in this example, $u = y - f(x; \beta)$, so you would type
\begin{verbatim}
gmm (y - <expression for f(x; \beta)>, ...)
\end{verbatim}
The advantage of writing the substitutable expression directly in terms of $u$ is that you are not restricted to fitting models with additive error terms as you are with \texttt{nl} and \texttt{nlsur}.

You specify substitutable expressions just like any other mathematical expression involving scalars and variables, such as those you would use with Stata’s \texttt{generate} command, except that the parameters to be estimated are bound in braces. See [U] 13.2 Operators and [U] 13.3 Functions for more information on expressions. Parameter names must follow the same conventions as variable names. See [U] 11.3 Naming conventions.

For example, say that the $t$th observation on a sample moment is
\begin{equation}
    u_t = 1 - \beta \{(1 + r_{t+1})(c_{t+1}/c_t)^{\gamma}\}
\end{equation}
where $t$ denotes time period, $\beta$ and $\gamma$ are the parameters to be estimated, and $r$ and $c$ are variables in your dataset. Then you would type
\begin{verbatim}
gmm (1 - {beta}*{(1 + F.r)*(F.c/c)^(-1*{gamma})}), ...
\end{verbatim}
Because $\beta$ and $\gamma$ are parameters, we enclose them in braces. Also notice our use of the forward operator to refer to the values of $r$ and $c$ one period ahead; time-series operators are allowed in substitutable expressions as long as you have previously \texttt{tsset} (see [TS] \texttt{tsset}) your data. See [U] 13.9 Time-series operators for more information on time-series operators.

To specify initial values for some parameters, you can include an equal sign and the initial value after a parameter:
\begin{verbatim}
gmm (1 - {beta}*{(1 + F.r)*(F.c/c)^(-1*{gamma=1})}), ...
\end{verbatim}
would initialize $\gamma$ to be one. If you do not specify an initial value for a parameter, it is initialized to zero.

Frequently, even nonlinear functions contain linear combinations of variables. As an example, suppose you have this moment equation:
\begin{equation}
    u = \{y - \exp(\beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3)\} / \exp(\beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3)
\end{equation}
Instead of typing
\begin{verbatim}
gmm ((y - \exp({beta1}*x1 + {beta2}*x2 + {beta3}*x3)) / \exp({beta1}*x1 + {beta2}*x2 + {beta3}*x3)) ...
\end{verbatim}

you can type

\[ \text{gmm} \left( \frac{y - \exp(\{xb:x_1 \ x_2 \ x_3\})}{\exp(\{xb:\})} \right) \ldots. \]

The notation \( \{xb:x_1 \ x_2 \ x_3\} \) tells \text{gmm} that you want a linear combination of the variables \( x_1, x_2, \) and \( x_3 \). We named this linear combination \( xb \), so \text{gmm} will name the three parameters corresponding to the three variables \( xb_\_x1, xb_\_x2, \) and \( xb_\_x3 \). You can name the linear combination anything you wish (subject to Stata's naming conventions for variable names); \text{gmm} then names the parameter corresponding to variable \( x \ lc_\_x \), where \( lc \) is the name of your linear combination. You cannot use the same name for both an individual parameter and a linear combination. You can, however, refer to one parameter in a linear combination after it has been declared as you would any other parameter by using the notation \( \{lc_\_x\} \). Linear combinations do not include a constant term.

Once we have declared the variables in the linear combination \( xb \), we can subsequently refer to the linear combination in our substitutable expression by using the notation \( xb:\). The colon is not optional; it tells \text{gmm} that you are referring to a previously declared linear combination, not an individual parameter. This shorthand notation is also handy when specifying derivatives, as we will show later.

In general, there are three rules to follow when defining substitutable expressions:

1. Parameters of the model are bound in braces: \( \{b0\}, \{param\}, \) etc.
2. Initial values for parameters are given by including an equal sign and the initial value inside the braces: \( \{b0=1\}, \{param=3.571\}, \) etc.
3. Linear combinations of variables can be included using the notation \( \{eqname:varlist\}: \{xb: mpg \ price \ weight\}, \{score: \ w \ x \ z\}, \) etc. Parameters of linear combinations are initialized to zero.

If you specify initial values by using the \texttt{from()} option, they override whatever initial values are given within the substitutable expression. Substitutable expressions are so named because, once values are assigned to the parameters, the resulting expressions can be handled by \texttt{generate} and \texttt{replace}.

> Example 1: OLS regression

In \textit{Introduction}, we stated that OLS is an MM estimator. Say that we want to fit the model

\[ mpg = \beta_0 + \beta_1 \text{weight} + \beta_2 \text{length} + u \]

where \( u \) is an i.i.d. error term. We type
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. gmm (mpg - {b1}*weight - {b2}*length - {b0}), instruments(weight length)

**Step 1**
Iteration 0:  GMM criterion Q(b) = 475.4138
Iteration 1:  GMM criterion Q(b) = 3.305e-20
Iteration 2:  GMM criterion Q(b) = 3.795e-27

**Step 2**
Iteration 0:  GMM criterion Q(b) = 7.401e-28
Iteration 1:  GMM criterion Q(b) = 3.771e-31

**GMM estimation**
Number of parameters = 3
Number of moments = 3
Initial weight matrix: Unadjusted Number of obs = 74
GMM weight matrix: Robust

| Coef. | Std. Err. | z    | P>|z|   | [95% Conf. Interval] |
|-------|-----------|------|-------|----------------------|
| /b1   | -.0038515 | .0019472 | -1.98 | 0.048    | -.0076678 -.0000351 |
| /b2   | -.0795935 | .0677528 | -1.17 | 0.240    | -.2123864 .0531995 |
| /b0   | 47.88487  | 7.505985 | 6.38  | 0.000    | 33.17341 62.59633  |

Instruments for equation 1: weight length _cons

Recall that the moment condition for OLS regression is $E(xu) = 0$, where $x$, the list of instruments, is the same as the list of regressors in the model. In our command, we defined the residual term, $u$, inside parentheses by using a substitutable expression; because linear combinations declared in substitutable expressions do not include a constant term, we included our own ($b0$). Inside the instruments() option, we listed our instruments; by default, gmm includes a constant term among the instrument list.

Because the number of moments equals the number of parameters we are estimating, the model is said to be “just identified” or “exactly identified.” Therefore, the choice of weight matrix has no impact on the solution to (2), and the criterion function $Q(\beta)$ achieves its minimum value at zero.

The OLS estimator is a one-step GMM estimator, but we did not bother to specify the onestep option because the model is just identified. Doing a second step of GMM estimation affects neither the point estimates nor the standard errors, so to keep the syntax as simple as possible, we did not include the onestep option. The first step of estimation resulted in $Q(\beta) = 0$ as expected, and the second step of estimation did not change the minimized value of $Q(\beta)$. ($4 \times 10^{-27}$ and $3 \times 10^{-31}$ are both zero for all practical purposes.)

When you do not specify either the wmatrix() or the vce() option, gmm reports heteroskedasticity-robust standard errors. The parameter estimates reported here match those that we would obtain from the command

. regress mpg weight length, vce(robust)

The standard errors reported by that regress command would be larger than those reported by gmm by a factor of sqrt(74/71) because regress makes a small-sample adjustment to the estimated variance matrix while gmm does not. Likewise, had we specified the vce(unadjusted) option with our gmm command, then our standard errors would differ by a factor of sqrt(74/71) from those reported by regress without the vce(robust) option.

Using the notation for linear combinations of parameters, we could have typed

. gmm (mpg - {xb: weight length} - {b0}), instruments(weight length)
and obtained identical results. Instead of having parameters b1 and b2, with this syntax we would have parameters xb_weight and xb_length.

> Example 2: Instrumental-variables regression

In Introduction, we mentioned that 2SLS can be viewed as a GMM estimator. In example 1 of [R] ivregress, we fit by 2SLS a model of rental rates (rent) as a function of the value of owner-occupied housing (hsngval) and the percentage of the population living in urban areas (pcturban):

\[
rent = \beta_0 + \beta_1 hsngval + \beta_2 pcturban + u
\]

by 2SLS. We argued that random shocks that affect rental rates likely also affect housing values, so we treated hsngval as an endogenous variable. As additional instruments, we used family income, faminc, and three regional dummies (reg2–reg4).

To replicate the results of ivregress 2sls by using gmm, we type

```
use http://www.stata-press.com/data/r13/hsng2
.gmm (rent - {xb:hsngval pcturban} - {b0}),
> instruments(pcturban faminc reg2-reg4) vce(unadjusted) onestep
```

**Step 1**

Iteration 0:  GMM criterion Q(b) = 56115.03
Iteration 1:  GMM criterion Q(b) = 110.91583
Iteration 2:  GMM criterion Q(b) = 110.91583

Instruments for equation 1: pcturban faminc reg2 reg3 reg4 _cons

We specified vce(unadjusted) so that we would obtain an unadjusted VCE matrix and our standard errors would match those reported in [R] ivregress.

Pay attention to how we specified the instruments() option. In Introduction, we mentioned that the moment conditions for the 2SLS estimator are \( E(zu) = 0 \), and we mentioned that if some elements of x (the regressors) are not endogenous, then they should also appear in z. In this model, we assume the regressor pcturban is exogenous, so we included it in the list of instrumental variables. Commands like ivregress, ivprobit, and ivtobit accept standard varlists, so they can deduce the exogenous regressors in the model. Because gmm accepts arbitrary functions in the form of substitutable expressions, it has no way of discerning the exogenous variables of the model on its own.

Also notice that we specified the onestep option. The 2SLS estimator is a one-step GMM estimator that is based on a weight matrix that assumes the error terms are i.i.d. Unlike the previous example, here we had more instruments than parameters, so the minimized value of \( Q(\beta) \) is nonzero. We discuss the weight matrix and its relationship to two-step estimation next.

```
The weight matrix and two-step estimation

Recall our definition of the GMM estimator given in (2). The estimator, $\hat{\beta}$, depends on the choice of the weight matrix, $W$. Under relatively mild assumptions, our estimator, $\hat{\beta}$, is consistent regardless of the choice of $W$, so how are we to decide what $W$ to use? The most common solution is to use the two-step estimator, which we now describe.

A key result in Hansen’s (1982) seminal paper is that if we denote by $S$ the covariance matrix of the moment conditions, then the optimal (in a way we make precise later) GMM estimator is the one that uses a weight matrix equal to the inverse of the moment covariance matrix. That is, if we let $S = \text{Cov}(zu)$, then we want to use $W = S^{-1}$. But how do we obtain $S$ in the first place?

If we assume that the errors are i.i.d., then

$$\text{Cov}(zu) = E(u^2zz^\prime) = \sigma^2 E(zz^\prime)$$

where $\sigma^2$ is the variance of $u$. Because $\sigma^2$ is a positive scalar, we can ignore it when solving (2). Thus we compute

$$\hat{W}_1 = \left(\frac{1}{N} \sum_i z_i z_i^\prime\right)^{-1}$$

which does not depend on any unknown model parameters. (Notice that $\hat{W}_1$ is the same weight matrix used in 2SLS.) Given $\hat{W}_1$, we can solve (2) to obtain an initial estimate, say, $\hat{\beta}_1$.

Our estimate, $\hat{\beta}_1$, is consistent, so by Slutsky’s theorem, the sample residuals $\hat{u}$ computed at this value of $\beta$ will also be consistent. Using virtually the same arguments used to justify the Huber/Eicker/White heteroskedasticity-robust VCE, if we assume that the residuals are independent though not identically distributed, we can estimate $S$ as

$$\hat{S} = \frac{1}{N} \sum_i \hat{u}_i^2 z_i z_i^\prime$$

Then, in the second step, we re-solve (2), using $\hat{W}_2 = \hat{S}^{-1}$, yielding the two-step GMM estimate $\hat{\beta}_2$. If the residuals exhibit clustering, you can specify $\text{wmatrix(cluster varname)}$ so that $\text{gmm}$ computes a weight matrix that does not assume the $u_i$’s are independent within clusters identified by $\text{varname}$. You can specify $\text{wmatrix(hac ...)}$ to obtain weight matrices that are suitable for when the $u_i$’s exhibit autocorrelation as well as heteroskedasticity.

We could take the point estimates from the second round of estimation and use them to compute yet another weight matrix, $\hat{W}_3$, say, re-solve (2) yet again, and so on, stopping when the parameters or weight matrix do not change much from one iteration to the next. This procedure is known as the iterative GMM estimator and is obtained with the $\text{igmm}$ option. Asymptotically, the two-step and iterative GMM estimators have the same distribution. However, Hall (2005, 90) suggests that the iterative estimator may have better finite-sample properties.

Instead of computing $\hat{W}_1$ as in (4), we could simply choose $\hat{W}_1 = I$, the identity matrix. The initial estimate, $\hat{\beta}_1$, would still be consistent. You can request this behavior by specifying the $\text{winitial(identity)}$ option. However, if you specify all your moment equations of the form $E(zu) = 0$, we recommend using the default $\text{winitial(unadjusted)}$ instead; the rescaling of the moment conditions implied by using a homoskedastic initial weight matrix makes the numerical routines used to solve (2) more stable.
If you fit a model with more than one of the moment equations of the form \( E \{ h(z; \beta) \} = 0 \), then you must use \textit{winitial(identity)} or \textit{winitial(unadjusted, independent)}. With moment equations of that form, you do not specify a list of instruments, and \textit{gmm} cannot evaluate (4)—the matrix expression in parentheses would necessarily be singular, so it cannot be inverted.

### Example 3: Two-step linear GMM estimator

From the previous discussion and the comments in \textit{Introduction}, we see that the linear 2SLS estimator is a one-step GMM estimator where we use the weight matrix defined in (4) that assumes the errors are i.i.d. If we use the 2SLS estimate of \( \beta \) to obtain the sample residuals, compute a new weight matrix based on those residuals, and then do a second step of GMM estimation, we obtain the linear two-step GMM estimator as implemented by \textit{ivregress gmm}.

In example 3 of \textit{[R] ivregress}, we fit the model of rental rates as discussed in example 2 above. We now allow the residuals to be heteroskedastic, though we will maintain our assumption that they are independent. We type

```
. gmm (rent - \{xb:hsngval pcturban\} - \{b0\}), inst(pcturban faminc reg2-reg4)
```

Step 1

| Iteration 0: GMM criterion Q(b) = 56115.03 |
| Iteration 1: GMM criterion Q(b) = 110.91583 |
| Iteration 2: GMM criterion Q(b) = 110.91583 |

Step 2

| Iteration 0: GMM criterion Q(b) = 0.2406087 |
| Iteration 1: GMM criterion Q(b) = 0.13672801 |
| Iteration 2: GMM criterion Q(b) = 0.13672801 (backed up) |

Instruments for equation 1: pcturban faminc reg2 reg3 reg4 _cons

By default, \textit{gmm} computes a heteroskedasticity-robust weight matrix before the second step of estimation, though we could have specified \textit{wmatrix(robust)} if we wanted to be explicit. Because we did not specify the \textit{vce()} option, \textit{gmm} used a heteroskedasticity-robust one. Our results match those in example 3 of \textit{[R] ivregress}. Moreover, the only substantive difference between this example and example 2 is that here we did not specify the \textit{onestep} option, so we obtain the two-step estimates.
Obtaining standard errors

This section is a bit more theoretical and can be skipped on first reading. However, the information is sufficiently important that you should return to this section at some point.

So far in our discussion, we have focused on point estimation without much mention of how we obtain the standard errors of the estimates. We also mentioned that if we choose $W$ to be the inverse of the covariance matrix of the moment conditions, then we obtain the “optimal” GMM estimator. We elaborate those points now.

Using mostly standard statistical arguments, we can show that for the GMM estimator defined in (2), the variance of $\hat{\beta}$ is given by

$$\text{Var}(\hat{\beta}) = \frac{1}{N} \left\{ \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{G}(\hat{\beta}) \right\}^{-1} \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{S} \mathbf{W} \mathbf{G}(\hat{\beta}) \left\{ \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{G}(\hat{\beta}) \right\}^{-1}$$  \hspace{1cm} (5)

where

$$\mathbf{G}(\hat{\beta}) = \frac{1}{N} \sum_i \mathbf{z}_i \left. \frac{\partial u_i}{\partial \beta} \right|_{\beta=\hat{\beta}}$$

or

$$\mathbf{G}(\hat{\beta}) = \frac{1}{N} \sum_i \left. \frac{\partial h_i}{\partial \beta} \right|_{\beta=\hat{\beta}}$$

as the case may be and $\mathbf{S} = E(\mathbf{z} \mathbf{u} \mathbf{u}' \mathbf{z}')$.

Assuming the vce(unadjusted) option is not specified, gmm reports standard errors based on the robust variance matrix defined in (5). For the two-step estimator, $\mathbf{W}$ is the weight matrix requested using the wmatrix() option, and it is calculated based on the residuals obtained after the first estimation step. The second-step point estimates and residuals are obtained, and $\mathbf{S}$ is calculated based on the specification of the vce() option. For the iterated estimator, $\mathbf{W}$ is calculated based on the second-to-last round of estimation, while $\mathbf{S}$ is based on the residuals obtained after the last round of estimation. Computation of the covariance matrix for the one-step estimator is, perhaps surprisingly, more involved; we discuss the covariance matrix with the one-step estimator in the technical note at the end of this section.

If we choose the weight matrix to be the inverse of the covariance matrix of the moment conditions so that $\mathbf{W} = \mathbf{S}^{-1}$, then (5) simplifies substantially:

$$\text{Var}(\hat{\beta}) = \frac{1}{N} \left\{ \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{G}(\hat{\beta}) \right\}^{-1} \hspace{1cm} (6)$$

The GMM estimator constructed using this choice of weight matrix along with the covariance matrix in (6) is known as the “optimal” GMM estimator. One can show that if in fact $\mathbf{W} = \mathbf{S}^{-1}$, then the variance in (6) is smaller than the variance in (5) of any other GMM estimator based on the same moment conditions but with a different choice of weight matrix. Thus the optimal GMM estimator is also known as the efficient GMM estimator, because it has the smallest variance of any estimator based on the given moment conditions.

To obtain standard errors from gmm based on the optimal GMM estimator, you specify the vce(unadjusted) option. We call that VCE unadjusted because we do not recompute the residuals after estimation to obtain the matrix $\mathbf{S}$ required in (5) or allow for the fact that those residuals may not be i.i.d. Some statistical packages by default report standard errors based on (6) and offer standard errors based on (5) only as an option or not at all. While the optimal GMM estimator is theoretically appealing, Cameron and Trivedi (2005, 177) suggest that in finite samples it need not perform better than the GMM estimator that uses (5) to obtain standard errors.
Computing the covariance matrix of the parameters after using the one-step estimator is actually a bit more complex than after using the two-step or iterative estimators. We can illustrate most of the intricacies by using linear regression with moment conditions of the form $E\{x(y - x'\beta)\} = 0$.

If you specify `winitial(unadjusted)` and `vce(unadjusted)`, then the initial weight matrix will be computed as

$$\hat{W}_1 = \left(\frac{1}{N} \sum_i x_i x_i'\right)^{-1}$$

(7)

Moreover, for linear regression, we can show that

$$\bar{G}(\hat{\beta}) = \frac{1}{N} \sum_i x_i x_i'$$

so that (6) becomes

$$\text{Var}(\hat{\beta}) = \frac{1}{N} \left\{ \left(\frac{1}{N} \sum_i x_i x_i'\right)^{-1} \left(\frac{1}{N} \sum_i x_i x_i'\right)^{-1} \left(\frac{1}{N} \sum_i x_i x_i'\right) \right\}^{-1}$$

$$= \left(\sum_i x_i x_i'\right)^{-1}$$

$$= (X'X)^{-1}$$

(8)

However, we know that the nonrobust covariance matrix for the OLS estimator is actually $\hat{\sigma}^2 (X'X)^{-1}$. What is missing from (8) is the scalar $\hat{\sigma}^2$, the estimated variance of the residuals. When you use the one-step estimator and specify `winitial(unadjusted)`, the weight matrix (7) does not include the $\hat{\sigma}^2$ term because gmm does not have a consistent estimate of $\beta$ from which it can then estimate $\sigma^2$. The point estimates are still correct, because multiplying the weight matrix by a scalar factor does not affect the solution to the minimization problem.

To circumvent this issue, if you specify `winitial(unadjusted)` and `vce(unadjusted)`, gmm uses the estimated $\hat{\beta}$ (which is consistent) to obtain a new unadjusted weight matrix that does include the term $\hat{\sigma}^2$ so that evaluating (6) will yield correct standard errors.

If you use the two-step or iterated GMM estimators, this extra effort is not needed to obtain standard errors because the first-step (and subsequent steps’) estimate of $\beta$ is consistent and can be used to estimate $\sigma^2$ or some other weight matrix based on the `wmatrix()` option. Straightforward algebra shows that this extra effort is also not needed if you request any type of adjusted (robust) covariance matrix with the one-step estimator.

A similar issue arises when you specify `winitial(identity)` and `vce(unadjusted)` with the one-step estimator. Again the solution is to compute an unadjusted weight matrix after obtaining $\hat{\beta}$ so that (6) provides the correct standard errors.

We have illustrated the problem and solution using a single-equation linear model. However, the problem arises whenever you use the one-step estimator with an unadjusted VCE, regardless of the number of equations; and gmm handles all the details automatically. Computation of Hansen’s $J$ statistic presents an identical issue, and gmm takes care of that as well.
If you supply your own initial weight matrix by using \texttt{winitial(matname)}, then the standard errors (as well as the $J$ statistic reported by \texttt{estat overid}) are based on that weight matrix. You should verify that the weight matrix you provide will yield appropriate statistics.

### Exponential (Poisson) regression models

Exponential regression models are frequently encountered in applied work. For example, they can be used as alternatives to linear regression models on log-transformed dependent variables, obviating the need for post-hoc transformations to obtain predicted values in the original metric of the dependent variable. When the dependent variable represents a discrete count variable, they are also known as Poisson regression models; see Cameron and Trivedi (2013).

For now, we consider models of the form

$$y = \exp(x'\beta) + u$$  \hspace{1cm} (9)

where $u$ is a zero-mean additive error term so that $E(y) = \exp(x'\beta)$. Because the error term is additive, if $x$ represents strictly exogenous regressors, then we have the population moment condition

$$E[x\{y - \exp(x'\beta)\}] = 0$$ \hspace{1cm} (10)

Moreover, because the number of parameters in the model is equal to the number of instruments, there is no point to using the two-step GMM estimator.

#### Example 4: Exponential regression

Cameron and Trivedi (2010, 323) fit a model of the number of doctor visits based on whether the patient has private insurance, whether the patient has a chronic disease, gender, and income. Here we fit that model by using \texttt{gmm}. To allow for potential excess dispersion, we will obtain a robust \texttt{VCE} matrix, which is the default for \texttt{gmm} anyway. We type

```stata
. use http://www.stata-press.com/data/r13/docvisits
. gmm (docvis - \exp({xb:private chronic female income}+{b0})),
> instruments(private chronic female income) onestep
```

Step 1

Iteration 0: GMM criterion Q(b) = 16.853973
Iteration 1: GMM criterion Q(b) = 2.2706472
Iteration 2: GMM criterion Q(b) = .19088097
Iteration 3: GMM criterion Q(b) = .00041101
Iteration 4: GMM criterion Q(b) = 3.939e-09
Iteration 5: GMM criterion Q(b) = 6.572e-19

Instruments for equation 1: private chronic female income _cons
Our point estimates agree with those reported by Cameron and Trivedi to at least six significant digits; the small discrepancies are attributable to different optimization techniques and convergence criteria being used by \texttt{gmm} and \texttt{poisson}. The standard errors differ by a factor of $\sqrt{4412/4411}$ because \texttt{gmm} uses $N$ in the denominator of the formula for the robust covariance matrix, while the robust covariance matrix estimator used by \texttt{poisson} uses $N - 1$.

\begin{itemize}
\item \textbf{Technical note}
\end{itemize}

That the GMM and maximum likelihood estimators of the exponential regression model coincide is not a general property of these two classes of estimators. The maximum likelihood estimator solves the score equations

$$\frac{1}{N} \sum_{i=1}^{N} \frac{\partial \ln \ell_i}{\partial \beta} = 0$$

where $\ell_i$ is the likelihood for the $i$th observation. These score equations can be viewed as the sample analogues of the population moment conditions

$$E \left\{ \frac{\partial \ln \ell_i}{\partial \beta} \right\} = 0$$

establishing that maximum likelihood estimators represent a subset of the class of GMM estimators.

For the Poisson model,

$$\ln \ell_i = -\exp(x_i'\beta) + y_i x_i' \beta - \ln y_i!$$

so the score equations are

$$\frac{1}{N} \sum_{i=1}^{N} x_i \{y_i - \exp(x_i'\beta)\} = 0$$

which are just the sample moment conditions implied by (10) that we used in the previous example. That is why our results using \texttt{gmm} match Cameron and Trivedi’s results using \texttt{poisson}.

On the other hand, an intuitive set of moment conditions to consider for GMM estimation of a probit model is

$$E[x_i \{y - \Phi(x_i'\beta)\}] = 0$$

where $\Phi()$ is the standard normal cumulative distribution function. Differentiating the likelihood function for the maximum likelihood probit estimator, we can show that the corresponding score equations are

$$\frac{1}{N} \sum_{i=1}^{N} x_i \left[ y_i \frac{\phi(x_i'\beta)}{\Phi(x_i'\beta)} - (1 - y_i) \frac{\phi(x_i'\beta)}{1 - \Phi(x_i'\beta)} \right] = 0$$

where $\phi()$ is the standard normal density function. These two moment conditions are not equivalent, so the maximum likelihood and GMM probit estimators are distinct.
Example 5: Comparison of GMM and maximum likelihood

Using the automobile dataset, here we fit a probit model of foreign on gear_ratio, length, and headroom using first the score equations and then the intuitive set of GMM equations. We type

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. global xb "{b1}*gear_ratio + {b2}*length + {b3}*headroom + {b0}"
. global phi "normalden($xb)"
. global Phi "normal($xb)"
. gmm (foreign*$phi/$Phi - (1-foreign)*$phi/(1-$Phi)), instruments(gear_ratio length headroom) onestep
(output omitted)
. estimates store ml
. gmm (foreign - $Phi), instruments(gear_ratio length headroom) onestep
(output omitted)
. estimates store gmm
. estimates table ml gmm, b se
```

The coefficients on gear_ratio and length are close for the two estimators. The GMM estimate of the coefficient on headroom is twice that of the maximum likelihood estimate, though the relatively large standard errors imply that this difference is not significant. You can verify that the coefficients in the column marked "ml" match those you would obtain using probit. We have not discussed the differences among standard errors based on the various GMM and maximum-likelihood covariance matrix estimators to avoid tedious algebra, though you can verify that the robust covariance matrix after one-step GMM estimation differs by only a finite-sample adjustment factor of \((N/N - 1)\) from the robust covariance matrix reported by probit. Both the maximum likelihood and GMM probit estimators require the normality assumption, and the maximum likelihood estimator is efficient if that normality assumption is correct; therefore, in this particular example, there is no reason to prefer the GMM estimator.

We can modify (10) easily to allow for endogenous regressors. Suppose that \(x_j\) is endogenous in the sense that \(E(u|x_j) \neq 0\). Then (10) is no longer a valid moment condition. However, suppose we have some variables other than \(x\) such that \(E(u|z) = 0\). We can instead use the moment conditions
\[ E(\mathbf{zu}) = E[\mathbf{z} \{ y - \exp(\mathbf{x}'\beta) \}] = 0 \]  

(11)

As usual, if some elements of \( \mathbf{x} \) are exogenous, then they should appear in \( \mathbf{z} \) as well.

**Example 6: Exponential regression with endogenous regressors**

Returning to the model discussed in example 4, here we treat income as endogenous; unobservable factors that determine a person’s income may also affect the number of times a person visits a doctor. We use a person’s age and race as instruments. These are valid instruments if we believe that age and race influence a person’s income but do not have a direct impact on the number of doctor visits. (Whether this belief is justified is another matter; we test that belief in [R] `gmm postestimation`.) Because we have more instruments (seven) than parameters (five), we have an overidentified model. Therefore, the choice of weight matrix does matter. We will utilize the default two-step GMM estimator. In the first step, we will use a weight matrix that assumes the errors are i.i.d. In the second step, we will use a weight matrix that assumes heteroskedasticity. When you specify `twostep`, these are the defaults for the first- and second-step weight matrices, so we do not have to use the `winitial()` or `wmatrix()` options. We will again obtain a robust VCE, which is also the default. We type

```
. use http://www.stata-press.com/data/r13/docvisits
. gmm (docvis - exp({xb:private chronic female income}+{b0})), > instruments(private chronic female age black hispanic) twostep
```

Instruments for equation 1: private chronic female age black hispanic _cons

Once we control for the endogeneity of income, we find that its coefficient has quadrupled in size. Additionally, access to private insurance has less of an impact on the number of doctor visits and gender has more of an impact.
Technical note

Although perhaps at first tempting, unlike the Poisson model, you cannot simply replace $x$ in the moment conditions for the probit (or logit) model with a vector of instruments, $z$, if you have endogenous regressors. See Wilde (2008).

Mullahy (1997) considers a slightly more complicated version of the exponential regression model that incorporates nonadditive unobserved heterogeneity. His model can be written as

$$y_i = \exp(x_i' \beta) \eta_i + \epsilon_i$$

where $\eta_i > 0$ is an unobserved heterogeneity term that may be correlated with $x_i$. One result from his paper is that instead of using the additive moment condition (10), we can use the multiplicative moment condition

$$E \left\{ z \frac{y - \exp(x' \beta)}{\exp(x' \beta)} \right\} = E[z \{y \exp(-x' \beta) - 1\}] = 0$$

Windmeijer and Santos Silva (1997) discuss the use of additive versus multiplicative moment conditions with endogenous regressors and note that a set of instruments that satisfies the additive moment conditions will not also satisfy the multiplicative moment conditions. They remark that which to use is an empirical issue that can at least partially be settled by using the test of overidentifying restrictions that is implemented by `estat overid` after `gmm` to ascertain whether the instruments for a given model are valid. See `[R] gmm postestimation` for information on the test of overidentifying restrictions.

Specifying derivatives

By default, `gmm` calculates derivatives numerically, and the method used produces accurate results for the vast majority of applications. However, if you refit the same model repeatedly or else have the derivatives available, then `gmm` will run more quickly if you supply it with analytic derivatives.

When you use the interactive version of `gmm`, you specify derivatives using substitutable expressions in much the same way you specify the moment equations. There are three rules you must follow:

1. As with the substitutable expressions that define residual equations, you bind parameters of the model in braces: `{b0}`, `{param}`, etc.
2. You must specify a derivative for each parameter that appears in each moment equation. If a parameter does not appear in a moment equation, then you do not specify a derivative for that parameter in that moment equation.
3. If you declare a linear combination in an equation, then you specify a derivative with respect to that linear combination. `gmm` applies the chain rule to obtain the derivatives with respect to the individual parameters encompassed by that linear combination.

We illustrate with several examples.

Example 7: Derivatives for a single-equation model

Consider a simple exponential regression model with one exogenous regressor and a constant term. We have

$$u_i = y_i - \exp(\beta_0 + \beta_1 x_i)$$

Now

$$\frac{\partial u_i}{\partial \beta_0} = -\exp(\beta_0 + \beta_1 x_i) \quad \text{and} \quad \frac{\partial u_i}{\partial \beta_1} = -x_i \exp(\beta_0 + \beta_1 x_i)$$
In Stata, we type

```
.gmm (docvis - exp({b0} + {b1}*income)), instruments(income)
> deriv(/b0 = -1*exp({b0} + {b1}*income))
> deriv(/b1 = -1*income*exp({b0}+{b1}*income)) onestep
```

Step 1
Iteration 0:  GMM criterion Q(b) = 9.1548611
Iteration 1:  GMM criterion Q(b) = 3.5146131
Iteration 2:  GMM criterion Q(b) = .01344695
Iteration 3:  GMM criterion Q(b) = 3.690e-06
Iteration 4:  GMM criterion Q(b) = 4.606e-13
Iteration 5:  GMM criterion Q(b) = 1.501e-26

GMM estimation

| Coef. | Std. Err. | z    | P>|z|   | [95% Conf. Interval] |
|-------|-----------|------|------|----------------------|

| /b1   | .0046702  | .0009715 | 4.81  | 0.000 | .0027662 .0065743|

Instruments for equation 1: income _cons

Notice how we specified the `derivative()` option for each parameter. We simply specified a slash, the name of the parameter, an equal sign, then a substitutable expression that represents the derivative. Because our model has only one residual equation, we do not need to specify equation numbers in the `derivative()` options.

When you specify a linear combination of variables, your derivative should be with respect to the entire linear combination. For example, say we have the residual equation

\[ u_i = y - \exp(x_i'\beta + \beta_0) \]

for which we would type

```
.gmm (y - exp({xb: x1 x2 x3} + {b0}) ...)
```

Then in addition to the derivative \( \frac{\partial u_i}{\partial \beta_0} \), we are to compute and specify

\[
\frac{\partial u_i}{\partial x_i'\beta} = -\exp(x_i'\beta + \beta_0)
\]

Using the chain rule, \( \frac{\partial u_i}{\partial \beta_j} = \frac{\partial u_i}{\partial (x_i'\beta)} \times \frac{\partial (x_i'\beta)}{\partial \beta_j} = -x_{ij}\exp(x_i'\beta + \beta_0) \). Stata does this last calculation automatically. It knows the variables in the linear combination, so all it needs is the derivative of the residual function with respect to the linear combination. This allows you to change the variables in your linear combination without having to change the derivatives.

**Example 8: Derivatives with a linear combination**

We refit the model described in the example illustrating exponential regression with endogenous regressors, now providing analytic derivatives. We type
. gmm (docvis - exp({xb:private chronic female income}+{b0})),
> instruments(private chronic female age black hispanic)
> derivative(/xb = -1*exp({xb:} + {b0}))
> derivative(/b0 = -1*exp({xb:} + {b0}))

Step 1
Iteration 0: GMM criterion Q(b) = 16.910173
Iteration 1: GMM criterion Q(b) = 0.82270871
Iteration 2: GMM criterion Q(b) = 0.21831995
Iteration 3: GMM criterion Q(b) = 0.12673694
Iteration 4: GMM criterion Q(b) = 0.12672369
Iteration 5: GMM criterion Q(b) = 0.12672365

Step 2
Iteration 0: GMM criterion Q(b) = 0.00234641
Iteration 1: GMM criterion Q(b) = 0.00215957
Iteration 2: GMM criterion Q(b) = 0.00215911
Iteration 3: GMM criterion Q(b) = 0.00215911

GMM estimation
Number of parameters = 5
Number of moments = 7

Robust

|        | Coef.  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|--------|--------|-----------|-------|-----|----------------------|
| /xb_private | 0.535335 | 0.159904  | 3.35  | 0.001 | 0.221929 - 0.848741 |
| /xb_chronic | 1.090126 | 0.0617659 | 17.65 | 0.000 | 0.9690668 1.211185 |

In the first derivative() option, we specified the name of the linear combination, xb, instead of an individual parameter’s name. We already declared the variables of our linear combination in the substitutable expression for the residual equation, so in our substitutable expressions for the derivatives, we can use the shorthand notation {xb:} to refer to it.

Our point estimates are identical to those we obtained earlier. The standard errors and confidence intervals differ by only trivial amounts.

Exponential regression models with panel data

In addition to supporting cross-sectional and time-series data, gmm also works with panel-data models. Here we illustrate gmm’s panel-data capabilities by expanding our discussion of exponential regression models to allow for panel data. This also provides us the opportunity to demonstrate the moment-evaluator program version of gmm. Our discussion is based on Blundell, Griffith, and Windmeijer (2002). Also see Wooldridge (1999) for further discussion of nonlinear panel-data models.

First, we expand (9) for panel data. With individual heterogeneity term $\eta_i$, we have

$$E(y_{it}|x_{it}, \eta_i) = \exp(x_{it}^{'}\beta + \eta_i) = \mu_{it}\nu_i$$

where $\mu_{it} = \exp(x_{it}^{'}\beta)$ and $\nu_i = \exp(\eta_i)$. Note that there is no constant term in this model because its effect cannot be disentangled from $\nu_i$. With an additive idiosyncratic error term, we have the regression model

$$y_{it} = \mu_{it}\nu_i + \epsilon_{it}$$
We do not impose the assumption $E(x_{it}\eta_i) = 0$, so $\eta_i$ can be considered a fixed effect in the sense that it may be correlated with the regressors.

As discussed by Blundell, Griffith, and Windmeijer (2002), if $x_{it}$ is strictly exogenous, meaning $E(x_{it}\epsilon_{is}) = 0$ for all $t$ and $s$, then we can estimate the parameters of the model by using the sample moment conditions

$$
\sum_i \sum_t x_{it} \left( y_{it} - \mu_{it} \frac{\bar{y}_i}{\bar{\mu}_i} \right) = 0
$$

(13)

where $\bar{y}_i$ and $\bar{\mu}_i$ are the means of $y_{it}$ and $\mu_{it}$ for panel $i$, respectively. Because $\bar{\mu}_i$ depends on the parameters of the model, it must be recomputed each time \texttt{gmm} needs to evaluate the residual equation. Therefore, we cannot use the substitutable expression version of \texttt{gmm}. Instead, we must use the moment-evaluator program version.

The moment-evaluator program version of \texttt{gmm} functions much like the function-evaluator program versions of \texttt{nl} and \texttt{nlsur}. The program you write is passed one or more variables to be filled in with the residuals evaluated at the parameter values specified in an option passed to your program. For the fixed-effects Poisson model with strictly exogenous regressors, our first crack at a function-evaluator program is

```
program gmm_poi
    version 13
    syntax varlist if, at(name)
    quietly {
        tempvar mu mubar ybar
        gen double 'mu' = exp(x1*'at'[1,1] + x2*'at'[1,2] + x3*'at'[1,3]) 'if'
        egen double 'mubar' = mean('mu') 'if', by(id)
        egen double 'ybar' = mean(y) 'if', by(id)
        replace 'varlist' = y - 'mu'*'ybar'/\mubar 'if'
    }
end
```

You can save your program in an ado-file named \texttt{name.ado}, where \texttt{name} is the name you use for your program; here we would save the program in the ado-file \texttt{gmm.poi.ado}. Alternatively, if you are working from within a do-file, you can simply define the program before calling \texttt{gmm}. The \texttt{syntax} statement declares that we are expecting to receive a \texttt{varlist}, containing the names of variables whose values we are to replace with the values of the residual equations, and an \texttt{if} expression that will mark the estimation sample; because our model has one residual equation, \texttt{varlist} will consist of one variable. \texttt{at()} is a required option to our program, and it will contain the name of a matrix containing the parameter values at which we are to evaluate the residual equation. All moment-evaluator programs must accept the \texttt{varlist}, \texttt{if} condition, and \texttt{at()} option.

The first part of our program computes $\mu_{it}$. In the model we will fit shortly, we have three regressors, named $x_1, x_2$, and $x_3$. The \texttt{at} vector will have three elements, one for each of those variables. Notice that we included \texttt{if} at the end of each statement that affects variables to restrict the computations to the relevant estimation sample. The two \texttt{egen} statements compute $\bar{\mu}_i$ and $\bar{y}_i$; in the example dataset we will use shortly, the panel variable is named \texttt{id}, and for simplicity we hardcoded that variable into our program as well. Finally, we compute the residual equation, which is the portion of (13) bound in parentheses.
Example 9: Panel Poisson with strictly exogenous regressors

To fit our model, we type

```stata
. use http://www.stata-press.com/data/r13/poisson1
. gmm gmm_poi, nequations(1) parameters(b1 b2 b3)
    > instruments(x1 x2 x3, noconstant) vce(cluster id) onestep
```

Step 1
Iteration 0:  GMM criterion Q(b) =  51.99142
Iteration 1:  GMM criterion Q(b) =  .04345191
Iteration 2:  GMM criterion Q(b) =  8.720e-06
Iteration 3:  GMM criterion Q(b) =  7.115e-13
Iteration 4:  GMM criterion Q(b) =  5.130e-27

GMM estimation
Number of parameters =  3

| /b1     | 1.94866      | .1000265  | 19.48| 0.000| 1.752612 2.144709   |
| /b2     | -2.966119    | .0923592  | -32.12| 0.000| -3.14714 -2.785099 |
| /b3     | 1.008634     | .1156561  | 8.72 | 0.000| .781952  1.235315  |

Instruments for equation 1: x1 x2 x3

All three of our regressors are strictly exogenous, so they can serve as their own regressors. There is no constant term in the model (it would be unidentified), so we exclude a constant term from our list of instruments. We have one residual equation as indicated by nequations(1), and we have three parameters, named b1, b2, and b3. The order in which you declare parameters in the parameters() option determines the order in which they appear in the ‘at’ vector in the moment-evaluator program. We specified vce(cluster id) to obtain standard errors that allow for correlation among observations within each panel.

The program we just wrote is sufficient to fit the model to the poisson1 dataset, but if we want to fit that model to other datasets, we would need to change the variable names and perhaps account for having a different number of parameters as well. Despite those limitations, if you just want to fit a single model, that program is adequate.

Next we take advantage of the ability to specify full equation names in the parameters() option and rewrite our evaluator program so that we can more easily change the variables in our model. This approach is particularly useful if some of the moment equations are linear in the parameters, because then we can use matrix score (see [P] matrix score) to evaluate those moments.
Our new evaluator program is

```
program gmm_poieq
    version 13
    syntax varlist if, at(name)
    quietly {
        tempvar mu mubar ybar
        matrix score double 'mu' = 'at' 'if', eq(#1)
        replace 'mu' = exp('mu')
        egen double 'mubar' = mean('mu') 'if', by(id)
        egen double 'ybar' = mean(y) 'if', by(id)
        replace 'varlist' = y - 'mu'*'ybar'/'mubar' 'if'
    }
end
```

Rather than using `generate` to compute the temporary variable `'mu'`, we used `matrix score` to obtain the linear combination \( x'_{it} \beta \) and then called `replace` to compute \( \exp(x'_{it} \beta) \).

Example 10: Panel Poisson using matrix score

To fit our model, we type

```stata
use http://www.stata-press.com/data/r13/poisson1
gmm gmm_poieq, nequations(1) parameters(y:x1 y:x2 y:x3)>
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep
```

Step 1
Iteration 0:  GMM criterion Q(b) = 51.99142
Iteration 1:  GMM criterion Q(b) = 0.04345191
Iteration 2:  GMM criterion Q(b) = 8.720e-06
Iteration 3:  GMM criterion Q(b) = 7.115e-13
Iteration 4:  GMM criterion Q(b) = 5.106e-27

GMM estimation

|            | Robust Coef. | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|------------|--------------|-----------|------|------|----------------------|

| x3         | 1.008634     | .1156561  | 8.72 | 0.000| .781952              | 1.235315 |

Instruments for equation 1: x1 x2 x3

Instead of specifying simple parameter names in the `parameters()` option, we specified an equation name and the variables associated with that equation. We named our equation `y`, but you could use any valid Stata name. When we use this syntax, the rows of the coefficient table are grouped by the equation names.

Say we wanted to refit our model using just `x1` and `x3` as regressors. We do not need to make any changes to `gmm_poieq`. We just change the specification of the `parameters()` option:

```stata
use http://www.stata-press.com/data/r13/poisson1
gmm gmm_poieq, nequations(1) parameters(y:x1 y:x3) />
> instruments(x1 x3, noconstant) vce(cluster id) onestep
```
In this evaluator program, we have still hard-coded the name of the dependent variable. The next two examples include methods to tackle that shortcoming.

---

**Technical note**

Say we specify the `parameters()` option like this:

```
. gmm ..., parameters(y1:x1 y1:x2 y1:_cons y2:_cons y3:x1 y3:_cons)
```

Then the `at` vector passed to our program will have the following column names attached to it:

```
`at'[1,6]
    y1:  y1:  y1:  y2:  y3:  y3:
    x1  x2  _cons  _cons  x1  _cons
```

Typing

```
. matrix score double eq1 = `at', eq(#1)
```

is equivalent to typing

```
. generate double eq1 = x1*`at'[1,1] + x2*`at'[1,2] + `at'[1,3]
```

with one important difference. If we change some of the variables in the `parameters()` option when we call `gmm`, `matrix score` will compute the correct linear combination. If we were to use the `generate` statement instead, then every time we wanted to change the variables in our model, we would have to modify that statement as well.

The command

```
. matrix score double alpha = `at', eq(#2) scalar
```

is equivalent to

```
. scalar alpha = `at'[1,4]
```

Thus even if you specify equation and variable names in the `parameters()` option, you can still have scalar parameters in your model.

---

When past values of the idiosyncratic error term affect the value of a regressor, we say that regressor is *predetermined*. When one or more regressors are predetermined, sample moment condition (10) is no longer valid. However, Chamberlain (1992) shows that a simple alternative is to consider moment conditions of the form

\[
\sum_i \sum_{t=2}^T x_{i,t-1} \left( y_{i,t-1} - \mu_{i,t-1} \frac{y_{it}}{\mu_{it}} \right) = 0
\]  

(14)

Also see Wooldridge (1997) and Windmeijer (2000) for other moment conditions that can be used with predetermined regressors.
Example 11: Panel Poisson with predetermined regressors

Here we refit the previous model, treating all the regressors as predetermined and using the moment conditions in (14). Our moment-evaluator program is

```stata
program gmm_poipre
    version 13
    syntax varlist if, at(name) mylhs(varlist)
    quietly {
        tempvar mu
        matrix score double 'mu' = 'at' 'if', eq(#1)
        replace 'mu' = exp('mu')
        replace 'varlist' = L.'mylhs' - L.'mu'*'mylhs'/'mu' 'if'
    }
end
```

To compute the moment equation, we used lag-operator notation so that Stata properly handles gaps in our panel dataset. We also made our program accept an additional option that we will use to pass in the dependent variable. When we specify this option in our `gmm` statement, it will get passed to our evaluator program because `gmm` will not recognize the option as one of its own. Equation (14) shows that we are to use the first lags of the regressors as instruments, so we type

```
    . gmm gmm_poipre, mylhs(y) nequations(1) vce(cluster id) onestep
        > parameters(y:x1 y:x2 y:x3) instruments(L.(x1 x2 x3), noconstant)
```

Here, like earlier with strictly exogenous regressors, the number of instruments equals the number of parameters, so there is no gain to using the two-step or iterated estimators. However, if you do have more instruments than parameters, you will most likely want to use one of those other estimators instead.

Instead of making our program accept the `mylhs()` option, we could have used Stata’s `coleq` extended macro function to determine the dependent variable based on the column names attached to the ‘at’ vector; see [P] macro. Then we could refit our model with a different dependent variable by changing the `eqname` used in the `parameters()` option. In the next example, we take this approach.
In the previous example, we used $x_{i,t-1}$ as instruments. A more efficient GMM estimator would also use $x_{i,t-2}, x_{i,t-3}, \ldots, x_{i,1}$ as instruments in period $t$ as well. gmm’s `xtinstruments()` option allows you to specify instrument lists that grow as $t$ increases. Later we discuss the `xtinstruments()` option in detail in the context of linear dynamic panel-data models.

When a regressor is contemporaneously correlated with the idiosyncratic error term, we say that regressor is endogenous. Windmeijer (2000) shows that here we can use the moment condition

$$
\sum_{i} \sum_{t=3}^{T} x_{i,t-2} \left( \frac{y_{it}}{\mu_{it}} - \frac{y_{i,t-1}}{\mu_{i,t-1}} \right)
$$

Here we use the second lag of the endogenous regressor as an instrument. If a variable is strictly exogenous, it can of course serve as its own instrument.

Example 12: Panel Poisson with endogenous regressors

Here we refit the model, treating $x_3$ as endogenous and $x_1$ and $x_2$ as strictly exogenous. Our moment-evaluator program is

```stata
program gmm_poiend
    version 13
    syntax varlist if, at(name)
    quietly {
        tempvar mu
        matrix score double `mu' = `at' `if', eq(#1)
        replace `mu' = exp(`mu')
        local mylhs : coleq `at'
        local mylhs : word 1 of `mylhs'
        replace `varlist' = `mylhs'/`mu' - L.'mylhs'/L.'mu' `if'
    }
end
```

Now we call `gmm` using $x_1$, $x_2$, and $L2.x3$ as instruments:
. use http://www.stata-press.com/data/r13/poisson2
  . gmm gmm_poiend, nequations(1) vce(cluster id) onestep
> parameters(y:x1 y:x2 y:x3) instruments(x1 x2 L2.x3, noconstant)

| x2     | -2.865858 | .2151529  | -13.32 | 0.000 | -3.28755 — -2.444167|
| x3     | 4.961867 | 14.91462  | 0.33  | 0.739 | -24.27025 — 34.19399|

The warning at the top of the output indicates that we have 500 panels in our dataset. Our moment equation includes lagged terms and therefore cannot be evaluated for the first time period within each panel. Warning messages like that can be ignored once you know why they occurred. If you receive a warning message that you were not expecting, you should first investigate the cause of the warning before trusting the results. As in the previous example, instead of using just $x_{i,t-2}$ as an instrument, we could use all further lags of $x_{it}$ as instruments as well.

Rational-expectations models

Macroeconomic models typically assume that agents’ expectations about the future are formed rationally. By rational expectations, we mean that agents use all information available when forming their forecasts, so the forecast error is uncorrelated with the information available when the forecast was made. Say that at time $t$, people make a forecast, $\hat{y}_{t+1}$, of variable $y$ in the next period. If $\Omega_t$ denotes all available information at time $t$, then rational expectations implies that $E \{ (\hat{y}_{t+1} - y_{t+1}) | \Omega_t \} = 0$. If $\Omega_t$ denotes observable variables such as interest rates or prices, then this conditional expectation can serve as the basis of a moment condition for GMM estimation.

Example 13: Fitting a Euler equation

In a well-known article, Hansen and Singleton (1982) consider a model of portfolio decision making and discuss parameter estimation using GMM. We will consider a simple example with one asset in which the agent can invest. A consumer wants to maximize the present value of his lifetime utility derived from consuming the good. On the one hand, the consumer is impatient, so he would rather consume today than wait until tomorrow. On the other hand, if he consumes less today, he can invest more of his money, earning more interest that he can then use to consume more of the good tomorrow. Thus there is a tradeoff between having his cake today or sacrificing a bit today to have more cake tomorrow.
If we assume a specific form for the agent’s utility function, known as the constant relative-risk aversion utility function, we can show that the Euler equation is

$$E \left[ z_t \left\{ 1 - \beta (1 + r_{t+1})(c_{t+1}/c_t)^{-\gamma} \right\} \right] = 0$$

where $\beta$ and $\gamma$ are the parameters to estimate, $r_t$ is the return to the financial asset, and $c_t$ is consumption in period $t$. $\beta$ measures the agent’s discount factor. If $\beta$ is near one, the agent is patient and is more willing to forgo consumption this period. If $\beta$ is close to zero, the agent is less patient and prefers to consume more now. The parameter $\gamma$ characterizes the agent’s utility function. If $\gamma$ equals zero, the utility function is linear. As $\gamma$ tends toward one, the utility function tends toward $u = \log(c)$.

We have data on 3-month Treasury bills ($r_t$) and consumption expenditures ($c_t$). As instruments, we will use lagged rates of return and past growth rates of consumption. We will use the two-step estimator and a weight matrix that allows for heteroskedasticity and autocorrelation up to four lags with the Bartlett kernel. In Stata, we type

```
. use http://www.stata-press.com/data/r13/cr
. generate cgrowth = c / L.c
(1 missing value generated)
. gmm (1 - {b=1}*(1+F.r)*(F.c/c)^(-1*{gamma=1})),
> inst(L.r L2.r cgrowth L.cgrowth) wmat(hac nw 4) twostep
```

The warning message at the top of the output appears because the forward operator in our substitutable expression says that residuals can be computed only for 239 observations; our dataset contains 240 observations. Our estimate of $\beta$ is near one, in line with expectations and published results. However, our estimate of $\gamma$ implies risk-loving behavior and therefore a poorly specified model.
System estimators

In many economic models, two or more variables are determined jointly through a system of simultaneous equations. Indeed, some of the earliest work in econometrics, including that of the Cowles Commission, was centered around estimation of the parameters of simultaneous equations. The 2SLS and IV estimators we have already discussed are used in some circumstances to estimate such parameters. Here we focus on the joint estimation of all the parameters of systems of equations, and we begin with the well-known three-stage least-squares (3SLS) estimator.

Recall that the 2SLS estimator is based on the moment conditions $E(\mathbf{z}_i u_i) = 0$. The 2SLS estimator can be used to estimate the parameters of one equation of a system of structural equations. Moreover, with the 2SLS estimator, we do not even need to specify the structural relationship among all the endogenous variables; we need to specify only the equation on which interest focuses and simply estimate the exogenous variables of the model. If we are willing to specify the complete system of structural equations, then assuming our model is correctly specified, by estimating all the equations jointly, we can obtain estimates that are more efficient than equation-by-equation 2SLS.

In $\texttt{R}$, we fit a simple two-equation macroeconomic model:

\[
\begin{align*}
\text{consump} &= \beta_0 + \beta_1 \text{wagepriv} + \beta_2 \text{wagegovt} + \epsilon_1 \quad (15) \\
\text{wagepriv} &= \beta_3 + \beta_4 \text{consump} + \beta_5 \text{govt} + \beta_6 \text{capital1} + \epsilon_2 \quad (16)
\end{align*}
\]

where $\text{consump}$ represents aggregate consumption; $\text{wagepriv}$ and $\text{wagegovt}$ are total wages paid by the private and government sectors, respectively; $\text{govt}$ is government spending; and $\text{capital1}$ is the previous period’s capital stock. We are not willing to assume that $\epsilon_1$ and $\epsilon_2$ are independent, so we must treat both $\text{consump}$ and $\text{wagepriv}$ as endogenous. Suppose that a random shock makes $\epsilon_2$ positive. Then by (16), $\text{wagepriv}$ will be higher than it otherwise would. Moreover, $\epsilon_1$ will either be higher or lower, depending on the correlation between it and $\epsilon_2$. The shock to $\epsilon_2$ has made both $\text{wagepriv}$ and $\epsilon_1$ move, implying that in (15) $\text{wagepriv}$ is an endogenous regressor. A similar argument shows that $\text{consump}$ is an endogenous regressor in the second equation. In our model, $\text{wagegovt}$, $\text{govt}$, and $\text{capital1}$ are all exogenous variables.

Let $\mathbf{z}_1$ and $\mathbf{z}_2$ denote the instruments for the first and second equations, respectively; we will discuss what comprises them shortly. We have two sets of moment conditions:

\[
E \left\{ \begin{bmatrix} \mathbf{z}_1 (\text{consump} - \beta_0 - \beta_1 \text{wagepriv} - \beta_2 \text{wagegovt}) \\ \mathbf{z}_2 (\text{wagepriv} - \beta_3 - \beta_4 \text{consump} - \beta_5 \text{govt} - \beta_6 \text{capital1}) \end{bmatrix} \right\} = 0 \quad (17)
\]

One of the defining characteristics of 3SLS is that the errors are homoskedastic conditional on the instrumental variables. Using this assumption, we have

\[
E \left[ \begin{bmatrix} \mathbf{z}_1 \epsilon_1 \\ \mathbf{z}_2 \epsilon_2 \end{bmatrix} \begin{bmatrix} \mathbf{z}_1' \epsilon_1 \\ \mathbf{z}_2' \epsilon_2 \end{bmatrix} \right] = \begin{bmatrix} \sigma_{11} E(\mathbf{z}_1 \mathbf{z}_1') & \sigma_{12} E(\mathbf{z}_1 \mathbf{z}_2') \\ \sigma_{21} E(\mathbf{z}_2 \mathbf{z}_1') & \sigma_{22} E(\mathbf{z}_2 \mathbf{z}_2') \end{bmatrix} \quad (18)
\]

where $\sigma_{ij} = \text{cov}(\epsilon_i, \epsilon_j)$. Let $\Sigma$ denote the $2 \times 2$ matrix with typical element $\sigma_{ij}$.

The second defining characteristic of the 3SLS estimator is that it uses all the exogenous variables as instruments for all equations; here $\mathbf{z}_1 = \mathbf{z}_2 = (\text{wagegovt}, \text{govt}, \text{capital1}, 1)$, where the 1 indicates a constant term. From our discussion on the weight matrix and two-step estimation, we want to use the sample analogue of the matrix inverse of the right-hand side of (18) as our weight matrix.

To implement the 3SLS estimator, we apparently need to know $\Sigma$ or at least have a consistent estimator of it. The solution is to fit (15) and (16) by 2SLS, use the sample residuals $\hat{\epsilon}_1$ and $\hat{\epsilon}_2$ to estimate $\Sigma$, then estimate the parameters of (17) via GMM by using the weight matrix just discussed.
Example 14: 3SLS estimation

3SLS is easier to do using *gmm* than it sounds. The 3SLS estimator is a two-step GMM estimator. In the first step, we do the equivalent of 2SLS on each equation, and then we compute a weight matrix based on (18). Finally, we perform a second step of GMM with this weight matrix.

In Stata, we type

```
. use http://www.stata-press.com/data/r13/klein, clear
. gmm (eq1: consump - {b0} - {xb: wagepriv wagegovt})
>     (eq2: wagepriv - {c0} - {xc: consump govt capital1}),
>     instruments(eq1: wagegovt govt capital1)
>     instruments(eq2: wagegovt govt capital1)
>     winitial(unadjusted, independent) wmatrix(unadjusted) twostep
```

**Step 1**

Iteration 0:  GMM criterion Q(b) = 4195.4487
Iteration 1:  GMM criterion Q(b) = .22175631
Iteration 2:  GMM criterion Q(b) = .22175631 (backed up)

**Step 2**

Iteration 0:  GMM criterion Q(b) = .09716589
Iteration 1:  GMM criterion Q(b) = .07028208
Iteration 2:  GMM criterion Q(b) = .07028208

**GMM estimation**

Instruments for equation 1: wagegovt govt capital1 _cons
Instruments for equation 2: wagegovt govt capital1 _cons

The **independent** suboption of the **winitial()** option tells *gmm* to assume that the residuals are independent across equations; this suboption sets \( \sigma_{12} = \sigma_{21} = 0 \) in (18). Assuming both homoskedasticity and cross-equation independence is equivalent to fitting the two equations of our model independently by 2SLS. The **wmatrix()** option controls how the weight matrix is computed based on the first-step parameter estimates before the second step of estimation; here we request a weight matrix that assumes conditional homoskedasticity but that does not impose the cross-equation independence like the initial weight matrix we used. In this example, we also illustrated how to name equations and how equation names can be used in the **instruments()** option. Our results are identical to those in [R] *reg3*.

We could have specified our instruments with the syntax

```
instruments(wagegovt govt capital1)
```

because *gmm* uses the variables listed in the **instruments()** option for all equations unless you specify which equations the list of instruments is to be used with. However, we wanted to emphasize that the same instruments are being used for both equations; in a moment, we will discuss an estimator that does not use the same instruments in all equations.
In the previous example, if we omit the `twostep` option, the resulting coefficients will be equivalent to equation-by-equation 2SLS, which Wooldridge (2010, 216) calls the “system 2SLS estimator”. Eliminating the `twostep` option makes the `wmatrix()` option irrelevant, so that option can be eliminated as well.

So far, we have developed the traditional 3SLS estimator. Wooldridge (2010, chap. 8) discusses the “GMM 3SLS” estimator that extends the traditional 3SLS estimator by allowing for heteroskedasticity and different instruments for different equations.

Generalizing (18) to an arbitrary number of equations, we have

$$E(Z'\epsilon\epsilon'Z) = E(Z'\Sigma Z)$$

(19)

where

$$Z = \begin{bmatrix} z_1 & 0 & \cdots & 0 \\ 0 & z_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & z_m \end{bmatrix}$$

and $\Sigma$ is now $m \times m$. Equation (19) is the multivariate analogue of a homoskedasticity assumption; for each equation, the error variance is constant for all observations, as is the covariance between any two equations’ errors.

We can relax this homoskedasticity assumption by considering different weight matrices. For example, if we continue to assume that observations are independent but not necessarily identically distributed, then by specifying `wmatrix(robust)`, we would obtain a weight matrix that allows for heteroskedasticity:

$$\hat{W} = \frac{1}{N} \sum_i Z_i'\hat{\epsilon}_i\hat{\epsilon}_i'Z_i$$

This is the weight matrix in Wooldridge’s (2010, 218) Procedure 8.1, “GMM with Optimal Weighting Matrix”. By default, `gmm` would report standard errors based on his covariance matrix (8.27); specifying `vce(unadjusted)` would provide the optimal GMM standard errors. If you have multiple observations for each individual or firm in your dataset, you could specify `wmatrix(cluster id)`, where `id` identifies individuals or firms. This would allow arbitrary within-individual correlation, though it does not account for an individual-specific fixed or random effect. In both cases, we would continue to use `winitial(unadjusted, independent)` so that the first-step estimates are the system 2SLS estimates.

Wooldridge (2010, sec. 9.6) discusses instances where it is necessary to use different instruments in different equations. The GMM 3SLS estimator with different instruments in different equations but with conditional homoskedasticity is what Hayashi (2000, 275) calls the “full-information instrumental variables efficient” (FIVE) estimator. Implementing the FIVE estimator is easy with `gmm`. For example, say we have a two-equation system, where `kids`, `age`, `income`, and `education` are all valid instruments for the first equation; but `education` is not a valid instrument for the second equation. Then our syntax would take the form

```plaintext
    gmm (<mexp_1>) (<mexp_2>), instruments(1:kids age income education)
                       instruments(2:kids age income)
```

The following syntax is equivalent:

```plaintext
    gmm (<mexp_1>) (<mexp_2>), instruments(kids age income)
                       instruments(1:education)
```
Because we did not specify a list of equations in the second example’s first \texttt{instruments()} option, those variables are used as instruments in both equations. You can use whichever syntax you prefer. The first requires a bit more typing but is arguably more transparent.

If all the regressors in the model are exogenous, then the traditional 3SLS estimator is the seemingly unrelated regression (SUR) estimator. Here you would specify all the regressors as instruments.

### Dynamic panel-data models

Commands in Stata that work with panel data expect the data to be in the “long” format, meaning that each row of the dataset consists of one subobservation that is a member of a logical observation (represented by the panel identifier variable). See \texttt{[D reshape}} for a discussion of the long versus “wide” data forms. \texttt{gmm} is no exception in this respect when used with panel data. From a theoretical perspective, however, it is sometimes easier to view GMM estimators for panel data as system estimators in which we have \(N\) observations on a system of \(T\) equations, where \(N\) and \(T\) are the number of observations and panels, respectively, rather than a single-equation estimator with \(NT\) observations. Usually, each of the \(T\) equations will in fact be the same, though we will want to specify different instruments for each of these equations.

In a dynamic panel-data model, lagged values of the dependent variable are included as regressors. Here we consider a simple model with one lag of the dependent variable \(y\) as a regressor and a vector of strictly exogenous regressors, \(x_{it}\):

\[
y_{it} = \rho y_{i,t-1} + x'_{it}\beta + u_i + \epsilon_{it} \tag{20}
\]

\(u_i\) can be either a fixed- or a random-effect term, in the sense that we do not require \(x_{it}\) to be independent of it. Even with the assumption that \(\epsilon_{it}\) is i.i.d., the presence of both \(y_{i,t-1}\) and \(u_i\) in (20) renders both the standard fixed- and random-effects estimators to be inconsistent because of the well-known Nickell (1981) bias. OLS regression of \(y_{it}\) on \(y_{i,t-1}\) and \(x_{it}\) also produces inconsistent estimates, because \(y_{i,t-1}\) will be correlated with the error term.

#### Technical note

Stata has the \texttt{xtabond}, \texttt{xtdpd}, and \texttt{xtdpdsys} commands (see \texttt{[XT xtabond}, \texttt{[XT xtdpd}, and \texttt{[XT xtdpdsys]} to fit equations like (20), and for everyday use those commands are preferred because they offer features such as Windmeijer (2005) bias-corrected standard errors to account for the bias of traditional two-step GMM standard errors seen in dynamic panel-data models and, being linear estimators, only require you to specify variable names instead of complete equations. However, using \texttt{gmm} has several pedagogical advantages, including the ability to tie those model-specific commands into a more general framework, a clear illustration of how certain types of instrument matrices for panel-data models are formed, and demonstrations of several advanced features of \texttt{gmm}.

First-differencing (20) removes the panel-specific \(u_i\) term:

\[
y_{it} - y_{i,t-1} = \rho(y_{i,t-1} - y_{i,t-2}) + (x_{it} - x_{i,t-1})'\beta + (\epsilon_{it} - \epsilon_{i,t-1}) \tag{21}
\]

However, now \((y_{i,t-1} - y_{i,t-2})\) is correlated with \((\epsilon_{it} - \epsilon_{i,t-1})\). Thus we need an instrument that is correlated with the former but not the latter. The lagged variables in (21) mean that equation is not estimable for \(t < 3\), so consider when \(t = 3\). We have

\[
y_{i3} - y_{i2} = \rho(y_{i2} - y_{i1}) + (x_{i3} - x_{i2})'\beta + (\epsilon_{i3} - \epsilon_{i2}) \tag{22}
\]
In the Arellano–Bond (1991) estimator, lagged levels of the dependent variable are used as instruments. With our assumption that the \( \epsilon_{it} \) are i.i.d., (20) intimates that \( y_{i1} \) can serve as an instrumental variable when we fit (22).

Next consider (21) when \( t = 4 \). We have

\[
y_{i4} - y_{i3} = \rho(y_{i3} - y_{i2}) + (x_{i4} - x_{i3})'\beta + (\epsilon_{i4} - \epsilon_{i3})
\]

Now (20) shows that both \( y_{i1} \) and \( y_{i2} \) are uncorrelated with the error term \( (\epsilon_{i4} - \epsilon_{i3}) \), so we have two instruments available. For \( t = 5 \), you can show that \( y_{i1}, y_{i2}, \) and \( y_{i3} \) can serve as instruments. As may now be apparent, one of the key features of these dynamic panel-data models is that the errors are i.i.d. First, rewrite (21) for panel \( i \) as

\[
y_i - y_i^L = \rho (y_i^L - y_i^{LL}) + (X_i - X_i^L)\beta + (\epsilon_i - \epsilon_i^L)
\]

where \( y_i = (y_{i3}, \ldots, y_{iT}) \) and \( y_i^L = (y_{i2}, \ldots, y_{i,T-1}) \), \( y_i^{LL} = (y_{i1}, \ldots, y_{i,T-2}) \), and \( X_i, X_i^L, \epsilon_i, \) and \( \epsilon_i^L \) are defined analogously. Let \( Z \) denote the full matrix of instruments for panel \( i \), including the variables specified in both the \textit{instruments()} and \textit{xtinstruments()} options; the exact structure is detailed in \textit{Methods and formulas}.

By assumption, \( \epsilon_{it} \) is i.i.d., so the first-difference \( (\epsilon_{it} - \epsilon_{i,t-1}) \) is necessarily autocorrelated with correlation \(-0.5\). Therefore, we should not use a weight matrix that assumes the errors are independent. For dynamic panel-data models, we can show that the appropriate initial weight matrix is

\[
\hat{W} = \left( \frac{1}{N} \sum_i Z_i' H_D Z_i \right)^{-1}
\]

where

\[
H_D = \begin{bmatrix}
1 & -0.5 & 0 & \ldots & 0 & 0 \\
-0.5 & 1 & -0.5 & \ldots & 0 & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
0 & 0 & 0 & \ldots & 1 & -0.5 \\
0 & 0 & 0 & \ldots & -0.5 & 1 \\
\end{bmatrix}
\]

We can obtain this initial weight matrix by specifying \textit{winitial(xt D)}. The letter D indicates that the equation we are estimating is specified in first-differences.

\section*{Example 15: Arellano–Bond estimator}

Say we want to fit the model

\[
n_{it} = \rho n_{i,t-1} + \beta_1 w_{it} + \beta_2 w_{i,t-1} + \beta_3 k_{it} + \beta_4 k_{i,t-1} + u_i + \epsilon_{it}
\]

(23)

where we assume that \( w_{it} \) and \( k_{it} \) are strictly exogenous. First-differencing, our residual equation is

\[
\epsilon_{it}^* = (\epsilon_{it} - \epsilon_{i,t-1}) = n_{it} - n_{i,t-1} - \rho (n_{i,t-1} - n_{i,t-2}) - \beta_1 (w_{it} - w_{i,t-1}) \\
- \beta_2 (w_{i,t-1} - w_{i,t-2}) - \beta_3 (k_{it} - k_{i,t-1}) - \beta_4 (k_{i,t-1} - k_{i,t-2})
\]

(24)
In Stata, we type

```

```
Instruments for equation 1:  
  XT-style: L(2/.) .n   
  Standard: D.w LD.w D.k LD.k
```

Because \( w \) and \( k \) are strictly exogenous, we specified the variants of them that appear in (24) in the `instruments()` option; because there is no constant term in the model, we specified `noconstant` to omit the constant from the instrument list.

We specified `xtinstruments(n, lags(2/.) )` to tell `gmm` what instruments to use for the lagged dependent variable included as a regressor in (23). Based on our previous discussion, lags two and higher of \( n_{i,t} \) can serve as instruments. The `lags(2/.)` suboption tells `gmm` that the first available instrument for \( n_{i,t} \) is the lag-two value \( n_{i,t-2} \). The “.” tells `gmm` to use all further lags of \( n_{i,t} \) as instruments as well. The instrument matrices in dynamic panel-data models can become large if the dataset has many time periods per panel. In those cases, you could specify, for example, `lags(2/4)` to use just lags two through four instead of using all available lags.

Our results are identical to those we would obtain using `xtabond` with the syntax

```
xtabond n L(0/1).w L(0/1).k, lags(1) noconstant vce(robust)
```

Had we left off the `vce(robust)` option in our call to `xtabond`, we would have had to specify `vce(unadjusted)` in our call to `gmm` to obtain the same standard errors.

⚠️ Technical note

`gmm` automatically excludes observations for which there are no valid observations for the panel-style instruments. However, it keeps in the estimation sample those observations for which fewer than the maximum number of instruments you requested are available. For example, if you specify the `lags(2/4)` suboption, you have requested three instruments, but `gmm` will keep observations even if only one or two instruments are available.
Example 16: Two-step Arellano–Bond estimator

Here we refit the model from example 15, using the two-step GMM estimator.

\[ \text{gmm (D.n - \{rho\} LD.n - \{xb:D.w LD.w D.k LD.k\}),} \]
\[ > \text{xtinstruments(n, lags(2/1)) instruments(D.w LD.w D.k LD.k, noconstant)} \]
\[ > \text{deriv(/rho = -1*LD.n) deriv(/xb = -1) winitial(xt D) wmatrix(robust)} \]
\[ > \text{vce(unadjusted)} \]

Step 1

Iteration 0:  GMM criterion Q(b) = .0011455
Iteration 1:  GMM criterion Q(b) = .00009103

Standard: D.w LD.w D.k LD.k

Our results match those you would obtain with the command
\[ \text{xtabond n L(0/1).(w k), lags(1) noconstant twostep} \]

Technical note

Had we specified \text{vce(robust)} in our call to \text{gmm}, we would have obtained the traditional sandwich-based robust covariance matrix, but our standard errors would not match those we would obtain by specifying \text{vce(robust)} with the \text{xtabond} command. The \text{xtabond, xtdpd, and xtdpdsys} commands implement a bias-corrected robust VCE for the two-step GMM dynamic panel-data estimator. Traditional VCEs computed after the two-step dynamic panel-data estimator have been shown to exhibit often-severe bias; see Windmeijer (2005).

Neither of the two dynamic panel-data examples (15 and 16) we have fit so far include a constant term. When a constant term is included, the dynamic panel-data estimator is in fact a two-equation system estimator. For notational simplicity, consider a simple model containing just a constant term and one lag of the dependent variable:

\[ y_{it} = \alpha + \rho y_{i,t-1} + u_i + \epsilon_{it} \]
First-differencing to remove the $u_i$ term, we have

$$y_{it} - y_{i,t-1} = \rho (y_{i,t-1} - y_{i,t-2}) + (\epsilon_{it} - \epsilon_{i,t-1})$$

(25)

This has also eliminated the constant term. If we assume $E(u_i) = 0$, which is reasonable if a constant term is included in the model, then we can recover $\alpha$ by including the moment condition

$$y_{it} = \alpha + \rho y_{i,t-1} + \epsilon'_{it}$$

(26)

where $\epsilon'_{it} = u_i + \epsilon_{it}$. The parameter $\rho$ continues to be identified by (25), so the only instrument we use with (26) is a constant term. As before, the error term $(\epsilon_{i,t} - \epsilon_{i,t-1})$ is necessarily autocorrelated with correlation coefficient $-0.5$, though the error term $\epsilon'_{it}$ is white noise. Therefore, our initial weight matrix should be

$$\hat{W} = \left( \frac{1}{N} \sum Z' H Z \right)^{-1}$$

where

$$H = \begin{bmatrix} H & 0 \\ 0 & I \end{bmatrix}$$

and $I$ is a conformable identity matrix.

One complication arises concerning the relevant estimation sample. Looking at (25), we apparently lose the first two observations from each panel because of the presence of $y_{i,t-2}$, but in (26) we need only to sacrifice one observation, for $y_{i,t-1}$. For most multiple-equation models, we need to use the same estimation sample for all equations. However, in dynamic panel-data models, we can use more observations to fit the equation in level form [(26) here] than the equation in first-differences [equation (25)]. To request this behavior, we specify the nocommonesample option to gmm. That option tells gmm to use as many observations as possible for each equation, ignoring the loss of observations due to lagging or differencing.

Example 17: Arellano–Bond estimator with constant term

Here we fit the model

$$n_{it} = \alpha + \rho n_{i,t-1} + u_i + \epsilon_{it}$$

Without specifying derivatives, our command would be

```
. gmm (D.n - {rho}*LD.n) (n - {alpha} - {rho}*L.n),
>     xtinstruments(1: n, lags(2/)) instruments(1:, noconstant) onestep
>     winitial(xt DL) vce(unadj) nocommonesample
```

We would specify winitial(xt DL) to obtain the required initial weight matrix. The notation DL indicates that our first moment equation is in first-differences and the second moment equation is in levels (not first-differenced). We exclude a constant in the instrument list for the first equation, because first-differencing removed the constant term. Because we do not specify the instruments() option for the second moment equation, a constant is used by default.

This example also provides us the opportunity to illustrate how to specify derivatives for multiple-equation GMM models. Within the derivative() option, instead of specifying just the parameter name, now you must specify the equation name or number, a slash, and the parameter name to which the derivative applies. In Stata, we type
. gmm (D.n - {rho}*LD.n) (n - {alpha} - {rho}*L.n),
> xtinstruments(1: n, lags(2/)). instruments(1:, noconstant)
> derivative(1/rho = -1*LD.n) derivative(2/alpha = -1)
> derivative(2/rho = -1*L.n) winitial(xt DL) vce(unadj)
> nocommonesample onestep

Step 1
Iteration 0:  GMM criterion Q(b) = .09894466
Iteration 1:  GMM criterion Q(b) = .00023508
Iteration 2:  GMM criterion Q(b) = .00023508

Instruments for equation 1:
  XT-style: L(2/).n
Instruments for equation 2:
  Standard: _cons

These results are identical to those we would obtain by typing

xtabond n, lags(1)

Because we specified nocommonesample, gmm did not report the number of observations used in the header of the output. In this dataset, there are in fact 1,031 observations on 140 panels. In the second equation, the presence of the lagged value of n reduces the sample size for that equation to 1031 - 140 = 891. In the first equation, we lose the first two observations per panel due to lagging and differencing, leading to 751 usable observations. These tallies are listed after the coefficient table in the output.

Technical note

Specifying

xtinstruments(x1 x2 x3, lags(1/3))

differs from

instruments(L(1/3).(x1 x2 x3))

in how observations are excluded from the estimation sample. When you use the latter syntax, gmm must exclude the first three observations from each panel when computing the moment equation: you requested three lags of each regressor be used as instruments, so the first residual that could be interacted with those instruments is the one for \( t = 4 \). On the other hand, when you use xtinstruments(), you are telling gmm that you would like to use up to the first three lags of x1, x2, and x3 as instruments but that using just one lag is acceptable. Because most panel datasets have a relatively modest number of observations per panel, dynamic instrument lists are typically used so that the number of usable observations is maximized. Dynamic instrument lists also accommodate the fact that there are more valid instruments for later time periods than earlier time periods.
Specifying panel-style instruments using the `xtinstruments()` option also affects how the standard instruments specified in the `instruments()` option are treated. To illustrate, suppose we have a balanced panel dataset with $T = 5$ observations per panel and we specify

```
gmm ..., xtinstruments(w, lags(1/2)) instruments(x)
```

We will lose the first observation because we need at least one lag of $w$ to serve as an instrument. Our instrument matrix for panel $i$ will therefore be

$$ Z_i = \begin{bmatrix}
  w_{i1} & 0 & 0 & 0 \\
  0 & w_{i1} & 0 & 0 \\
  0 & w_{i2} & 0 & 0 \\
  0 & 0 & w_{i2} & 0 \\
  0 & 0 & w_{i3} & 0 \\
  0 & 0 & 0 & w_{i3} \\
  0 & 0 & 0 & w_{i4} \\
  x_{i2} & x_{i3} & x_{i4} & x_{i5} \\
  1 & 1 & 1 & 1
\end{bmatrix} \tag{27} $$

The vector of ones in the final row represents the constant term implied by the `instruments()` option. Because we lost the first observation, the residual vector $u_i$ will be $4 \times 1$. Thus our moment conditions for the $i$th panel can be written in matrix notation as

$$ E\{Z_i u_i(\beta)\} = E \left\{ Z_i \begin{bmatrix} u_{i2}(\beta) \\ u_{i3}(\beta) \\ u_{i4}(\beta) \\ u_{i5}(\beta) \end{bmatrix} \right\} = 0 $$

The moment conditions corresponding to the final two rows of (27) say that

$$ E \left\{ \sum_{t=2}^{T=4} x_{it} u_{it}(\beta) \right\} = 0 \quad \text{and} \quad E \left\{ \sum_{t=2}^{T=4} u_{it}(\beta) \right\} = 0 $$

Because we specified panel-style instruments with the `xtinstruments()` option, `gmm` no longer uses moment conditions for strictly exogenous variables of the form $E\{x_{it} u_{it}(\beta)\} = 0$ for each $t$. Instead, the moment conditions now stipulate that the average (over $t$) of $x_{it} u_{it}(\beta)$ has expectation zero. This corresponds to the approach proposed by Arellano and Bond (1991, 280) and others.

When you request panel-style instruments with the `xtinstruments()` option, the number of instruments in the $Z_i$ matrix increases quadratically in the number of periods. The dynamic panel-data estimators we have discussed in this section are designed for datasets that contain a large number of panels and a modest number of time periods. When the number of time periods is large, estimators that use standard (non–panel-style) instruments are more appropriate.

We have focused on the Arellano–Bond dynamic panel-data estimator because of its relative simplicity. `gmm` can additionally fit any models that can be formulated using the `xtdpd` and `xtdpdsys` commands; see [XT] `xtdpd` and [XT] `xtdpdsys`. The key is to determine the appropriate instruments to use for the level and difference equations. You may find it useful to fit a version of your model with those commands to determine what instruments and XT-style instruments to use. We conclude this section with an example using the Arellano–Bover/Blundell–Bond estimator.
Example 18: Arellano–Bover/Blundell–Bond estimator

We fit a small model that includes one lag of the dependent variable \( n \) as a regressor as well as the contemporaneous and first lag of \( w \), which we assume are strictly exogenous. We could fit our model using `xtdpdysys` using the syntax

```plaintext
xtdpdysys n L(0/1).w, lags(1) twostep
```

Applying virtually all the syntax issues we have discussed so far, the equivalent `gmm` command is

```plaintext
.gmm (n - {rho}*L.n - {w}*w - {lagw}*L.w - {c})
> (D.n - {rho}*LD.n - {w}*D.w - {lagw}*LD.w),
> inst(2: D.w LD.w, noconstant)
> deriv(1/rho = -1*L.n) deriv(1/w = -1*w)
> deriv(1/lagw = -1*L.w) deriv(1/c = -1)
> deriv(2/rho = -1*LD.n) deriv(2/w = -1*D.w)
> deriv(2/lagw = -1*LD.w)
> winit(xt LD) wmatrix(robust) vce(unadjusted)
> nocommonesample
```

Details of moment-evaluator programs

In examples 9, 10, 11, and 12, we used moment-evaluator programs to evaluate moment conditions that could not be specified using the interactive version of `gmm`. In example 11, we also showed how to pass additional information to an evaluator program. Here we discuss how to make moment-evaluator programs provide derivatives and accept weights.
The complete specification for a moment-evaluator program’s syntax statement is

```
syntax varlist if [weight], at(name) options [derivatives(varlist)]
```

The macro ‘varlist’ contains the list of variables that we are to fill in with the values of our residual equations. The macro ‘if’ represents an if condition that restricts the estimation sample. The macro ‘at’ represents a vector containing the parameter values at which we are to evaluate our residual equations. options represent other options that you specify in your call to `gmm` and want to have passed to your moment-evaluator programs. In example 11, we included the `mylhs()` option so that we could pass the name of the dependent variable to our evaluator program.

Two new elements of the syntax statement allow for weights and derivatives. weight specifies the types of weights your program allows. The interactive version of `gmm` allows for `fweight`s, `aweight`s, and `pweight`s. However, unless you explicitly allow your moment evaluator program to accept weights, you cannot specify weights in your call to `gmm` with the moment-evaluator program version.

The derivatives() option is used to pass to your program a set of variables that you are to fill in with the derivatives of your residual equations with respect to the parameters.

To indicate that your program can calculate derivatives, you specify either the hasderivatives or the haslfderivatives option to `gmm`. The hasderivatives option indicates that your program calculates parameter-level derivatives; that method requires more work but can be applied to any GMM problem. The haslfderivatives option requires less work but can be used only when the model’s residual equations satisfy certain restrictions and you use the `<eqname>:` `<varname>` syntax with the parameters() option.

We first consider how to write the derivative computation logic to work with the hasderivatives option and provide an example; then we do the same for the haslfderivatives option.

Say you specify k parameters in the nparameters() or parameters() option and q equations in the nequations() or equations() option and you specify hasderivatives. Then ‘derivatives’ will contain k × q variables. The first k variables are for the derivatives of the first residual equation with respect to the k parameters, the second k variables are for the derivatives of the second residual equation, and so on.

**Example 19: Specifying derivatives with simple parameter names**

To focus on how to specify derivatives, we return to the simple moment-evaluator program we used in example 9, in which we had three regressors, and extend it to supply derivatives. The residual equation corresponding to moment condition (13) is

\[
 u_{it}(\beta) = y_{it} - \mu_{it} \frac{\overline{y}_i}{\overline{\mu}_i} 
\]

where \( \mu_{it}, \overline{\mu}_i, \) and \( \overline{y}_i \) were defined previously. Now

\[
 \frac{\partial}{\partial \beta_j} u_{it}(\beta) = -\mu_{it} \frac{\overline{y}_i}{\overline{\mu}_i} \left( x_{it}^{(j)} \frac{1}{T} \sum_{l=1}^{T} x_{il}^{(j)} \mu_{il} \right) 
\]

where \( x_{it}^{(j)} \) represents the jth element of \( x_{it} \).
Our moment-evaluator program is

```
program gmm_poideriv
version 13
syntax varlist if, at(name) [derivatives(varlist)]
quietly {
    // Calculate residuals as before
    tempvar mu mubar ybar
    gen double 'mu' = exp(x1*'at'[1,1] + x2*'at'[1,2] + x3*'at'[1,3]) 'if'
    egen double 'mubar' = mean('mu') 'if', by(id)
    egen double 'ybar' = mean(y) 'if', by(id)
    replace 'varlist' = y - 'mu'*'ybar'/mubar 'if'
    // Did -gmm- request derivatives?
    if "'derivatives'" == "" {
        exit // no, so we are done
    }
    // Calculate derivatives
    // We need the panel means of x1*mu, x2*mu, and x3*mu
    tempvar work x1mubar x2mubar x3mubar
    generate double 'work' = x1*'mu' 'if'
    egen double 'x1mubar' = mean('work') 'if', by(id)
    replace 'work' = x2*'mu' 'if'
    egen double 'x2mubar' = mean('work') 'if', by(id)
    replace 'work' = x3*'mu' 'if'
    egen double 'x3mubar' = mean('work') 'if', by(id)
    local d1: word 1 of 'derivatives'
    local d2: word 2 of 'derivatives'
    local d3: word 3 of 'derivatives'
    replace 'd1' = -1*'mu'*'ybar'/mubar^2*(x1*'mubar' - 'x1mubar')
    replace 'd2' = -1*'mu'*'ybar'/mubar^2*(x2*'mubar' - 'x2mubar')
    replace 'd3' = -1*'mu'*'ybar'/mubar^2*(x3*'mubar' - 'x3mubar')
}
end
```

The derivatives() option is made optional in the syntax statement by placing it in square brackets. If gmm needs to evaluate your moment equations but does not need derivatives at that time, then the derivatives() option will be empty. In our program, we check to see if that is the case, and, if so, exit without calculating derivatives. As is often the case with [R] ml as well, the portion of our program devoted to derivatives is longer than the code to compute the objective function.

The first part of our derivative code computes the term

\[
\frac{1}{T} \sum_{l=1}^{T} x_{il}^{(j)} \mu_{il}
\]

for \( x_{il}^{(j)} = x_1, x_2, \) and, \( x_3. \) The ‘derivatives’ macro contains three variable names, corresponding to the three parameters of the ‘at’ matrix. We extract those names into local macros ‘d1’, ‘d2’, and ‘d3’, and then fill in the variables those macros represent with the derivatives shown in (28).
With our program written, we fit our model by typing

```
. use http://www.stata-press.com/data/r13/poisson1
. gmm gmm_poideriv, nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep hasderivatives
```

**Step 1**

Iteration 0:  GMM criterion Q(b) =  51.99142
Iteration 1:  GMM criterion Q(b) =  0.04345191
Iteration 2:  GMM criterion Q(b) =  8.720e-06
Iteration 3:  GMM criterion Q(b) =  7.115e-13
Iteration 4:  GMM criterion Q(b) =  5.129e-27

**GMM estimation**

Number of parameters = 3
Number of moments = 3
Initial weight matrix: Unadjusted

|       | Coef. | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|-------|-------|-----------|-------|----|---|---------------------|
| /b1   | 1.94866 | .1000265 | 19.48 | 0.000 | 1.752612 | 2.144709 |

Instruments for equation 1: x1 x2 x3

Our results are identical to those in example 9. Another way to verify that our program calculates derivatives correctly would be to type

```
. gmm gmm_poideriv, nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep
```

Without the `hasderivatives` or `haslfderivatives` option, `gmm` will not request derivatives from your program, even if it contains code to compute them. If you have trouble obtaining convergence with the `hasderivatives` or `haslfderivatives` option but do not have trouble without specifying one of them, then you need to recheck your derivatives.

---

A GMM residual equation satisfies the linear-form restriction if the equation can be written in terms of a single observation in the dataset and if the equation for observation \( i \) does not depend on any observations \( j \neq i \). Cross-sectional models satisfy the linear-form restriction. Time-series models satisfy the linear-form restriction only when no lags or leads are used.

Panel-data models often do not satisfy the linear-form restriction. For example, recall moment condition (13) for a panel Poisson model. That residual equation included panel-level mean terms \( \bar{y}_i \) and \( \bar{\mu}_i \), so the residual equation for an individual observation depends on all the observations in the same panel.

When a residual equation does not satisfy the linear-form restriction, neither will its derivatives. To apply the chain rule, we need a way to multiply the `eqname`-level derivative by each of the variables...
in the equation to obtain parameter-level derivatives. In (28), for example, there is no way to factor out each \( x_{it}^{(j)} \) variable and obtain an \textit{eqname}-level derivative that we then multiply by each of the \( x_{it}^{(j)} \) s.

Suppose we do have a model with \( q = 2 \) moment equations, both of which do satisfy the linear-form restriction, and we specify the \texttt{parameters()} option like this:

\[
\texttt{. gmm ..., parameters(eq1:x1 eq1:x2 eq1:_cons eq2:_cons eq3:x1 eq3:x2 eq3:_cons)}
\]

We have specified \( n = 3 \) \textit{eqnames} in the \texttt{parameters()} option: \texttt{eq1}, \texttt{eq2}, and \texttt{eq3}. When we specify the \texttt{haslnderivatives} option, \texttt{gmm} will pass \( n \times q = 3 \times 2 = 6 \) variables in the \texttt{derivatives()} option. The first three variables are to be filled with

\[
\frac{\partial}{\partial \text{eq1}} u_{1i}(\beta) \quad \frac{\partial}{\partial \text{eq2}} u_{1i}(\beta) \quad \text{and} \quad \frac{\partial}{\partial \text{eq3}} u_{1i}(\beta)
\]

where \( u_{1j}(\beta) \) is the \( i \)th observation for the first moment equation. Then the second three variables are to be filled with

\[
\frac{\partial}{\partial \text{eq1}} u_{2i}(\beta) \quad \frac{\partial}{\partial \text{eq2}} u_{2i}(\beta) \quad \text{and} \quad \frac{\partial}{\partial \text{eq3}} u_{2i}(\beta)
\]

where \( u_{2j}(\beta) \) is the second moment equation. In this example, we filled in a total of six variables with derivatives. If we instead used the \texttt{hasderivatives} option, we would have filled \( k \times q = 7 \times 2 = 14 \) variables; moreover, if we wanted to change the number of variables in our model, we would have modified our evaluator program.

\section*{Example 20: Specifying derivatives with linear-form residual equations}

In examples 7 and 8, we showed how to specify derivatives with an exponential regression model when using the interactive version of \texttt{gmm}. Here we show how to write a moment-evaluator program for the exponential regression model, including derivatives.

The residual equation for observation \( i \) is

\[
u_{i} = y_{i} - \exp(x_{i}'\beta)
\]

where \( x_{i} \) may include a constant term. The derivative with respect to the linear combination \( x_{i}'\beta \) is

\[
\frac{\partial u_{i}}{\partial x_{i}'\beta} = -\exp(x_{i}'\beta)
\]

To verify this residual equation satisfies the linear-form restriction, we see that for the \( j \)th element of \( \beta \), we have

\[
\frac{\partial u_{i}}{\partial \beta_{j}} = -x_{ij} \exp(x_{i}'\beta) = \frac{\partial u_{i}}{\partial x_{i}'\beta} \times x_{ij}
\]

so that given \( \partial u_{i}/\partial x_{i}'\beta \), \texttt{gmm} can apply the chain rule to obtain the derivatives with respect to the individual parameters.
Our moment-evaluator program is

```
program gmm_poideriv2
    version 13
    syntax varlist if, at(name) [derivatives(varlist)]
    quietly {
        tempvar mu
        matrix score double 'mu' = 'at' 'if', eq(#1)
        replace 'mu' = exp('mu')
        local depvar : coleq 'at'
        local depvar : word 1 of 'depvar'
        replace 'varlist' = 'depvar' 'mu' 'if'
        // Did -gmm- request derivatives?
        if ''derivatives'' == '' {
            exit // no, so we are done
        }
        // Calculate derivatives
        // The derivatives macro only has one variable
        // for this model.

Instruments for equation 1: private chronic female age black hispanic _cons

Our results match those shown in example 8.
We can change the variables in our model just by changing the \texttt{parameters()} and \texttt{instruments()} options; we do not need to make any changes to the moment-evaluator program, because we used linear-form derivatives.

Depending on your model, allowing your moment-evaluator program to accept weights may be as easy as modifying the \texttt{syntax} command to allow them, or it may require significantly more work. If your program uses only commands like \texttt{generate} and \texttt{replace}, then just modifying the \texttt{syntax} command is all you need to do; \texttt{gmm} takes care of applying the weights to the observation-level residuals when computing the sample moments, derivatives, and weight matrices. On the other hand, if your moment-evaluator program computes residuals using statistics that depend on multiple observations, then you must apply the weights passed to your program when computing those statistics.

In our examples of panel Poisson with strictly exogenous regressors (9 and 18), we used the statistics $\mu_i$ and $y_i$ when computing the residuals. If we are to allow weights with our moment-evaluator program, then we must incorporate those weights when computing $\mu_i$ and $y_i$. Moreover, looking at the derivative in (28), the term highlighted in (29) is in fact a sample mean, so we must incorporate weights when computing it.

\textbf{Example 21: Panel Poisson with derivatives and weights}

Here we modify the program in example 19. to accept frequency weights. One complication immediately arises: we had been using \texttt{egen} to compute $\mu_i$ and $y_i$. \texttt{egen} does not accept weights, so we must compute $\mu_i$ and $y_i$ ourselves, incorporating any weights the user may specify. Our program is
Our syntax command now indicates that fweights are allowed. The first part of our code looks at the macro `exp`. If it is empty, then the user did not specify weights in their call to `gmm`; and we set the macro equal to 1, so that we weight each observation equally. After we compute $\mu$ it, we calculate $\mu_i$ and $\bar{y}_i$, taking into account weights. To compute frequency-weighted means for each panel, we just multiply each observation by its respective weight, sum over all observations in the panel, then divide by the sum of the weights for the panel. (See [U] 20.23 Weighted estimation for information on how to handle aweights and pweights.) We use the same procedure to compute the frequency-weighted variant of expression (29) in the derivative calculations.
To use our program, we type

```
. use http://www.stata-press.com/data/r13/poissonwts
. gmm gmm_poiderivfw [fw=fwt], nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep hasderivatives
(sum of wgt is 819)
```

Step 1
Iteration 0:  GMM criterion Q(b) = 49.8292
Iteration 1:  GMM criterion Q(b) = .11136736
Iteration 2:  GMM criterion Q(b) = .00008519
Iteration 3:  GMM criterion Q(b) = 7.110e-11
Iteration 4:  GMM criterion Q(b) = 5.596e-23

Instruments for equation 1: x1 x2 x3

Testing whether our program works correctly with frequency weights is easy. A frequency-weighted dataset is just a compact form of a larger dataset in which identical observations are omitted and a frequency-weight variable is included to tell us how many times each observation in the smaller dataset appears in the larger dataset. Therefore, we can expand our smaller dataset by the frequency-weight variable and then refit our model without specifying frequency weights. If we obtain the same results, our program works correctly. When we type

```
. expand fw
. gmm gmm_poiderivfw, nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep
```

we obtain the same results as before.

**Stored results**

`gmm` stores the following in `e()`:

**Scalars**
- `e(N)` number of observations
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_aux)` number of auxiliary parameters
- `e(n_moments)` number of moments
- `e(n_eq)` number of equations in moment-evaluator program
- `e(Q)` criterion function
- `e(J)` Hansen $J$ $\chi^2$ statistic
- `e(J_df)` $J$ statistic degrees of freedom
- `e(k_i)` number of parameters in equation $i$
- `e(has_xtinst)` 1 if panel-style instruments specified, 0 otherwise
- `e(N_clust)` number of clusters
- `e(type)` 1 if interactive version, 2 if moment-evaluator program version
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations used by iterative GMM estimator
- `e(converged)` 1 if converged, 0 otherwise

**Macros**
- `e(cmd)` `gmm`
- `e(cmdline)` command as typed
- `e(title)` title specified in `title()`
- `e(title_2)` title specified in `title2()`
- `e(clustvar)` name of cluster variable
- `e(inst_i)` equation $i$ instruments
- `e(eqnames)` equation names
- `e(winit)` initial weight matrix used
- `e(winitname)` name of user-supplied initial weight matrix
- `e(estimator)` onestep, twostep, or igmm
- `e(rhs)` variables specified in `variables()`
- `e(params_i)` equation $i$ parameters
- `e(wmatrix)` `wmtype` specified in `wmatrix()`
- `e(vce)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(params)` parameter names
- `e(sexp_i)` substitutable expression for equation $i$
- `e(evalprogs)` moment-evaluator program
- `e(evalopts)` options passed to moment-evaluator program
- `e(nocommonesample)` `nocommonesample`, if specified
- `e(technique)` optimization technique
- `e(properties)` `b V`
- `e(estat_cmd)` program used to implement `estat`
- `e(predict)` program used to implement `predict`
- `e(marginsnotok)` predictions disallowed by `margins`

**Matrices**
- `e(b)` coefficient vector
- `e(init)` initial values of the estimators
- `e(Wuser)` user-supplied initial weight matrix
- `e(W)` weight matrix used for final round of estimation
- `e(S)` moment covariance matrix used in robust VCE computations
- `e(N_byequation)` number of observations per equation, if `nocommonesample` specified
- `e(V)` variance–covariance matrix
- `e(V_modelbased)` model-based variance

**Functions**
- `e(sample)` marks estimation sample
Methods and formulas

Let \( q \) denote the number of moment equations. For observation \( i, i = 1, \ldots, N \), write the \( j \)th moment equation as \( z_{ij} u_{ij}(\beta_j) \) for \( j = 1, \ldots, q \). \( z_{ij} \) is a \( 1 \times m_j \) vector, where \( m_j \) is the number of instruments specified for equation \( j \). Let \( m = m_1 + \cdots + m_q \).

Our notation can incorporate moment conditions of the form \( h_{ij}(w_{ij}; \beta_j) \) with instruments \( w_{ij} \) by defining \( z_{ij} = 1 \) and \( u_{ij}(\beta_j) = h_{ij}(w_{ij}; \beta_j) \), so except when necessary we do not distinguish between the two types of moment conditions. We could instead use notation so that all our moment conditions are of the form \( h_{ij}(w_{ij}; \beta_j) \), or we could adopt notation that explicitly combines both forms of moment equations. However, because moment conditions of the form \( z_i' u_i(\beta) \) are arguably more common, we use that notation.

Let \( \beta \) denote a \( k \times 1 \) vector of parameters, consisting of all the unique parameters of \( \beta_1, \ldots, \beta_q \). Then we can stack the moment conditions and write them more compactly as \( Z_i' u_i(\beta) \), where

\[
Z_i = \begin{bmatrix}
z_{i1} & 0 & \cdots & 0 \\
0 & z_{i2} & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \cdots & z_{iq}
\end{bmatrix} \quad \text{and} \quad u_i(\beta) = \begin{bmatrix}
u_{i1}(\beta_1) \\
u_{i2}(\beta_2) \\
\vdots \\
u_{iq}(\beta_j)
\end{bmatrix}
\]

The GMM estimator \( \hat{\beta} \) is the value of \( \beta \) that minimizes

\[
Q(\beta) = \left\{ N^{-1} \sum_{i=1}^{N} Z_i' u_i(\beta) \right\}' W \left\{ N^{-1} \sum_{i=1}^{N} Z_i' u_i(\beta) \right\} \quad (A1)
\]

for \( q \times q \) weight matrix \( W \).

By default, \texttt{gmm} minimizes \( (A1) \) using the Gauss–Newton method. See Hayashi (2000, 498) for a derivation. This technique is typically faster than quasi-Newton methods and does not require second-order derivatives.

Methods and formulas are presented under the following headings:

- Initial weight matrix
- Weight matrix
- Variance–covariance matrix
- Hansen’s J statistic
- Panel-style instruments

Initial weight matrix

If you specify \texttt{winitial(identity)}, then we set \( W = I_q \).

If you specify \texttt{winitial(unadjusted)}, then we create matrix \( \Lambda \) with typical submatrix

\[
\Lambda_{rs} = N^{-1} \sum_{i=1}^{N} z_{ir} z_{is}
\]

for \( r = 1, \ldots, q \) and \( s = 1, \ldots, q \). If you include the \texttt{independent} suboption, then we set \( \Lambda_{rs} = 0 \) for \( r \neq s \). The weight matrix \( W \) equals \( \Lambda^{-1} \).

If you specify \texttt{winitial(matname)}, then we set \( W \) equal to Stata matrix \texttt{matname}. 
If you specify `winitial(xt xtspec)`, then you must specify one or two items in `xtspec`, one for each equation. `gmm` allows you to specify at most two moment equations when you specify `winitial(xt xtspec)`, one in first-differences and one in levels. We create the block-diagonal matrix $H$ with typical block $H_j$. If the $j$th element of `xtspec` is “L”, then $H_j$ is the identity matrix of suitable dimension. If the $j$th element of `xtspec` is “D”, then

$$
H_j = \begin{bmatrix}
1 & -0.5 & 0 & \ldots & 0 & 0 \\
-0.5 & 1 & -0.5 & \ldots & 0 & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
0 & 0 & 0 & \ldots & 1 & -0.5 \\
0 & 0 & 0 & \ldots & -0.5 & 1
\end{bmatrix}
$$

Then

$$
\Lambda_H = N_g^{-1} \sum_{g=1}^{g=N_G} Z_g' H Z_g
$$

where $g$ indexes panels in the dataset, $N_G$ is the number of panels, $Z_g$ is the full instrument matrix for panel $g$, and $W = \Lambda_H^{-1}$. See Panel-style instruments below for a discussion of how $Z_g$ is formed.

**Weight matrix**

Specification of the weight matrix applies only to the two-step and iterative estimators. When you use the onestep option, the `wmatrix()` option is ignored.

We first evaluate $(A1)$ using the initial weight matrix described above and then compute $u_i(\hat{\beta})$. In all cases, $W = \Lambda^{-1}$. If you specify `wmatrix(unadjusted)`, then we create $\Lambda$ to have typical submatrix

$$
\Lambda_{rs} = \sigma_{rs} N^{-1} \sum_{i=1}^{N} Z_{ir}' Z_{is}
$$

where

$$
\sigma_{rs} = N^{-1} \sum_{i=1}^{N} u_{ir}(\hat{\beta}) u_{is}(\hat{\beta})
$$

and $r$ and $s$ index moment equations. For all types of weight matrices, if the independent suboption is specified, then $\Lambda_{rs} = 0$ for $r \neq s$, where $\Lambda_{rs}$ measures the covariance between moment conditions for equations $r$ and $s$.

If you specify `wmatrix(robust)`, then

$$
\Lambda = N^{-1} \sum_{i=1}^{N} Z_i u_i(\hat{\beta}) u_i'(\hat{\beta}) Z_i'
$$

If you specify `wmatrix(cluster clustvar)`, then

$$
\Lambda = N^{-1} \sum_{c=1}^{c=N_C} q_c q_c'
$$
where $c$ indexes clusters, $N_C$ is the number of clusters, and

$$q_c = \sum_{i \in c_j} Z_i u_i(\hat{\beta})$$

If you specify `wmatrix(hac kernel [#])`, then

$$\Lambda = N^{-1} \sum_{i=1}^{N} Z_i u_i(\hat{\beta})u_i(\hat{\beta})'Z_i' + N^{-1} \sum_{l=1}^{l=n-1} \sum_{i=l+1}^{N} K(l, m) \left\{ Z_i u_i(\hat{\beta})u'_{i-l}(\hat{\beta})Z'_{i-l} + Z_{i-l} u_{i-l}(\hat{\beta})u'_i(\hat{\beta})Z'_i \right\}$$

where $m = # \text{ if } # \text{ is specified and } m = N - 2 \text{ otherwise}$. Define $z = l/(m + 1)$. If `kernel` is `bartlett` or `nwest`, then

$$K(l, m) = \begin{cases} 1 - z & 0 \leq z \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

If `kernel` is `parzen` or `gallant`, then

$$K(l, m) = \begin{cases} 1 - 6z^2 + 6z^3 & 0 \leq z \leq 0.5 \\ 2(1 - z)^3 & 0.5 < z \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

If `kernel` is `quadraticspectral` or `andrews`, then

$$K(l, m) = \begin{cases} 1 & z = 0 \\ 3\{\sin(\theta)/\theta - \cos(\theta)\}/\theta^2 & \text{otherwise} \end{cases}$$

where $\theta = 6\pi z/5$.

If `wmatrix(hac kernel opt)` is specified, then `gmm` uses Newey and West’s (1994) automatic lag-selection algorithm, which proceeds as follows. Define $h$ to be an $m \times 1$ vector of ones. Note that this definition of $h$ is slightly different than the one used by `ivregress`. There, the element of $h$ corresponding to the constant term equals zero, effectively ignoring the effect of the constant in determining the optimal lag length. Here we include the effect of the constant term. Now define

$$f_i = \{Z'_i u_i(\beta)\}' h$$

$$\hat{\sigma}_j = N^{-1} \sum_{i=j+1}^{N} f_i f_{i-j} \quad j = 0, \ldots, m^*$$

$$\hat{s}(q) = 2 \sum_{j=1}^{j=m^*} \hat{\sigma}_j j^q$$

$$\hat{s}(0) = \hat{\sigma}_0 + 2 \sum_{j=1}^{j=m^*} \hat{\sigma}_j$$

$$\hat{\gamma} = c_\gamma \left\{ \left( \frac{\hat{s}(q)}{\hat{s}(0)} \right)^2 \right\}^{1/(2q+1)}$$

$$m = \hat{\gamma} N^{1/(2q+1)}$$
where \( q, m^*, \) and \( c_\gamma \) depend on the kernel specified:

<table>
<thead>
<tr>
<th>Kernel</th>
<th>( q )</th>
<th>( m^* )</th>
<th>( c_\gamma )</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bartlett/Newey–West</td>
<td>1</td>
<td>( \text{int}\left{20(T/100)^{2/9}\right} )</td>
<td>1.1447</td>
</tr>
<tr>
<td>Parzen/Gallant</td>
<td>2</td>
<td>( \text{int}\left{20(T/100)^{4/25}\right} )</td>
<td>2.6614</td>
</tr>
<tr>
<td>Quadratic spectral/Andres</td>
<td>2</td>
<td>( \text{int}\left{20(T/100)^{2/25}\right} )</td>
<td>1.3221</td>
</tr>
</tbody>
</table>

where \( \text{int}(x) \) denotes the integer obtained by truncating \( x \) toward zero. For the Bartlett and Parzen kernels, the optimal lag is \( \min\{\text{int}(m), m^*\} \). For the quadratic spectral kernel, the optimal lag is \( \min\{m, m^*\} \).

**Variance–covariance matrix**

If you specify `vce(unadjusted)`, then the VCE matrix is computed as

\[
\text{Var}(\hat{\beta}) = N^{-1} \left\{ \overline{G}(\hat{\beta})' W \overline{G}(\hat{\beta}) \right\}^{-1} \tag{A2}
\]

where

\[
\overline{G}(\hat{\beta}) = N^{-1} \sum_{i=1}^{N} Z'_i \frac{\partial u_i(\beta)}{\partial \beta} \bigg|_{\beta = \hat{\beta}} \tag{A3}
\]

For the two-step and iterated estimators, we use the weight matrix \( W \) that was used to compute the final-round estimate \( \hat{\beta} \).

When you do not specify analytic derivatives, \texttt{gmm} must compute the Jacobian matrix (A3) numerically. By default, \texttt{gmm} computes each element of the matrix individually by using the Mata \texttt{deriv()} function; see [M-5] \texttt{deriv()}. This procedure results in accurate derivatives but can be slow if your model has many instruments or parameters.

When you specify the \texttt{quickderivatives} option, \texttt{gmm} computes all derivatives corresponding to parameter \( \beta_j, j = 1, \ldots, q \), at once, using two-sided derivatives with a step size of \( |\beta_j| \epsilon^{1/3} \), where \( \epsilon \) is the machine precision of a double precision number (approximately \( 2.22045 \times 10^{-16} \)). This method requires just two evaluations of the model’s moments to compute an entire column of (A3) and therefore has the most impact when you specify many instruments or moment equations so that (A3) has many rows.

For the one-step estimator, how the unadjusted VCE is computed depends on the type of initial weight matrix requested and the form of the moment equations. If you specify two or more moment equations of the form \( h_{ij}(w_{ij}; \beta_j) \), then \texttt{gmm} issues a warning message and computes a heteroskedasticity-robust VCE because here the matrix \( Z'Z \) is necessarily singular; moreover, here you must use the identity matrix as the initial weight matrix. Otherwise, if you specify \texttt{winitial(identity)} or \texttt{winitial(unadjusted)}, then \texttt{gmm} first computes an unadjusted weight matrix based on \( \hat{\beta} \) before evaluating (A2). If you specify \texttt{winitial(matname)}, then (A2) is evaluated based on \texttt{matname}; the user is responsible for verifying that the VCE and other statistics so produced are appropriate.

All types of robust VCEs computed by \texttt{gmm} take the form

\[
\text{Var}(\hat{\beta}) = N^{-1} \left\{ \overline{G}(\hat{\beta})' W \overline{G}(\hat{\beta}) \right\}^{-1} \overline{G}(\hat{\beta})' W S W \overline{G}(\hat{\beta}) \left\{ \overline{G}(\hat{\beta})' W \overline{G}(\hat{\beta}) \right\}^{-1}
\]
For the one-step estimator, \( W \) represents the initial weight matrix requested using the \texttt{winitial()} option, and \( S \) is computed based on the specification of the \texttt{vce()} option. The formulas for the \( S \) matrix are identical to the ones that define the \( \Lambda \) matrix in \textit{Weight matrix} above, except that \( S \) is computed after the moment equations are reevaluated using the final estimate of \( \hat{\beta} \). For the two-step and iterated GMM estimators, computation of \( W \) is controlled by the \texttt{wmatrix()} option based on the penultimate estimate of \( \hat{\beta} \).

For details on computation of the VCE matrix with dynamic panel-data models, see \textit{Panel-style instruments} below.

\section*{Hansen’s J statistic}

Hansen’s (1982) \( J \) test of overidentifying restrictions is \( J = N \times Q(\hat{\beta}) \). \( J \sim \chi^2(m - k) \). If \( m < k \), \texttt{gmm} issues an error message without estimating the parameters. If \( m = k \), the model is just-identified and \( J \) is saved as missing (“.”). For the two-step and iterated GMM estimators, the \( J \) statistic is based on the last-computed weight matrix as determined by the \texttt{wmatrix()} option. For the one-step estimator, \texttt{gmm} recomputes a weight matrix as described in the second paragraph of \textit{Variance–covariance matrix} above. To obtain Hansen’s \( J \) statistic, you use \texttt{estat overid}; see \textit{[R] gmm postestimation}.

\section*{Panel-style instruments}

Here we discuss several issues that arise only when you specify panel-style instruments by using the \texttt{xtinstruments()} option. When you specify the \texttt{xtinstruments()} option, we can no longer consider the instruments for one observation in isolation; instead, we must consider the instrument matrix for an entire panel at once. In the following discussion, we let \( T \) denote the number of time periods in a panel. To accommodate unbalanced datasets, conceptually we simply use zeros as instruments and residuals for time periods that are missing in a panel.

We consider the case where you specify both an equation in levels and an equation in differences, yielding two residual equations. Let \( u_{p,t}^L(\beta) \) denote the residual for the level equation for panel \( p \) in period \( t \), and let \( u_{p,t}^D(\beta) \) denote the residual for the corresponding difference equation. Now define the \( 2T \times 1 \) vector \( u_p(\beta) \) as

\[
 u_p(\beta) = [u_{p,1}^L(\beta), u_{p,2}^L(\beta), \ldots, u_{p,T}^L(\beta), u_{p,2}^D(\beta), u_{p,3}^D(\beta), \ldots, u_{p,T}^D(\beta)]
\]

The \( T + 1 \) element of \( u_p(\beta) \) is \( u_{p,2}^D(\beta) \) since we lose the first observation of the difference equation because of differencing.

We write the moment conditions for the \( p \)th panel as \( Z_p u_p(\beta) \). To see how \( Z_p \) is defined, let \( w_{p,t}^L \) and \( w_{p,t}^D \) denote the vectors of panel-style instruments for the level and difference equations, respectively, and let time be denoted by \( t \); we discuss their dimensions momentarily. Also let \( x_{p,t}^L \) and \( x_{p,t}^D \) denote the vectors of instruments specified in \texttt{instruments()} for the level and difference equations at time \( t \). Without loss of generality, for our discussion we assume that you specify the level equation first. Then \( Z_p \) has the form
To see how the $w$ vectors are formed, suppose you specify
\[ \text{xtinstruments(eq(1): d, lags(a/b))} \]

Then $w^L_t$ will be a $(b-a+1) \times 1$ vector consisting of $d_{t-a}, \ldots, d_{t-b}$. If $(t-a) \leq 0$, then instead we set $w^L_t = 0$. If $(t-a) > 0$ but $(t-b) \leq 0$, then we create $w^L_t$ to consist of $d_{t-a}, \ldots, d_1$. With this definition, $(b-a+1)$ defines the maximum number of lags of $d$ used, but \text{gmm} will proceed with fewer lags if all $(b-a+1)$ lags are not available. If you specify two panel-style instruments, $d$ and $e$, say, then $w^L_t$ will consist of $d_{t-a}, \ldots, d_{t-b}, e_{t-a}, \ldots, e_{t-b}$. $w^D_t$ is handled analogously.

The $x^L_t$ vectors are simply $j \times 1$ vectors, where $j$ is the number of regular instruments specified with the \texttt{instruments()} option; these vectors include a “1” unless you specify the \texttt{noconstant} suboption.

Looking carefully at (A4), you will notice that for dynamic panel-data models, moment conditions corresponding to the instruments $x^L_{pt}$ take the form
\[
E \left[ \sum_{t=1}^{T} x^L_{pt} u^L_{pt}(\beta) \right] = 0
\]
and likewise for $x^D_{pt}$. Instead of having separate moment conditions for each time period, there is one moment condition equal to the average of individual periods’ moments. See Arellano and Bond (1991, 280). To include separate moment conditions for each time period, instead of specifying, say,
\[ \text{instruments(1: x)} \]
you could instead first generate a variable called \texttt{one} equal to unity for all observations and specify
\[ \text{xtinstruments(1: x one)} \]
(Creating the variable \texttt{one} is necessary because a constant is not automatically included in variable lists specified in \texttt{xtinstruments()}.)

Unbalanced panels are essentially handled by including zeros rows and columns of $Z_p$ and $u_p(\beta)$ corresponding to missing time periods. However, the numbers of instruments and moment conditions reported by \texttt{gmm} do not reflect this trickery and instead reflect the numbers of instruments and moment conditions that are not manipulated in this way. Moreover, \texttt{gmm} includes code to work through these situations efficiently without actually having to fill in zeros.

When you specify \texttt{winitial(xt ...)}, the one-step unadjusted VCE is computed as
\[
\text{Var}(\hat{\beta}) = \hat{\sigma}_1^2 A_{HH}
\]
where $\Lambda_H$ was defined previously,

$$
\hat{\sigma}_I^2 = (N - k)^{-1} \sum_{p=1}^{p=P} u_p^D(\hat{\beta})
$$

and $u_p^D(\hat{\beta}) = [u_{p2}^D(\hat{\beta}), \ldots, u_{pT}^D(\hat{\beta})]$. Here we use $(N - k)^{-1}$ instead of $N^{-1}$ to match $xtdpd$.

**Special-interest postestimation command**

`estat overid` reports Hansen’s $J$ statistic, which is used to determine the validity of the overidentifying restrictions in a GMM model. If the model is correctly specified in the sense that $E\{z_iu_i(\beta)\} = 0$, then the sample analog to that condition should hold at the estimated value of $\beta$. Hansen’s $J$ statistic is valid only if the weight matrix is optimal, meaning that it equals the inverse of the covariance matrix of the moment conditions. Therefore, `estat overid` only reports Hansen’s $J$ statistic after two-step or iterated estimation, or if you specified `winitial(matname)` when calling `gmm`. In the latter case, it is your responsibility to determine the validity of the $J$ statistic.

**Syntax for predict**

`predict [type] newvar [if] [in] [, eq]`  
`predict [type] {stub*, newvar1 ... newvarq} [if] [in]`
Residuals are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

You specify one new variable and (optionally) `equation()`, or you specify `stub*` or `q` new variables, where `q` is the number of moment equations.

**Menu for predict**

Statistics > Postestimation > Predictions, residuals, etc.

**Option for predict**

`equation(#eqno | eqname)`, `equation(#1)`, or `equation(demand)`

`equation(#eqno | eqname)` specifies the equation for which residuals are desired. Specifying `equation(#1)` indicates that the calculation is to be made for the first moment equation. Specifying `equation(demand)` would indicate that the calculation is to be made for the moment equation named `demand`, assuming there is an equation named `demand` in the model.

If you specify one new variable name and omit `equation()`, results are the same as if you had specified `equation(#1)`.

For more information on using `predict` after multiple-equation estimation commands, see [R] predict.

**Syntax for estat overid**

```bash
estat overid
```

**Menu for estat**

Statistics > Postestimation > Reports and statistics

**Remarks and examples**

As we noted in *Introduction* of [R] gmm, underlying generalized method of moments (GMM) estimators is a set of `l` moment conditions, $E\{z_i u_i(\beta)\} = 0$. When `l` is greater than the number of parameters, `k`, any size-`k` subset of the moment conditions would yield a consistent parameter estimate. We remarked that the parameter estimates we would obtain would in general depend on which `k` moment conditions we used. However, if all our moment conditions are indeed valid, then the parameter estimates should not differ too much regardless of which `k` moment conditions we used to estimate the parameters. The test of overidentifying restrictions is a model specification test based on this observation. The test of overidentifying restrictions requires that the number of moment conditions be greater than the number of parameters in the model.

Recall that the GMM criterion function is

$$Q = \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\}' W \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\}$$
The test of overidentifying restrictions is remarkably simple. If \( W \) is an optimal weight matrix, under the null hypothesis \( H_0 : E\{z_iu_i(\beta)\} = 0 \), the test statistic \( J = N \times Q \sim \chi^2(l-k) \). A large test statistic casts doubt on the null hypothesis.

For the test to be valid, \( W \) must be optimal, meaning that \( W \) must be the inverse of the covariance matrix of the moment conditions:

\[
W^{-1} = E\{z_iu_i(\beta)u_i'(\beta)z_i'\}
\]

Therefore, \texttt{estat overid} works only after the two-step and iterated estimators, or if you supplied your own initial weight matrix by using the \texttt{winitial(matname)} option to \texttt{gmm} and used the one-step estimator.

Often the overidentifying restrictions test is interpreted as a test of the validity of the instruments \( z \). However, other forms of model misspecification can sometimes lead to a significant test statistic. See Hall (2005, sec. 5.1) for a discussion of the overidentifying restrictions test and its behavior in correctly and misspecified models.

### Example 1

In example 6 of \texttt{[R] gmm}, we fit an exponential regression model of the number of doctor visits based on the person’s gender, income, possession of private health insurance, and presence of a chronic disease. We argued that the variable \( \text{income} \) may be endogenous; we used the person’s age and race as additional instrumental variables. Here we refit the model and test the specification of the model. We type

```
. use http://www.stata-press.com/data/r13/docvisits
. gmm (docvis - exp({xb:private chronic female income} + {b0})),
    > instruments(private chronic female age black hispanic)
    (output omitted)
. estat overid
```

Test of overidentifying restriction:
Hansen’s \( J \) chi2(2) = 9.52598 (p = 0.0085)

The \( J \) statistic is significant even at the 1% significance level, so we conclude that our model is misspecified. One possibility is that age and race directly affect the number of doctor visits, so we are not justified in excluding them from the model.

A simple technique to explore whether any of the instruments is invalid is to examine the statistics

\[
r_j = W_{jj}^{1/2} \left\{ \frac{1}{N} \sum_{i=1}^{N} z_{ij}u_i(\hat{\beta}) \right\}
\]

for \( j = 1, \ldots, k \), where \( W_{jj} \) denotes the \( j \)th diagonal element of \( W \), \( u_i(\hat{\beta}) \) denotes the sample residuals, and \( k \) is the number of instruments. If all the instruments are valid, then the scaled sample moments should at least be on the same order of magnitude. If one (or more) instrument’s \( r_j \) is large in absolute value relative to the others, then that could be an indication that instrument is not valid.

In Stata, we type

```
. predict double r if e(sample) // obtain residual from the model
. matrix W = e(W) // retrieve weight matrix
. local i 1
. // loop over each instrument and compute r_j
. foreach var of varlist private chronic female age black hispanic {
    2.     generate double r'var' = r'*var'*sqrt(W[', 'i', ',', 'i'])
    3.     local ++i
. }
```
We notice that the $r_j$ statistics for `age`, `black`, and `hispanic` are larger than those for the other instruments in our model, supporting our suspicion that age and race may have a direct impact on the number of doctor visits.

**Stored results**

The `estat overid` stores the following in `r()`:

Scalar

- `r(J)` : Hansen’s $J$ statistic
- `r(J_df)` : $J$ statistic degrees of freedom
- `r(J_p)` : $J$ statistic $p$-value

grmeanby — Graph means and medians by categorical variables

**Syntax**

```
grmeanby varlist [if] [in] [weight], summarize(varname) [, options]
```

**Options**

<table>
<thead>
<tr>
<th>Description</th>
<th>Syntax</th>
</tr>
</thead>
<tbody>
<tr>
<td>Main</td>
<td></td>
</tr>
<tr>
<td><em>summarize(varname)</em></td>
<td>graph mean (or median) of varname</td>
</tr>
<tr>
<td>median</td>
<td>graph medians; default is to graph means</td>
</tr>
<tr>
<td>Plot</td>
<td></td>
</tr>
<tr>
<td>cline_options</td>
<td>change the look of the lines</td>
</tr>
<tr>
<td>marker_options</td>
<td>change look of markers (color, size, etc.)</td>
</tr>
<tr>
<td>marker_label_options</td>
<td>add marker labels; change look or position</td>
</tr>
<tr>
<td>Y axis, X axis, Titles, Legend, Overall</td>
<td>any options other than by() documented in [G-3] twoway_options</td>
</tr>
</tbody>
</table>

*summarize(varname)* is required.

**Menu**

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Graph means/medians by groups

**Description**

`grmeanby` graphs the (optionally weighted) means or medians of `varname` according to the values of the variables in `varlist`. The variables in `varlist` may be string or numeric and, if numeric, may be labeled.

**Options**

- `summarize(varname)` is required; it specifies the name of the variable whose mean or median is to be graphed.
- `median` specifies that the graph is to be of medians, not means.
cline_options affect the rendition of the lines through the markers, including their color, pattern, and width; see [G-3] cline_options.

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.

marker_label_options specify if and how the markers are to be labeled; see [G-3] marker_label_options.

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples

The idea of graphing means of categorical variables was shown in Chambers and Hastie (1992, 3). Because this was shown in the context of an S function for making such graphs, it doubtless has roots going back further than that. grmeanby is, in any case, another implementation of what we will assume is their idea.

Example 1

Using a variation of our auto dataset, we graph the mean of mpg by foreign, rep77, rep78, and make:

```
. use http://www.stata-press.com/data/r13/auto1
   (Automobile Models)
. grmeanby foreign rep77 rep78 make, sum(mpg)
```

If we had wanted a graph of medians rather than means, we could have typed

```
. grmeanby foreign rep77 rep78 make, sum(mpg) median
```

**Title**

**hausman — Hausman specification test**

**Syntax**

```
hausman name-consistent [ name-efficient ] [ , options ]
```

**Options**

- **Main**
  - `constant` include estimated intercepts in comparison; default is to exclude
  - `alleqs` use all equations to perform test; default is first equation only
  - `skip(eqlist)` skip specified equations when performing test
  - `equations(matchlist)` associate/compare the specified (by number) pairs of equations
  - `force` force performance of test, even though assumptions are not met
  - `df(#)` use # degrees of freedom
  - `sigmamore` base both (co)variance matrices on disturbance variance estimate from efficient estimator
  - `sigmaless` base both (co)variance matrices on disturbance variance estimate from consistent estimator

- **Advanced**
  - `tconsistent(string)` consistent estimator column header
  - `tefficient(string)` efficient estimator column header

where `name-consistent` and `name-efficient` are names under which estimation results were stored via `estimates store`; see `[R] estimates store.`

A period (.) may be used to refer to the last estimation results, even if these were not already stored.

Not specifying `name-efficient` is equivalent to specifying the last estimation results as “.”.

**Menu**

Statistics > Postestimation > Tests > Hausman specification test

**Description**

`hausman` performs Hausman’s (1978) specification test.

**Options**

- `constant` specifies that the estimated intercept(s) be included in the model comparison; by default, they are excluded. The default behavior is appropriate for models in which the constant does not have a common interpretation across the two models.
alleqs specifies that all the equations in the models be used to perform the Hausman test; by default, only the first equation is used.

skipeqs(eqlist) specifies in eqlist the names of equations to be excluded from the test. Equation numbers are not allowed in this context, because the equation names, along with the variable names, are used to identify common coefficients.

equations(matchlist) specifies, by number, the pairs of equations that are to be compared.

The matchlist in equations() should follow the syntax

\[
\#_c:#_e \[\#_c:#_e[,...]\]
\]

where \#_c (\#_e) is an equation number of the always-consistent (efficient under \(H_0\)) estimator. For instance, equations(1:1), equations(1:1, 2:2), or equations(1:2).

If equations() is not specified, then equations are matched on equation names.

equations() handles the situation in which one estimator uses equation names and the other does not. For instance, equations(1:2) means that equation 1 of the always-consistent estimator is to be tested against equation 2 of the efficient estimator. equations(1:1, 2:2) means that equation 1 is to be tested against equation 1 and that equation 2 is to be tested against equation 2. If equations() is specified, the alleqs and skipeqs options are ignored.

force specifies that the Hausman test be performed, even though the assumptions of the Hausman test seem not to be met, for example, because the estimators were pweighted or the data were clustered.

df(#) specifies the degrees of freedom for the Hausman test. The default is the matrix rank of the variance of the difference between the coefficients of the two estimators.

sigmamore and sigmaless specify that the two covariance matrices used in the test be based on a common estimate of disturbance variance (\(\sigma^2\)).

sigmamore specifies that the covariance matrices be based on the estimated disturbance variance from the efficient estimator. This option provides a proper estimate of the contrast variance for so-called tests of exogeneity and overidentification in instrumental-variables regression.

sigmaless specifies that the covariance matrices be based on the estimated disturbance variance from the consistent estimator.

These options can be specified only when both estimators store e(sigma) or e(rmse), or with the xtreg command. e(sigma_e) is stored after the xtreg command with the fe or mle option. e(rmse) is stored after the xtreg command with the re option.

sigmamore or sigmaless are recommended when comparing fixed-effects and random-effects linear regression because they are much less likely to produce a non–positive-definite-differenced covariance matrix (although the tests are asymptotically equivalent whether or not one of the options is specified).

tconsistent(string) and tefficient(string) are formatting options. They allow you to specify the headers of the columns of coefficients that default to the names of the models. These options will be of interest primarily to programmers.
Remarks and examples

*hausman* is a general implementation of Hausman’s (1978) specification test, which compares an estimator $\hat{\theta}_1$ that is known to be consistent with an estimator $\hat{\theta}_2$ that is efficient under the assumption being tested. The null hypothesis is that the estimator $\hat{\theta}_2$ is indeed an efficient (and consistent) estimator of the true parameters. If this is the case, there should be no systematic difference between the two estimators. If there exists a systematic difference in the estimates, you have reason to doubt the assumptions on which the efficient estimator is based.

The assumption of efficiency is violated if the estimator is pweighted or the data are clustered, so *hausman* cannot be used. The test can be forced by specifying the *force* option with *hausman*. For an alternative to using *hausman* in these cases, see [R] *suest*.

To use *hausman*, you

```
. (compute the always-consistent estimator)
. estimates store name-consistent
. (compute the estimator that is efficient under $H_0$)
. hausman name-consistent
```

Alternatively, you can turn this around:

```
. (compute the estimator that is efficient under $H_0$)
. estimates store name-efficient
. (fit the less-efficient model)
. (compute the always-consistent estimator)
. hausman . name-efficient
```

You can, of course, also compute and store both the always-consistent and efficient-under-$H_0$ estimators and perform the Hausman test with

```
. hausman name-consistent name-efficient
```

> Example 1

Prob>\chi^2 = 0.0000

Under the current specification, our initial hypothesis that the individual-level effects are adequately modeled by a random-effects model is resoundingly rejected. This result is based on the rest of our model specification, and random effects might be appropriate for some alternate model of wages.

Jerry Allen Hausman was born in West Virginia in 1946. He studied economics at Brown and Oxford, has been at MIT since 1972, and has made many outstanding contributions to econometrics and applied microeconomics.

Example 2

A stringent assumption of multinomial and conditional logit models is that outcome categories for the model have the property of independence of irrelevant alternatives (IIA). Stated simply, this assumption requires that the inclusion or exclusion of categories does not affect the relative risks associated with the regressors in the remaining categories.

One classic example of a situation in which this assumption would be violated involves the choice of transportation mode; see McFadden (1974). For simplicity, postulate a transportation model with the four possible outcomes: rides a train to work, takes a bus to work, drives the Ford to work, and drives the Chevrolet to work. Clearly, “drives the Ford” is a closer substitute to “drives the Chevrolet” than it is to “rides a train” (at least for most people). This means that excluding “drives the Ford” from the model could be expected to affect the relative risks of the remaining options and that the model would not obey the IIA assumption.

Using the data presented in [R] mlogit, we will use a simplified model to test for IIA. The choice of insurance type among indemnity, prepaid, and uninsured is modeled as a function of age and gender. The indemnity category is allowed to be the base category, and the model including all three outcomes is fit. The results are then stored under the name allcats.

. estimates store allcats

Under the IIA assumption, we would expect no systematic change in the coefficients if we excluded one of the outcomes from the model. (For an extensive discussion, see Hausman and McFadden [1984].) We reestimate the parameters, excluding the uninsured outcome, and perform a Hausman test against the fully efficient full model.

The syntax of the if condition on the mlogit command simply identified the "Uninsured" category with the insure value label; see [U] 12.6.3 Value labels. On examining the output from hausman, we see that there is no evidence that the IIA assumption has been violated.

Because the Hausman test is a standardized comparison of model coefficients, using it with mlogit requires that the base outcome be the same in both competing models. In particular, if the most-frequent category (the default base outcome) is being removed to test for IIA, you must use the baseoutcome() option in mlogit to manually set the base outcome to something else. Or you can use the equation() option of the hausman command to align the equations of the two models.

Having the missing values for the square root of the diagonal of the covariance matrix of the differences is not comforting, but it is also not surprising. This covariance matrix is guaranteed to be positive definite only asymptotically (it is a consequence of the assumption that one of the estimators is efficient), and assurances are not made about the diagonal elements. Negative values along the diagonal are possible, and the fourth column of the table is provided mainly for descriptive use.

We can also perform the Hausman IIA test against the remaining alternative in the model:

```
. mlogit insure age male if insure != "Prepaid":insure
```

```
Iteration 0:  log likelihood = -132.59913
Iteration 1:  log likelihood = -131.78009

\[ b = \text{consistent under Ho and Ha; obtained from mlogit} \]
\[ B = \text{inconsistent under Ha, efficient under Ho; obtained from mlogit} \]

Test: Ho: difference in coefficients not systematic

\[ \chi^2(3) = (b-B)'[(V_b-V_B)^{-1}](b-B) \]
\[ = -0.18 \quad \chi^2 < 0 \Rightarrow \text{model fitted on these data fails to meet the asymptotic assumptions of the Hausman test; see } \text{suest} \text{ for a generalized test} \]

Here the $\chi^2$ statistic is actually negative. We might interpret this result as strong evidence that we cannot reject the null hypothesis. Such a result is not an unusual outcome for the Hausman test, particularly when the sample is relatively small—there are only 45 uninsured individuals in this dataset.

Are we surprised by the results of the Hausman test in this example? Not really. Judging from the $z$ statistics on the original multinomial logit model, we were struggling to identify any structure in the data with the current specification. Even when we were willing to assume IIA and computed the efficient estimator under this assumption, few of the effects could be identified as statistically different from those on the base category. Trying to base a Hausman test on a contrast (difference) between two poor estimates is just asking too much of the existing data.

In example 2, we encountered a case in which the Hausman was not well defined. Unfortunately, in our experience this happens fairly often. Stata provides an alternative to the Hausman test that overcomes this problem through an alternative estimator of the variance of the difference between the two estimators. This other estimator is guaranteed to be positive semidefinite. This alternative estimator also allows a widening of the scope of problems to which Hausman-type tests can be applied by relaxing the assumption that one of the estimators is efficient. For instance, you can perform Hausman-type tests to clustered observations and survey estimators. See [R] suest for details.

### Stored results

The `hausman` command stores the following in `r()`:

- Scalars
  - `r(chi2)` $\chi^2$ statistic
  - `r(df)` degrees of freedom for the $\chi^2$ statistic
  - `r(p)` $p$-value for the $\chi^2$ statistic
  - `r(rank)` rank of $(V_b-V_B)^{(-1)}$
Methods and formulas

The Hausman statistic is distributed as $\chi^2$ and is computed as

$$H = (\beta_c - \beta_e)'(V_c - V_e)^{-1}(\beta_c - \beta_e)$$

where

- $\beta_c$ is the coefficient vector from the consistent estimator
- $\beta_e$ is the coefficient vector from the efficient estimator
- $V_c$ is the covariance matrix of the consistent estimator
- $V_e$ is the covariance matrix of the efficient estimator

When the difference in the variance matrices is not positive definite, a Moore–Penrose generalized inverse is used. As noted in Gourieroux and Monfort (1995, 125–128), the choice of generalized inverse is not important asymptotically.

The number of degrees of freedom for the statistic is the rank of the difference in the variance matrices. When the difference is positive definite, this is the number of common coefficients in the models being compared.

Acknowledgment

Portions of hausman are based on an early implementation by Jeroen Weesie of the Department of Sociology at Utrecht University, The Netherlands.

*select() and twostep are required.

The full specification is select([ depvar_s = varlist_s [, noconstant ] ]).

### indepvars and varlist_s may contain factor variables; see [U] 11.4.3 Factor variables.

depvar, indepvars, varlist_s, and depvar_s may contain time-series operators; see [U] 11.4.4 Time-series varlists.

bootstrap, by, fp, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

aweights are not allowed with the jackknife prefix; see [R] jackknife.

twostep, vce(), first, nskip, and weights are not allowed with the svy prefix; see [SVY] svy.

pweights, aweights, fweights, and iweights are allowed with maximum likelihood estimation; see [U] 11.1.6 weight.

No weights are allowed if twostep is specified.

display_option does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

### Menu

**heckman for maximum likelihood estimates**

Statistics > Sample-selection models > Heckman selection model (ML)

**heckman for two-step consistent estimates**

Statistics > Sample-selection models > Heckman selection model (two-step)
Description

`heckman` fits regression models with selection by using either Heckman’s two-step consistent estimator or full maximum likelihood.

Options for Heckman selection model (ML)

```
select([ depvar_s = ] varlist_s [, noconstant offset(varname_o) ]) specifies the variables and options for the selection equation. It is an integral part of specifying a Heckman model and is required. The selection equation should contain at least one variable that is not in the outcome equation.

If depvar_s is specified, it should be coded as 0 or 1, with 0 indicating an observation not selected and 1 indicating a selected observation. If depvar_s is not specified, observations for which depvar is not missing are assumed selected, and those for which depvar is missing are assumed not selected.

noconstant suppresses the selection constant term (intercept).

offset(varname_o) specifies that selection offset varname_o be included in the model with the coefficient constrained to be 1.

noconstant, offset(varname), constraints(constraints), collinear; see [R] estimation options.
```

```
se/robust

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.
```

```
reporting

level(#) ; see [R] estimation options.
```

```
first specifies that the first-step probit estimates of the selection equation be displayed before estimation.

noshare specifies that a full maximum-likelihood model with only a constant for the regression equation be fit. This model is not displayed but is used as the base model to compute a likelihood-ratio test for the model test statistic displayed in the estimation header. By default, the overall model test statistic is an asymptotically equivalent Wald test that all the parameters in the regression equation are zero (except the constant). For many models, this option can substantially increase estimation time.

nshazard(newvar) and mills(newvar) are synonyms; either will create a new variable containing the nonselection hazard—what Heckman (1979) referred to as the inverse of the Mills’ ratio—from the selection equation. The nonselection hazard is computed from the estimated parameters of the selection equation.

nocnsreport; see [R] estimation options.
```

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] estimation options.
Maximization

`maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init Specs);` see [R] maximize. These options are seldom used.

Setting the optimization type to `technique(bhhh)` resets the default `vcetype` to `vce(opg)`.

The following option is available with `heckman` but is not shown in the dialog box: `coeflegend`; see [R] estimation options.

### Options for Heckman selection model (two-step)

```
Model
```

`select([ depvar_s = ] varlist [, noconstant ])` specifies the variables and options for the selection equation. It is an integral part of specifying a Heckman model and is required. The selection equation should contain at least one variable that is not in the outcome equation.

If `depvar_s` is specified, it should be coded as 0 or 1, with 0 indicating an observation not selected and 1 indicating a selected observation. If `depvar_s` is not specified, observations for which `depvar_s` is not missing are assumed selected, and those for which `depvar_s` is missing are assumed not selected.

`noconstant` suppresses the selection constant term (intercept).

`twostep` specifies that Heckman’s (1979) two-step efficient estimates of the parameters, standard errors, and covariance matrix be produced.

`noconstant`; see [R] estimation options.

`rhosigma`, `rhotrunc`, `rholimited`, and `rhoforce` are rarely used options to specify how the two-step estimator (option `twostep`) handles unusual cases in which the two-step estimate of $\rho$ is outside the admissible range for a correlation, $[-1,1]$. When $\text{abs}(\rho) > 1$, the two-step estimate of the coefficient variance–covariance matrix may not be positive definite and thus may be unusable for testing. The default is `rhosigma`.

`rhosigma` specifies that $\rho$ be truncated, as with the `rhotrunc` option, and that the estimate of $\sigma$ be made consistent with $\hat{\rho}$, the truncated estimate of $\rho$. So, $\hat{\sigma} = \beta_m \hat{\rho}$; see Methods and formulas for the definition of $\beta_m$. Both the truncated $\rho$ and the new estimate of $\hat{\sigma}$ are used in all computations to estimate the two-step covariance matrix.

`rhotrunc` specifies that $\rho$ be truncated to lie in the range $[-1,1]$. If the two-step estimate is less than $-1$, $\rho$ is set to $-1$; if the two-step estimate is greater than 1, $\rho$ is set to 1. This truncated value of $\rho$ is used in all computations to estimate the two-step covariance matrix.

`rholimited` specifies that $\rho$ be truncated only in computing the diagonal matrix $\mathbf{D}$ as it enters $\mathbf{V}_{\text{twostep}}$ and $\mathbf{Q}$; see Methods and formulas. In all other computations, the untruncated estimate of $\rho$ is used.

`rhoforce` specifies that the two-step estimate of $\rho$ be retained, even if it is outside the admissible range for a correlation. This option may, in rare cases, lead to a non–positive-definite covariance matrix.

These options have no effect when estimation is by maximum likelihood, the default. They also have no effect when the two-step estimate of $\rho$ is in the range $[-1,1]$. 

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (conventional) and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

vce(conditional), the default, uses the two-step variance estimator derived by Heckman.

Reporting level(#) ; see [R] estimation options.

first specifies that the first-step probit estimates of the selection equation be displayed before estimation.

nshazard(newvar) and mills(newvar) are synonyms; either will create a new variable containing the nonselection hazard—what Heckman (1979) referred to as the inverse of the Mills’ ratio—from the selection equation. The nonselection hazard is computed from the estimated parameters of the selection equation.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fwrap(#), fwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

The following option is available with heckman but is not shown in the dialog box: coeflegend; see [R] estimation options.

Remarks and examples

The Heckman selection model (Gronau 1974; Lewis 1974; Heckman 1976) assumes that there exists an underlying regression relationship,

\[ y_j = x_j \beta + u_{1j} \]  

regression equation

The dependent variable, however, is not always observed. Rather, the dependent variable for observation \( j \) is observed if

\[ z_j \gamma + u_{2j} > 0 \]  

selection equation

where

\[ u_1 \sim N(0, \sigma) \]
\[ u_2 \sim N(0, 1) \]
\[ \text{corr}(u_1, u_2) = \rho \]

When \( \rho \neq 0 \), standard regression techniques applied to the first equation yield biased results. heckman provides consistent, asymptotically efficient estimates for all the parameters in such models.

In one classic example, the first equation describes the wages of women. Women choose whether to work, and thus, from our point of view as researchers, whether we observe their wages in our data. If women made this decision randomly, we could ignore that not all wages are observed and use ordinary regression to fit a wage model. Such an assumption of random participation, however, is unlikely to be true; women who would have low wages may be unlikely to choose to work, and thus the sample of observed wages is biased upward. In the jargon of economics, women choose not to work when their personal reservation wage is greater than the wage offered by employers. Thus women who choose not to work might have even higher offer wages than those who do work—they may have high offer wages, but they have even higher reservation wages. We could tell a story that competency is related to wages, but competency is rewarded more at home than in the labor force.
In any case, in this problem—which is the paradigm for most such problems—a solution can be found if there are some variables that strongly affect the chances for observation (the reservation wage) but not the outcome under study (the offer wage). Such a variable might be the number of children in the home. (Theoretically, we do not need such identifying variables, but without them, we depend on functional form to identify the model. It would be difficult for anyone to take such results seriously because the functional form assumptions have no firm basis in theory.)

Example 1

In the syntax for `heckman`, `depvar` and `indepvars` are the dependent variable and regressors for the underlying regression model to be fit ($y = X\beta$), and `varlist` are the variables ($Z$) thought to determine whether `depvar` is observed or unobserved (selected or not selected). In our female wage example, the number of children at home would be included in the second list. By default, `heckman` assumes that missing values (see [U] 12.2.1 Missing values) of `depvar` imply that the dependent variable is unobserved (not selected). With some datasets, it is more convenient to specify a binary variable (`depvar`$s$) that identifies the observations for which the dependent is observed/selected (`depvar`$s$ $\neq$ 0) or not observed (`depvar`$s$ = 0); `heckman` will accommodate either type of data.

We have a (fictional) dataset on 2,000 women, 1,343 of whom work:

```
. use http://www.stata-press.com/data/r13/womenwk
. summarize age educ married children wage
```

We will assume that the hourly wage is a function of education and age, whereas the likelihood of working (the likelihood of the wage being observed) is a function of marital status, the number of children at home, and (implicitly) the wage (via the inclusion of age and education, which we think determine the wage):
. heckman wage educ age, select(married children educ age)

LR test of indep. eqns. (rho = 0):  chi2(1) = 61.20  Prob > chi2 = 0.0000

heckman assumes that wage is the dependent variable and that the first variable list (educ and age) are the determinants of wage. The variables specified in the select() option (married, children, educ, and age) are assumed to determine whether the dependent variable is observed (the selection equation). Thus we fit the model

\[
\text{wage} = \beta_0 + \beta_1 \text{educ} + \beta_2 \text{age} + u_1
\]

and we assumed that wage is observed if

\[
\gamma_0 + \gamma_1 \text{married} + \gamma_2 \text{children} + \gamma_3 \text{educ} + \gamma_4 \text{age} + u_2 > 0
\]

where \( u_1 \) and \( u_2 \) have correlation \( \rho \).

The reported results for the wage equation are interpreted exactly as though we observed wage data for all women in the sample; the coefficients on age and education level represent the estimated marginal effects of the regressors in the underlying regression equation. The results for the two ancillary parameters require some explanation. heckman does not directly estimate \( \rho \); to constrain \( \rho \) within its valid limits, and for numerical stability during optimization, it estimates the inverse hyperbolic tangent of \( \rho \):

\[
\text{atanh } \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)
\]
This estimate is reported as $\sqrt{\rho}$. In the bottom panel of the output, \texttt{heckman} undoes this transformation for you: the estimated value of $\rho$ is 0.7035061. The standard error for $\rho$ is computed using the delta method, and its confidence intervals are the transformed intervals of $\sqrt{\rho}$.

Similarly, $\sigma$, the standard error of the residual in the wage equation, is not directly estimated; for numerical stability, \texttt{heckman} instead estimates $\ln \sigma$. The untransformed $\sigma$ is reported at the end of the output: 6.004797.

Finally, some researchers—especially economists—are used to the selectivity effect summarized not by $\rho$ but by $\lambda = \rho \sigma$. \texttt{heckman} reports this, too, along with an estimate of the standard error and confidence interval.

\section*{Technical note}

If each of the equations in the model had contained many regressors, the \texttt{heckman} command could have become long. An alternate way of specifying our wage model would be to use Stata’s global macros. The following lines are an equivalent way of specifying our model:

\begin{verbatim}
. global wageeq "wage educ age"
. global seleq "married children educ age"
. heckman $wageeq, select($seleq)
\end{verbatim}

\section*{Technical note}

The reported model $\chi^2$ test is a Wald test that all coefficients in the regression model (except the constant) are 0. \texttt{heckman} is an estimation command, so you can use \texttt{test}, \texttt{testnl}, or \texttt{lrtest} to perform tests against whatever nested alternate model you choose; see [R] \texttt{test}, [R] \texttt{testnl}, and [R] \texttt{lrtest}.

The estimation of $\rho$ and $\sigma$ in the forms $\text{atanh} \rho$ and $\ln \sigma$ extends the range of these parameters to infinity in both directions, thus avoiding boundary problems during the maximization. Tests of $\rho$ must be made in the transformed units. However, because $\text{atanh}(0) = 0$, the reported test for $\text{atanh} \rho = 0$ is equivalent to the test for $\rho = 0$.

The likelihood-ratio test reported at the bottom of the output is an equivalent test for $\rho = 0$ and is computationally the comparison of the joint likelihood of an independent probit model for the selection equation and a regression model on the observed wage data against the Heckman model likelihood. Because $\chi^2 = 61.20$, this clearly justifies the Heckman selection equation with these data.

\section*{Example 2}

\texttt{heckman} supports the Huber/White/sandwich estimator of variance under the \texttt{vce(robust)} and \texttt{vce(cluster clustvar)} options or when \texttt{pweights} are used for population-weighted data; see [U] 20.21 \textbf{Obtaining robust variance estimates}. We can obtain robust standard errors for our wage model by specifying clustering on county of residence (the \texttt{county} variable).
. heckman wage educ age, select(married children educ age) vce(cluster county)

Iteration 0:  log pseudolikelihood = -5178.7009
Iteration 1:  log pseudolikelihood = -5178.3049
Iteration 2:  log pseudolikelihood = -5178.3045

Heckman selection model  Number of obs = 2000
(regression model with sample selection)  Censored obs = 657
Uncensored obs = 1343

Wald chi2(1) = .

(Std. Err. adjusted for 10 clusters in county)

Wald test of indep. eqns. (rho = 0): chi2(1) = 38.81  Prob > chi2 = 0.0000

The robust standard errors tend to be a bit larger, but we notice no systematic differences. This finding is not surprising because the data were not constructed to have any county-specific correlations or any other characteristics that would deviate from the assumptions of the Heckman model.

Example 3

Stata also produces Heckman’s (1979) two-step efficient estimator of the model with the twostep option. Maximum likelihood estimation of the parameters can be time consuming with large datasets, and the two-step estimates may provide a good alternative in such cases. Continuing with the women’s wage model, we can obtain the two-step estimates with Heckman’s consistent covariance estimates by typing
Technical note

The Heckman selection model depends strongly on the model being correct, much more so than ordinary regression. Running a separate probit or logit for sample inclusion followed by a regression, referred to in the literature as the two-part model (Manning, Duan, and Rogers 1987)—not to be confused with Heckman’s two-step procedure—is an especially attractive alternative if the regression part of the model arose because of taking a logarithm of zero values. When the goal is to analyze an underlying regression model or to predict the value of the dependent variable that would be observed in the absence of selection, however, the Heckman model is more appropriate. When the goal is to predict an actual response, the two-part model is usually the better choice.

The Heckman selection model can be unstable when the model is not properly specified or if a specific dataset simply does not support the model’s assumptions. For example, let’s examine the solution to another simulated problem.

LR test of indep. eqns. (rho = 0): chi2(1) = 25.67  Prob > chi2 = 0.0000

The model has converged to a value of \( \rho \) that is 1.0—within machine-rounding tolerances. Given the form of the likelihood for the Heckman selection model, this implies a division by zero, and it is surprising that the model solution turns out as well as it does. Reparameterizing \( \rho \) has allowed the estimation to converge, but we clearly have problems with the estimates. Moreover, if this had occurred in a large dataset, waiting for convergence might take considerable time.

This dataset was not intentionally developed to cause problems. It is actually generated by a “Heckman process” and when generated starting from different random values can be easily estimated. The luck of the draw here merely led to data that, despite the source, did not support the assumptions of the Heckman model.

The two-step model is generally more stable when the data are problematic. It even tolerates estimates of \( \rho \) less than \(-1\) and greater than 1. For these reasons, the two-step model may be preferred when exploring a large dataset. Still, if the maximum likelihood estimates cannot converge, or converge to a value of \( \rho \) that is at the boundary of acceptable values, there is scant support for fitting a Heckman selection model on the data. Heckman (1979) discusses the implications of \( \rho \) being exactly 1 or 0, together with the implications of other possible covariance relationships among the model’s determinants.
James Joseph Heckman was born in Chicago in 1944 and studied mathematics at Colorado College and economics at Princeton. He has taught economics at Columbia and (since 1973) at the University of Chicago. He has worked on developing a scientific basis for economic policy evaluation, with emphasis on models of individuals or disaggregated groups and the problems and possibilities created by heterogeneity, diversity, and unobserved counterfactual states. In 2000, he shared the Nobel Prize in Economics with Daniel L. McFadden.

Stored results

Methods and formulas

Regression estimates using the nonselection hazard (Heckman 1979) provide starting values for maximum likelihood estimation.

The regression equation is

$$y_j = x_j \beta + u_{1j}$$

The selection equation is

$$z_j \gamma + u_{2j} > 0$$
where
\[ u_1 \sim N(0, \sigma) \]
\[ u_2 \sim N(0, 1) \]
\[ \text{corr}(u_1, u_2) = \rho \]

The log likelihood for observation \( j \), \( \ln L_j = l_j \), is
\[
l_j = \begin{cases} 
  w_j \ln \Phi \left\{ \frac{z_j \gamma + (y_j - x_j \beta) \rho / \sigma}{\sqrt{1 - \rho^2}} \right\} - \frac{w_j}{2} \left( \frac{y_j - x_j \beta}{\sigma} \frac{\rho}{\sqrt{1 - \rho^2}} \right)^2 - w_j \ln(2\pi \sigma) & y_j \text{ observed} \\
  w_j \ln \Phi(-z_j \gamma) & y_j \text{ not observed} 
\end{cases}
\]

where \( \Phi(\cdot) \) is the standard cumulative normal and \( w_j \) is an optional weight for observation \( j \).

In the maximum likelihood estimation, \( \sigma \) and \( \rho \) are not directly estimated. Directly estimated are \( \ln \sigma \) and \( \text{atanh} \rho \):
\[ \text{atanh} \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right) \]

The standard error of \( \lambda = \rho \sigma \) is approximated through the propagation of error (delta) method; that is,
\[ \text{Var}(\lambda) \approx D \text{Var}\{(\text{atanh} \rho \ln \sigma)\} D' \]

where \( D \) is the Jacobian of \( \lambda \) with respect to \( \text{atanh} \rho \) and \( \ln \sigma \).

With maximum likelihood estimation, this command supports the Huber/White/sandwich estimator of the variance and its clustered version using \textit{vce(robust)} and \textit{vce(cluster clustvar)}, respectively. See \texttt{[P] _robust}, particularly \textit{Maximum likelihood estimators} and \textit{Methods and formulas}.

The maximum likelihood version of heckman also supports estimation with survey data. For details on VCEs with survey data, see \texttt{[SVY]} \textit{variance estimation}.

The two-step estimates are computed using Heckman’s (1979) procedure.

Probit estimates of the selection equation
\[ \text{Pr}(y_j \text{ observed} \mid z_j) = \Phi(z_j \gamma) \]
are obtained. From these estimates, the nonselection hazard—what Heckman (1979) referred to as the inverse of the Mills’ ratio, \( m_j \)—for each observation \( j \) is computed as
\[ m_j = \frac{\phi(z_j \hat{\gamma})}{\Phi(z_j \hat{\gamma})} \]
where \( \phi \) is the normal density. We also define
\[ \delta_j = m_j (m_j + \hat{\gamma} z_j) \]

Following Heckman, the two-step parameter estimates of \( \beta \) are obtained by augmenting the regression equation with the nonselection hazard \( m \). Thus the regressors become \([X \, m]\), and we obtain the additional parameter estimate \( \beta_m \) on the variable containing the nonselection hazard.
A consistent estimate of the regression disturbance variance is obtained using the residuals from the augmented regression and the parameter estimate on the nonselection hazard,

\[ \hat{\sigma}^2 = \mathbf{e}' \mathbf{e} + \beta_m^2 \sum_{j=1}^{N} \delta_j / N \]

The two-step estimate of \( \rho \) is then

\[ \hat{\rho} = \frac{\beta_m}{\hat{\sigma}} \]

Heckman derived consistent estimates of the coefficient covariance matrix on the basis of the augmented regression.

Let \( \mathbf{W} = [\mathbf{X} \ \mathbf{m}] \) and \( \mathbf{R} \) be a square, diagonal matrix of dimension \( N \), with \( (1 - \hat{\rho}^2 \delta_j) \) as the diagonal elements. The conventional VCE is

\[ \mathbf{V}_{\text{twostep}} = \hat{\sigma}^2 (\mathbf{W}'\mathbf{W})^{-1} (\mathbf{W}'\mathbf{RW} + \mathbf{Q})(\mathbf{W}'\mathbf{W})^{-1} \]

where

\[ \mathbf{Q} = \hat{\rho}^2 (\mathbf{W}'\mathbf{DZ}) \mathbf{V}_p (\mathbf{Z}'\mathbf{DW}) \]

where \( \mathbf{D} \) is the square, diagonal matrix of dimension \( N \) with \( \delta_j \) as the diagonal elements; \( \mathbf{Z} \) is the data matrix of selection equation covariates; and \( \mathbf{V}_p \) is the variance–covariance estimate from the probit estimation of the selection equation.

These statistics are available both in and out of sample; type `predict ... if e(sample) ... if wanted only for the estimation sample.`

*stdf* is not allowed with *svy* estimation results.

where *a* and *b* may be numbers or variables; *a* missing (a ≥ .) means −∞, and *b* missing (b ≥ .) means +∞; see [U] 12.2.1 Missing values.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

```
**Main**
```

*xb*, the default, calculates the linear prediction *x_j*b.

*stdp* calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

*stdf* calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by *stdf* are always larger than those produced by *stdp*; see *Methods and formulas* in [R] regress postestimation.
xbse1 calculates the linear prediction for the selection equation.

stdpsel calculates the standard error of the linear prediction for the selection equation.

pr\((a, b)\) calculates \(Pr(a < x_j b + u_1 < b)\), the probability that \(y_j\) given \(x_j\) would be observed in the interval \((a, b)\).

\(a\) and \(b\) may be specified as numbers or variable names; \(lb\) and \(ub\) are variable names;

\(pr(20, 30)\) calculates \(Pr(20 < x_j b + u_1 < 30)\);

\(pr(lb, ub)\) calculates \(Pr(lb < x_j b + u_1 < ub)\); and

\(pr(20, ub)\) calculates \(Pr(20 < x_j b + u_1 < ub)\).

\(a\) missing \((a \geq .)\) means \(-\infty\); \(pr(., 30)\) calculates \(Pr(-\infty < x_j b + u_j < 30)\);

\(pr(lb, 30)\) calculates \(Pr(-\infty < x_j b + u_j < 30)\) in observations for which \(lb \geq .\)

and calculates \(Pr(lb < x_j b + u_j < 30)\) elsewhere.

\(b\) missing \((b \geq .)\) means \(+\infty\); \(pr(20, .)\) calculates \(Pr(+\infty > x_j b + u_j > 20)\);

\(pr(20, ub)\) calculates \(Pr(+\infty > x_j b + u_j > 20)\) in observations for which \(ub \geq .\)

and calculates \(Pr(20 < x_j b + u_j < ub)\) elsewhere.

\(e(a, b)\) calculates \(E(x_j b + u_1 \mid a < x_j b + u_1 < b)\), the expected value of \(y_j\) given \(x_j\) conditional on \(y_j\) being in the interval \((a, b)\), meaning that \(y_j\) is truncated.

\(a\) and \(b\) are specified as they are for \(pr()\).

ystar\((a, b)\) calculates \(E(y_j^* \mid a < x_j b + u_1 < b)\), where \(y_j^* = a\) if \(x_j b + u_j \leq a\), \(y_j^* = b\) if \(x_j b + u_j \geq b\), and \(y_j^* = x_j b + u_j\) otherwise, meaning that \(y_j^*\) is censored.

\(a\) and \(b\) are specified as they are for \(pr()\).

ycond calculates the expected value of the dependent variable conditional on the dependent variable being observed, that is, selected; \(E(y_j \mid y_j \text{ observed})\).

yexpected calculates the expected value of the dependent variable \((y_j^*)\), where that value is taken to be 0 when it is expected to be unobserved; \(y_j^* = Pr(y_j \text{ observed})E(y_j \mid y_j \text{ observed})\).

The assumption of 0 is valid for many cases where nonselection implies nonparticipation (for example, unobserved wage levels, insurance claims from those who are uninsured) but may be inappropriate for some problems (for example, unobserved disease incidence).

nshazard and mills are synonyms; both calculate the nonselection hazard—what Heckman (1979) referred to as the inverse of the Mills’ ratio—from the selection equation.

psel calculates the probability of selection (or being observed):

\(Pr(y_j \text{ observed}) = Pr(z_j \beta + u_{2j} > 0)\).

nooffset is relevant when you specify \(\text{offset}(\text{varname})\) for heckman. It modifies the calculations made by \(\text{predict}\) so that they ignore the offset variable; the linear prediction is treated as \(x_j b\) rather than as \(x_j b + u\).

scores, not available with \(\text{twostep}\), calculates equation-level score variables.

The first new variable will contain \(\partial \ln L / \partial(x_j \beta)\).

The second new variable will contain \(\partial \ln L / \partial(z_j \gamma)\).

The third new variable will contain \(\partial \ln L / \partial(\text{atanh} \ rho)\).

The fourth new variable will contain \(\partial \ln L / \partial(\ln \sigma)\).
Remarks and examples

Example 1

The default statistic produced by `predict` after `heckman` is the expected value of the dependent variable from the underlying distribution of the regression model. In the wage model of [R] heckman, this is the expected wage rate among all women, regardless of whether they were observed to participate in the labor force:

```
use http://www.stata-press.com/data/r13/womenwk
heckman wage educ age, select(married children educ age) vce(cluster county)
(predict output omitted)
predict heckwage
(option xb assumed; fitted values)
```

It is instructive to compare these predicted wage values from the Heckman model with an ordinary regression model—a model without the selection adjustment:

```
regress wage educ age
```

<table>

| age   | .1465739 | .0187135 | 7.83  | 0.000 | .109863 .1832848 |
| _cons| 6.084875 | .8896182 | 6.84  | 0.000 | 4.339679 7.830071 |

```
predict regwage
(option xb assumed; fitted values)
summarize heckwage regwage
```

Since this dataset was concocted, we know the true coefficients of the wage regression equation to be 1, 0.2, and 1, respectively. We can compute the true mean wage for our sample.

```
generate truewage = 1 + .2*age + 1*educ
summarize truewage
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>regwage</td>
<td>2000</td>
<td>23.12291</td>
<td>3.241911</td>
<td>17.98218</td>
<td>32.66439</td>
</tr>
<tr>
<td>truewage</td>
<td>2000</td>
<td>21.3256</td>
<td>3.797904</td>
<td>15</td>
<td>32.8</td>
</tr>
</tbody>
</table>

Whereas the mean of the predictions from heckman is within 18 cents of the true mean wage, ordinary regression yields predictions that are on average about $1.80 per hour too high because of the selection effect. The regression predictions also show somewhat less variation than the true wages.

The coefficients from heckman are so close to the true values that they are not worth testing. Conversely, the regression equation is significantly off but seems to give the right sense. Would we be led far astray if we relied on the OLS coefficients? The effect of age is off by more than 5 cents per year of age, and the coefficient on education level is off by about 10%. We can test the OLS coefficient on education level against the true value by using `test`.
Not only is the OLS coefficient on education substantially lower than the true parameter, but the difference from the true parameter is also statistically significant beyond the 5% level. We can perform a similar test for the OLS age coefficient:

```
. test age = .2
     ( 1)  age = .2
      F( 1, 1340) = 8.15
     Prob > F = 0.0044
```

We find even stronger evidence that the OLS regression results are biased away from the true parameters.

### Example 2

Several other interesting aspects of the Heckman model can be explored with `predict`. Continuing with our wage model, we can obtain the expected wages for women conditional on participating in the labor force with the `ycond` option. Let’s get these predictions and compare them with actual wages for women participating in the labor force.

```
. use http://www.stata-press.com/data/r13/womenwk, clear
. heckman wage educ age, select(married children educ age)  
   (output omitted)
. predict hcndwage, ycond
. summarize wage hcndwage if wage != .
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>wage</td>
<td>1343</td>
<td>23.69217</td>
<td>6.305374</td>
<td>5.88497</td>
<td>45.80979</td>
</tr>
<tr>
<td>hcndwage</td>
<td>1343</td>
<td>23.68239</td>
<td>3.335087</td>
<td>16.18337</td>
<td>33.7567</td>
</tr>
</tbody>
</table>

We see that the average predictions from `heckman` are close to the observed levels but do not have the same mean. These conditional wage predictions are available for all observations in the dataset but can be directly compared only with observed wages, where individuals are participating in the labor force.

What if we were interested in making predictions about mean wages for all women? Here the expected wage is 0 for those who are not expected to participate in the labor force, with expected participation determined by the selection equation. These values can be obtained with the `yexpected` option of `predict`. For comparison, a variable can be generated where the wage is set to 0 for nonparticipants.

```
. predict hexpwage, yexpected
. generate wage0 = wage
   (657 missing values generated)
. replace wage0 = 0 if wage == .
   (657 real changes made)
```
Again we note that the predictions from `heckman` are close to the observed mean hourly wage rate for all women. Why aren't the predictions using `ycond` and `yexpected` equal to their observed sample equivalents? For the Heckman model, unlike linear regression, the sample moments implied by the optimal solution to the model likelihood do not require that these predictions match observed data. Properly accounting for the additional variation from the selection equation requires that the model use more information than just the sample moments of the observed wages.

heckoprobit — Ordered probit model with sample selection

Syntax

heckoprobit  depvar  indepvars  \[ if \] \[ in \] \[ weight \] ,

   select([ depvar = ]  varlist  \[ , \]  noconstant  offset(varname) \]) \[ options \]

options    Description

Model

* select()                  specify selection equation: dependent and independent
                          variables; whether to have constant term and offset variable

offset(varname)           include varname in model with coefficient constrained to 1

constraints(constraints) apply specified linear constraints

collinear                keep collinear variables

SE/Robust

vce(vcetype)             vcetype may be oim, robust, cluster clustvar, opg, bootstrap,  
                          or jackknife

Reporting

level(#)                  set confidence level; default is level(95)

first                    report first-step probit estimates

noheader                  do not display header above parameter table

nofootnote                do not display footnotes below parameter table

noconsreport             do not display constraints

display_options          control column formats, row spacing, line width, display of omitted
                          variables and base and empty cells, and factor-variable labeling

Maximization

maximize_options         control the maximization process; seldom used

coefflegend             display legend instead of statistics

* select() is required.

The full specification is select([ depvar = ]  varlist  \[ , \]  noconstant  offset(varname) \]).

indepvars and varlist may contain factor variables; see [U] 11.4.3 Factor variables.

depvar, indepvars, depvar, and varlist may contain time-series operators; see [U] 11.4.4 Time-series varlists.

bootstrap, by, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

vce(), first, and weights are not allowed with the svy prefix; see [SVY] svy.

pweights, fweights, and iweights are allowed; see [U] 11.1.6 weight.

coefflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
Description

heckoprobit fits maximum-likelihood ordered probit models with sample selection.

Options

select([depvar_s =] varlist[, noconstant offset(varname_o)]). specifies the variables and options for the selection equation. It is an integral part of specifying a selection model and is required. The selection equation should contain at least one variable that is not in the outcome equation.

If depvar_s is specified, it should be coded as 0 or 1, 0 indicating an observation not selected and 1 indicating a selected observation. If depvar_s is not specified, observations for which depvar is not missing are assumed selected, and those for which depvar is missing are assumed not selected.

noconstant suppresses the selection constant term (intercept).

offset(varname_o) specifies that selection offset varname_o be included in the model with the coefficient constrained to be 1.

offset(varname), constraints(constraints), collinear; see [R] estimation options.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#); see [R] estimation options.

first specifies that the first-step probit estimates of the selection equation be displayed before estimation.

noheader suppresses the header above the parameter table, the display that reports the final log-likelihood value, number of observations, etc.

nofootnote suppresses the footnotes displayed below the parameter table.

nocnsreport; see [R] estimation options.

display_options: nolimited, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.
maximize_options: difficult, technique(algorithm_spec), iterate(#), [no] log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following option is available with heckoprobit but is not shown in the dialog box: coeflegend; see [R] estimation options.

Remarks and examples

heckoprobit estimates the parameters of a regression model for an ordered categorical outcome from a nonrandom sample known as a selected sample. Selected samples suffer from "selection on unobservables" because the errors that determine whether a case is missing are correlated with the errors that determine the outcome.

For ordered categorical regression from samples that do not suffer from selection on unobservables, see [R] oprobit or [R] ologit. For regression of a continuous outcome variable from a selected sample, see [R] heckman.

Even though we are interested in modeling a single ordinal outcome, there are two dependent variables in the ordered probit sample-selection model because we must also model the sample-selection process. First, there is the ordinal outcome \( y_j \). Second, there is a binary variable that indicates whether each case in the sample is observed or unobserved. To handle the sample-selection problem, we model both dependent variables jointly. Both variables are categorical. Their categorical values are determined by the values of linear combinations of covariates and normally distributed error terms relative to certain cutpoints that partition the real line. The error terms used in the determination of selection and the ordinal outcome value may be correlated.

The probability that the ordinal outcome \( y_j \) is equal to the value \( v_h \) is given by the probability that \( x_j \beta + u_{1j} \) falls within the cutpoints \( \kappa_{h-1} \) and \( \kappa_h \),

\[
Pr(y_j = v_h) = Pr(\kappa_{h-1} < x_j \beta + u_{1j} \leq \kappa_h)
\]

where \( x_j \) is the outcome covariates, \( \beta \) is the coefficients, and \( u_{1j} \) is a random-error term. The observed outcome values \( v_1, \ldots, v_H \) are integers such that \( v_i < v_m \) for \( i < m \). \( \kappa_0 \) is taken as \(-\infty\) and \( \kappa_H \) is taken as \(+\infty\).

We model the selection process for the outcome by

\[
s_j = 1(z_j \gamma + u_{2j} > 0)
\]

where \( s_j = 1 \) if we observed \( y_j \) and 0 otherwise, \( z_j \) is the covariates used to model the selection process, \( \gamma \) is the coefficients for the selection process, \( 1(\cdot) \) denotes the indicator function, and \( u_{2j} \) is a random-error term.

\((u_{1j}, u_{2j})\) have bivariate normal distribution with mean zero and variance matrix

\[
\begin{bmatrix}
1 & \rho \\
\rho & 1
\end{bmatrix}
\]
When $\rho \neq 0$, standard ordered probit techniques applied to the outcome equation yield inconsistent results. `heckoprobit` provides consistent, asymptotically efficient estimates for all the parameters in such models.

De Luca and Perotti (2011) describe the maximum likelihood estimator used in `heckoprobit`.

### Example 1

We have a simulated dataset containing a sample of 5,000 women, 3,480 of whom work. The outcome of interest is a woman’s job satisfaction, and we suspect that unobservables that determine job satisfaction and the unobservables that increase the likelihood of employment are correlated. Women may make a decision to work based on how satisfying their job would be. We estimate the parameters of an ordered probit sample-selection model for the outcome of job satisfaction (satisfaction) with selection on employment (work). Age (age) and years of education (education) are used as outcome covariates, and we also expect that they affect selection. Additional covariates for selection are marital status (married) and the number of children at home (children).

Here we estimate the parameters of the model with `heckoprobit`. We use the factorial interaction of `married` and `children` in `select()`. This specifies that the number of children and marital status affect selection, and it allows the effect of the number of children to differ among married and nonmarried women. The factorial interaction is specified using factor-variable notation, which is described in [U] 11.4.3 Factor variables.
. use http://www.stata-press.com/data/r13/womensat
(Job satisfaction, female)
. heckoprobit satisfaction education age,
> select(work=education age i.married##c.children)
Fitting oprobit model:
Iteration 0: log likelihood = -3934.1474
Iteration 1: log likelihood = -3571.886
Iteration 2: log likelihood = -3570.2616
Iteration 3: log likelihood = -3570.2616
Fitting selection model:
Iteration 0: log likelihood = -3071.0775
Iteration 1: log likelihood = -2565.5092
Iteration 2: log likelihood = -2556.8369
Iteration 3: log likelihood = -2556.8237
Iteration 4: log likelihood = -2556.8237
Comparison: log likelihood = -6127.0853

LR test of indep. eqns. (rho = 0):  chi2(1) = 88.10  Prob > chi2 = 0.0000

The output shows several iteration logs. The first iteration log corresponds to running the ordered probit model for those observations in the sample where we have observed the outcome. The second iteration log corresponds to running the selection probit model, which models whether we observe
our outcome of interest. If $\rho = 0$, the sum of the log likelihoods from these two models will equal the log likelihood of the ordered probit sample-selection model; this sum is printed in the iteration log as the comparison log likelihood. The final iteration log is for fitting the full ordered probit sample-selection model.

The Wald test in the header is highly significant, indicating a good model fit. All the covariates are statistically significant. The likelihood-ratio test in the footer indicates that we can reject the null hypothesis that the errors for outcome and selection are uncorrelated. This means that we should use the ordered probit sample-selection model instead of the simple ordered probit model.

The positive estimate of 0.63 for $\rho$ indicates that unobservables that increase job satisfaction tend to occur with unobservables that increase the chance of having a job.

Stored results

`heckoprobit` stores the following in `e()`:

Scalars

- `e(N)` number of observations
- `e(N_cens)` number of censored observations
- `e(N_cd)` number of completely determined observations
- `e(k_cat)` number of categories
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_aux)` number of auxiliary parameters
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(ll)` log likelihood
- `e(ll_c)` log likelihood, comparison model
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(chi2_c)` $\chi^2$ for comparison test
- `e(p_c)` $p$-value for comparison test
- `e(p)` significance of comparison test
- `e(rho)` $\rho$
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise
De Luca and Perotti (2011) provide an introduction to this model.

The ordinal outcome equation is

$$y_j = \sum_{h=1}^{H} v_h 1(\kappa_{h-1} < x_j \beta + u_{1j} \leq \kappa_h)$$

where $x_j$ is the outcome covariates, $\beta$ is the coefficients, and $u_{1j}$ is a random-error term. The observed outcome values $v_1, \ldots, v_H$ are integers such that $v_i < v_m$ for $i < m$. $\kappa_1, \ldots, \kappa_{H-1}$ are real numbers such that $\kappa_i < \kappa_m$ for $i < m$. $\kappa_0$ is taken as $-\infty$ and $\kappa_H$ is taken as $+\infty$.

The selection equation is

$$s_j = 1(z_j \gamma + u_{2j} > 0)$$

where $s_j = 1$ if we observed $y_j$ and 0 otherwise, $z_j$ is the covariates used to model the selection process, $\gamma$ is the coefficients for the selection process, and $u_{2j}$ is a random-error term.

$(u_{1j}, u_{2j})$ have bivariate normal distribution with mean zero and variance matrix

$$\begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}$$
Let $a_j = z_j \gamma + \text{offset}_j$ and $b_j = x_j \beta + \text{offset}_j$. This yields the log likelihood

$$
\ln L = \sum_{j \not\in S} w_j \ln \{ \Phi (-a_j) \} + \sum_{h=1}^{H} \sum_{j \in S} w_j \ln \{ \Phi_2 (a_j, \kappa_h - b_j, -\rho) - \Phi_2 (a_j, \kappa_{h-1} - b_j, -\rho) \}
$$

where $S$ is the set of observations for which $y_j$ is observed, $\Phi_2 (\cdot)$ is the cumulative bivariate normal distribution function (with mean $[0 \ 0]'$), $\Phi(\cdot)$ is the standard cumulative normal, and $w_j$ is an optional weight for observation $j$.

In the maximum likelihood estimation, $\rho$ is not directly estimated. Directly estimated is $\text{atanh} \ \rho$:

$$
\text{atanh} \ \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)
$$

From the form of the likelihood, it is clear that if $\rho = 0$, the log likelihood for the ordered probit sample-selection model is equal to the sum of the ordered probit model for the outcome $y$ and the selection model. We can perform a likelihood-ratio test by comparing the log likelihood of the full model with the sum of the log likelihoods for the ordered probit and selection models.

If you do not specify outcome(), pmargin (with one new variable specified) assumes outcome(#1).
You specify one or k new variables with pmargin, where k is the number of outcomes.
You specify one new variable with psel, xb, stdp, xbsel, and stdpsel.
These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

```plaintext
pmargin, the default, calculates the predicted marginal probabilities.
You specify one or k new variables, where k is the number of categories of the outcome variable y_j. If you specify the outcome() option, you must specify one new variable. If you specify one new variable and do not specify outcome(), outcome(#1) is assumed.
When outcome() is specified, the marginal probability that y_j is equal to the level outcome() is calculated. When outcome() is not specified, the marginal probabilities for each outcome level are calculated.
p1 calculates the predicted bivariate probabilities of outcome levels with selection.
You specify one or k new variables, where k is the number of categories of the outcome variable y_j. If you specify the outcome() option, you must specify one new variable. If you specify one new variable and do not specify outcome(), outcome(#1) is assumed.
```
When `outcome()` is specified, the bivariate probability that $y_j$ is equal to the level `outcome()` and that $y_j$ is observed is calculated. When `outcome()` is not specified, the bivariate probabilities for each outcome level and selection are calculated.

`p0` calculates the predicted bivariate probabilities of outcome levels with no selection.

You specify one or $k$ new variables, where $k$ is the number of categories of the outcome variable $y_j$. If you specify the `outcome()` option, you must specify one new variable. If you specify one new variable and do not specify `outcome()`, `outcome(#1)` is assumed.

When `outcome()` is specified, the bivariate probability that $y_j$ is equal to the level `outcome()` and that $y_j$ is not observed is calculated. When `outcome()` is not specified, the bivariate probabilities for each outcome level and no selection are calculated.

`pcond1` calculates the predicted probabilities of outcome levels conditional on selection.

You specify one or $k$ new variables, where $k$ is the number of categories of the outcome variable $y_j$. If you specify the `outcome()` option, you must specify one new variable. If you specify one new variable and do not specify `outcome()`, `outcome(#1)` is assumed.

When `outcome()` is specified, the probability that $y_j$ is equal to the level `outcome()` given that $y_j$ is observed is calculated. When `outcome()` is not specified, the probabilities for each outcome level conditional on selection are calculated.

`pcond0` calculates the predicted probabilities of outcome levels conditional on no selection.

You specify one or $k$ new variables, where $k$ is the number of categories of the outcome variable $y_j$. If you specify the `outcome()` option, you must specify one new variable. If you specify one new variable and do not specify `outcome()`, `outcome(#1)` is assumed.

When `outcome()` is specified, the probability that $y_j$ is equal to the level `outcome()` given that $y_j$ is not observed is calculated. When `outcome()` is not specified, the probabilities for each outcome level conditional on no selection are calculated.

`psel` calculates the predicted univariate (marginal) probability of selection.

`xb` calculates the linear prediction for outcome variable, which is $x_j \beta$ if `offset()` was not specified and $x_j \beta + \text{offset}_j \gamma$ if `offset()` was specified.

`stdp` calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`xbsel` calculates the linear prediction for the selection equation, which is $z_j \gamma$ if `offset()` was not specified in `select()` and $z_j \gamma + \text{offset}_j \gamma$ if `offset()` was specified in `select()`.

`stdpsel` calculates the standard error of the linear prediction for the selection equation.

`outcome(outcome)` specifies for which outcome the predicted probabilities are to be calculated. `outcome()` should contain either one value of the dependent variable or one of #1, #2, ..., with #1 meaning the first category of the dependent variable, #2 meaning the second category, etc.

`noffset` is relevant only if you specified `offset(varname)` for `heckoprobit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_j$. 
scores calculates equation-level score variables.

The first new variable will contain $\frac{\partial \ln L}{\partial (x_j \beta)}$.

The second new variable will contain $\frac{\partial \ln L}{\partial (z_j \gamma)}$.

When the dependent variable takes $k$ different values, new variables three through $k + 1$ will contain $\frac{\partial \ln L}{\partial (\kappa_j - 2)}$.

The last new variable will contain $\frac{\partial \ln L}{\partial (\text{atanh} \rho)}$.

Remarks and examples

Example 1

In example 1 of [R] heckoprobit, we examined a simulated dataset of 5,000 women, 3,480 of whom work and can thus report job satisfaction. Using job satisfaction (satisfaction) as the outcome variable and employment (work) as the selection variable, we estimated the parameters of an ordered probit sample-selection model. Covariates age (age), years of education (education), number of children (children), and marital status (married) are expected to affect selection. The outcome, job satisfaction, is affected by age (age) and education (education).

We first reestimate the parameters of the regression, but this time we request a robust variance estimator:

```
. use http://www.stata-press.com/data/r13/womensat
(Job satisfaction, female)
. heckoprobit satisfaction education age,
> select(work=education age i.married##c.children) vce(robust)
(output omitted)
```

We then use margins (see [R] margins) to estimate the average marginal effect of education on the probability of having low job satisfaction.

```
. margins, dydx(education) vce(unconditional)
Average marginal effects Number of obs = 5000
Expression : Pr(satisfaction=1), predict()
dy/dx w.r.t. : education

<table>
<thead>
<tr>
<th>Unconditional</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>dy/dx</td>
<td>Std. Err.</td>
</tr>
<tr>
<td>education</td>
<td>-.0234776</td>
</tr>
<tr>
<td>z</td>
<td>-12.24</td>
</tr>
<tr>
<td>P&gt;</td>
<td>z</td>
</tr>
<tr>
<td>[95% Conf. Interval]</td>
<td></td>
</tr>
<tr>
<td>-.027236</td>
<td>-.0197192</td>
</tr>
</tbody>
</table>
```

The estimated average marginal effect of education on the probability of having low job satisfaction is approximately $-0.023$.

Methods and formulas

The ordinal outcome equation is

$$y_j = \sum_{h=1}^{H} v_h 1(\kappa_{h-1} < x_j \beta + u_{1j} \leq \kappa_h)$$
where $x_j$ is the outcome covariates, $\beta$ is the coefficients, and $u_{1j}$ is a random-error term. The observed outcome values $v_1, \ldots, v_H$ are integers such that $v_i < v_m$ for $i < m$. $\kappa_1, \ldots, \kappa_{H-1}$ are real numbers such that $\kappa_i < \kappa_m$ for $i < m$. $\kappa_0$ is taken as $-\infty$ and $\kappa_H$ is taken as $+\infty$.

The selection equation is

$$ s_j = 1(z_j\gamma + u_{2j} > 0) $$

where $s_j = 1$ if we observed $y_j$ and 0 otherwise, $z_j$ is the covariates used to model the selection process, $\gamma$ is the coefficients for the selection process, and $u_{2j}$ is a random-error term.

$(u_{1j}, u_{2j})$ have bivariate normal distribution with mean zero and variance matrix

$$
\begin{bmatrix}
1 & \rho \\
\rho & 1
\end{bmatrix}
$$

The probability of selection is

$$ \Pr(s_j = 1) = \Phi(z_j\gamma + \text{offset}_j) \Phi(\cdot) \text{ is the standard cumulative normal distribution function.} $$

The probability of selection and the outcome $y_j = v_h$ is

$$ \Pr(y_j = v_h, s_j = 1) = \Phi_2(z_j\gamma + \text{offset}_j, \kappa_h - x_j\beta - \text{offset}_j, -\rho) - \Phi_2(z_j\gamma + \text{offset}_j, \kappa_{h-1} - x_j\beta - \text{offset}_j, -\rho) \Phi_2(\cdot) \text{ is the cumulative bivariate normal distribution function (with mean } [0 0]' \text{).} $$

The probability of $y_j$ not being selected and the outcome $y_j = v_h$ is

$$ \Pr(y_j = v_h, s_j = 0) = \Phi_2(-z_j\gamma - \text{offset}_j, \kappa_h - x_j\beta - \text{offset}_j, \rho) - \Phi_2(-z_j\gamma - \text{offset}_j, \kappa_{h-1} - x_j\beta - \text{offset}_j, \rho) $$

The probability of outcome $y_j = v_h$ given selection is

$$ \Pr(y_j = v_h|s_j = 1) = \frac{\Pr(y_j = v_h, s_j = 1)}{\Pr(s_j = 1)} $$

The probability of outcome $y_j = v_h$ given $y_j$ is not selected is

$$ \Pr(y_j = v_h|s_j = 0) = \frac{\Pr(y_j = v_h, s_j = 0)}{\Pr(s_j = 0)} $$

The marginal probabilities of the outcome $y_j$ are

$$ \Pr(y_j = v_1) = \Phi(\kappa_1 - x_j\beta - \text{offset}_j) $$
$$ \Pr(y_j = v_H) = 1 - \Phi(\kappa_{H-1} - x_j\beta - \text{offset}_j) $$
$$ \Pr(y_j = v_H) = \Phi(\kappa_h - x_j\beta - \text{offset}_j) - \Phi(\kappa_{h-1} - x_j\beta - \text{offset}_j) $$

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

`vce()`, first, nokip, and weights are not allowed with the svy prefix; see [SVY] svy.

`pweights`, `fweights`, and `iweights` are allowed; see [U] 11.1.6 weight.

`coeflegend` does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
heckprobit fits maximum-likelihood probit models with sample selection.

heckprob is a synonym for heckprobit.

Options

Model

`select([ depvar_s = ] varlist[, noconstant offset(varname_o) ])` specifies the variables and options for the selection equation. It is an integral part of specifying a selection model and is required. The selection equation should contain at least one variable that is not in the outcome equation.

If `depvar_s` is specified, it should be coded as 0 or 1, 0 indicating an observation not selected and 1 indicating a selected observation. If `depvar_s` is not specified, observations for which `depvar_s` is not missing are assumed selected, and those for which `depvar_s` is missing are assumed not selected.

`noconstant` suppresses the selection constant term (intercept).

`offset(varname_o)` specifies that selection offset `varname_o` be included in the model with the coefficient constrained to be 1.

`noconstant, offset(varname), constraints(constraints), collinear; see [R] estimation options`.

SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting

`level(#); see [R] estimation options`.

`first` specifies that the first-step probit estimates of the selection equation be displayed before estimation.

`noskip` specifies that a full maximum-likelihood model with only a constant for the regression equation be fit. This model is not displayed but is used as the base model to compute a likelihood-ratio test for the model test statistic displayed in the estimation header. By default, the overall model test statistic is an asymptotically equivalent Wald test that all the parameters in the regression equation are zero (except the constant). For many models, this option can substantially increase estimation time.

`nocnsreport; see [R] estimation options`.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, noflabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.
Maximization

\[ \text{maximize} \]

\[ \text{options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, } \]
\[ \text{gradient, showstep, hessian, showtolerance, tolerance(\#), } \]
\[ \text{ltolerance(\#), nrtolerance(\#), nonrtolerance, and from(init_specs); see [R] maximize. These options are } \]
\[ \text{seldom used.} \]

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following option is available with heckprobit but is not shown in the dialog box:
\[ \text{coeflegend; see [R] estimation options.} \]

### Remarks and examples

The probit model with sample selection (Van de Ven and Van Pragg 1981) assumes that there exists an underlying relationship

\[ y^*_j = x_j \beta + u_1 \]

such that we observe only the binary outcome

\[ y_{j}^{\text{probit}} = (y^*_j > 0) \]

The dependent variable, however, is not always observed. Rather, the dependent variable for observation \( j \) is observed if

\[ y_{j}^{\text{select}} = (z_j \gamma + w_2j > 0) \]

where

\[ u_1 \sim N(0,1) \]
\[ u_2 \sim N(0,1) \]
\[ \text{corr}(u_1, u_2) = \rho \]

When \( \rho \neq 0 \), standard probit techniques applied to the first equation yield biased results. heckprobit provides consistent, asymptotically efficient estimates for all the parameters in such models.

For the model to be well identified, the selection equation should have at least one variable that is not in the probit equation. Otherwise, the model is identified only by functional form, and the coefficients have no structural interpretation.

#### Example 1

We use the data from Pindyck and Rubinfeld (1998). In this dataset, the variables are whether children attend private school (private), number of years the family has been at the present residence (years), log of property tax (logptax), log of income (loginc), and whether one voted for an increase in property taxes (vote).

In this example, we alter the meaning of the data. Here we assume that we observe whether children attend private school only if the head of household voted for increasing the property taxes. This assumption is not true in the dataset, and we make it only to illustrate the use of this command.

We observe whether children attend private school only if the head of household voted for an increase in property taxes. We assume that the vote is affected by the number of years in residence, the current property taxes paid, and the household income. We wish to model whether children are sent to private school on the basis of the number of years spent in the current residence and the current property taxes paid.
The output shows several iteration logs. The first iteration log corresponds to running the probit model for those observations in the sample where we have observed the outcome. The second iteration log corresponds to running the selection probit model, which models whether we observe our outcome of interest. If $\rho = 0$, the sum of the log likelihoods from these two models will equal the log likelihood of the probit model with sample selection; this sum is printed in the iteration log as the comparison log likelihood. The third iteration log shows starting values for the iterations.
The final iteration log is for fitting the full probit model with sample selection. A likelihood-ratio test of the log likelihood for this model and the comparison log likelihood is presented at the end of the output. If we had specified the `vce(robust)` option, this test would be presented as a Wald test instead of as a likelihood-ratio test.

Example 2

In example 1, we could have obtained robust standard errors by specifying the `vce(robust)` option. We do this here and also eliminate the iteration logs by using the `nolog` option:

```
. heckprob private years logptax, sel(vote=years loginc logptax) vce(robust) nolog
```

```
Probit model with sample selection
Number of obs = 95
Censored obs = 36
Uncensored obs = 59
Wald chi2(2) = 2.55
Log pseudolikelihood = -74.24497 Prob > chi2 = 0.2798

Robust

| rho     | -.6994973 | .8327753  | -0.83 | 0.411| -.9994079  .981233   |

Wald test of indep. eqns. (rho = 0): chi2(1) = 0.28  Prob > chi2 = 0.5952

Regardless of whether we specify the `vce(robust)` option, the outcome is not significantly different from the outcome obtained by fitting the probit and selection models separately. This result is not surprising because the selection mechanism estimated was invented for the example rather than borne from any economic theory.
## Stored results

`heckprobit` stores the following in `e()`:

### Scalars

- `e(N)` number of observations
- `e(N_cens)` number of censored observations
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_aux)` number of auxiliary parameters
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(ll_c)` log likelihood, comparison model
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(chi2_c)` $\chi^2$ for comparison test
- `e(p_c)` $p$-value for comparison test
- `e(p)` significance of comparison test
- `e(rho)` $\rho$
- `e(rank)` rank of `e(V)`
- `e(rank0)` rank of `e(V)` for constant-only model
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

### Macros

- `e(cmd)` `heckprobit`
- `e(cmdline)` command as typed
- `e(depvar)` names of dependent variables
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(offset1)` offset for regression equation
- `e(offset2)` offset for selection equation
- `e(chi2type)` Wald or LR; type of model $\chi^2$ test
- `e(chi2_ct)` type of comparison $\chi^2$ test
- `e(vce)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` `max` or `min`: whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of ml method
- `e(user)` name of likelihood-evaluator program
- `e(technique)` maximization technique
- `e(properties)` `b V`
- `e(predict)` program used to implement `predict`
- `e(asbalanced)` factor variables fvset as `asbalanced`
- `e(asobserved)` factor variables fvset as `asobserved`

### Matrices

- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(ilog)` iteration log (up to 20 iterations)
- `e(gradient)` gradient vector
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

### Functions

- `e(sample)` marks estimation sample
Methods and formulas

Van de Ven and Van Pragg (1981) provide an introduction and an explanation of this model. The probit equation is

\[ y_j = (x_j \beta + u_{1j} > 0) \]

The selection equation is

\[ z_j \gamma + u_{2j} > 0 \]

where

\[ u_1 \sim N(0, 1) \]
\[ u_2 \sim N(0, 1) \]
\[ \text{corr}(u_1, u_2) = \rho \]

The log likelihood is

\[
\ln L = \sum_{j \in S, y_j \neq 0} w_j \ln \left\{ \Phi_2 \left( x_j \beta + \text{offset}_j \beta, z_j \gamma + \text{offset}_j \gamma, \rho \right) \right\} \\
+ \sum_{j \in S, y_j = 0} w_j \ln \left\{ \Phi_2 \left( -x_j \beta + \text{offset}_j \beta, z_j \gamma + \text{offset}_j \gamma, -\rho \right) \right\} \\
+ \sum_{j \not\in S} w_j \ln \left\{ 1 - \Phi \left( z_j \gamma + \text{offset}_j \gamma \right) \right\}
\]

where \( S \) is the set of observations for which \( y_j \) is observed, \( \Phi_2(\cdot) \) is the cumulative bivariate normal distribution function (with mean \([0 \ 0]\)'), \( \Phi(\cdot) \) is the standard cumulative normal, and \( w_j \) is an optional weight for observation \( j \).

In the maximum likelihood estimation, \( \rho \) is not directly estimated. Directly estimated is \( \text{atanh} \rho \):

\[
\text{atanh} \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)
\]

From the form of the likelihood, it is clear that if \( \rho = 0 \), the log likelihood for the probit model with sample selection is equal to the sum of the probit model for the outcome \( y \) and the selection model. We can perform a likelihood-ratio test by comparing the likelihood of the full model with the sum of the log likelihoods for the probit and selection models.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \texttt{[P] _robust}, particularly \texttt{Maximum likelihood estimators} and \texttt{Methods and formulas}.

\texttt{heckprobit} also supports estimation with survey data. For details on VCEs with survey data, see \texttt{[SVY] variance estimation}.

where \( \Phi(\cdot) \) is the standard normal distribution function and \( \Phi_2(\cdot) \) is the bivariate normal distribution function.

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

- **pmargin**, the default, calculates the univariate (marginal) predicted probability of success \( \Pr(y_j^{\text{probit}} = 1) \).
- **p11** calculates the bivariate predicted probability \( \Pr(y_j^{\text{probit}} = 1, y_j^{\text{select}} = 1) \).
- **p10** calculates the bivariate predicted probability \( \Pr(y_j^{\text{probit}} = 1, y_j^{\text{select}} = 0) \).
- **p01** calculates the bivariate predicted probability \( \Pr(y_j^{\text{probit}} = 0, y_j^{\text{select}} = 1) \).
- **p00** calculates the bivariate predicted probability \( \Pr(y_j^{\text{probit}} = 0, y_j^{\text{select}} = 0) \).
- **psel** calculates the univariate (marginal) predicted probability of selection \( \Pr(y_j^{\text{select}} = 1) \).
- **pcond** calculates the conditional (on selection) predicted probability of success \( \Pr(y_j^{\text{probit}} = 1, y_j^{\text{select}} = 1) / \Pr(y_j^{\text{select}} = 1) \).
- **xb** calculates the probit linear prediction \( x_j b \).
stdp calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

xbsel calculates the linear prediction for the selection equation.

stdpsel calculates the standard error of the linear prediction for the selection equation.

nooffset is relevant only if you specified offset(varname) for heckprobit. It modifies the calculations made by predict so that they ignore the offset variable; the linear prediction is treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_j$.

scores calculates equation-level score variables.

The first new variable will contain $\partial \ln L / \partial (x_j \beta)$. The second new variable will contain $\partial \ln L / \partial (z_j \gamma)$. The third new variable will contain $\partial \ln L / \partial (\text{atanh} \rho)$.

Remarks and examples

Example 1

It is instructive to compare the marginal predicted probabilities with the predicted probabilities that we would obtain by ignoring the selection mechanism. To compare the two approaches, we will synthesize data so that we know the “true” predicted probabilities.

First, we need to generate correlated error terms, which we can do using a standard Cholesky decomposition approach. For our example, we will clear any data from memory and then generate errors that have a correlation of 0.5 by using the following commands. We set the seed so that interested readers can type in these same commands and obtain the same results.

```
.set seed 12309
.set obs 5000
.obs was 0, now 5000
gen c1 = rnormal()
gen c2 = rnormal()
.matrix P = (1,.5\.5,1)
.matrix A = cholesky(P)
.local fac1 = A[2,1]
.local fac2 = A[2,2]
gen u1 = c1
gen u2 = 'fac1'*c1 + 'fac2'*c2
```

We can check that the errors have the correct correlation by using the `correlate` command. We will also normalize the errors so that they have a standard deviation of one, so we can generate a bivariate probit model with known coefficients. We do that with the following commands:
. correlate u1 u2  
      (obs=5000)  
      u1 u2  
      u1  1.0000  
      u2  0.5020  1.0000  

. summarize u1  
      (output omitted)  
. replace u1 = u1/r(sd)  
      (5000 real changes made)  
. summarize u2  
      (output omitted)  
. replace u2 = u2/r(sd)  
      (5000 real changes made)  
. drop c1 c2  
. gen x1 = runiform()-0.5  
. gen x2 = runiform()+1/3  
. gen y1s = 0.5 + 4*x1 + u1  
. gen y2s = 3 - 3*x2 + 0.5*x1 + u2  
. gen y1 = (y1s>0)  
. gen y2 = (y2s>0)  

We have now created two dependent variables, y1 and y2, which are defined by our specified coefficients. We also included error terms for each equation, and the error terms are correlated. We run heckprobit to verify that the data have been correctly generated according to the model:

\[ y_1 = 0.5 + 4x_1 + u_1 \]
\[ y_2 = 3 - 3x_2 + 0.5x_1 + u_2 \]

where we assume that \( y_1 \) is observed only if \( y_2 = 1 \).

. heckprobit y1 x1, sel(y2 = x1 x2) nolog  
Probit model with sample selection
Number of obs = 5000  
Censored obs = 1762  
Uncensored obs = 3238  
Wald chi2(1) = 953.71  
Log likelihood = -3679.5  
Prob > chi2 = 0.0000  

|             | Coef. | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|-------------|-------|-----------|------|------|----------------------|
| y1          |       |           |      |      |                      |

| /athrho     | 0.5186232 | 0.083546 | 6.21 | 0.000 | 0.354876 - 0.6823705 |
| rho         | 0.4766367 | 0.064568 |      |      | 0.3406927 - 0.6530583 |

LR test of indep. eqns. (rho = 0): chi2(1) = 40.43  Prob > chi2 = 0.0000
Now that we have verified that we have generated data according to a known model, we can obtain and then compare predicted probabilities from the probit model with sample selection and a (usual) probit model.

```stata
. predict pmarg
   (option pmargin assumed; Pr(y1=1))
. probit y1 x1 if y2==1
   (output omitted)
. predict phat
   (option pr assumed; Pr(y1))
```

Using the (marginal) predicted probabilities from the probit model with sample selection (pmarg) and the predicted probabilities from the (usual) probit model (phat), we can also generate the “true” predicted probabilities from the synthesized y1s variable and then compare the predicted probabilities:

```stata
. gen ptrue = normal(y1s)
. summarize pmarg ptrue phat
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>pmarg</td>
<td>5000</td>
<td>.6071226</td>
<td>.3147861</td>
<td>.0766334</td>
<td>.9907113</td>
</tr>
<tr>
<td>ptrue</td>
<td>5000</td>
<td>.5974195</td>
<td>.348396</td>
<td>5.53e-06</td>
<td>.9999999</td>
</tr>
<tr>
<td>phat</td>
<td>5000</td>
<td>.6568175</td>
<td>.3025085</td>
<td>.1059824</td>
<td>.9954919</td>
</tr>
</tbody>
</table>

Here we see that ignoring the selection mechanism (comparing the phat variable with the true ptrue variable) results in predicted probabilities that are much higher than the true values. Looking at the marginal predicted probabilities from the model with sample selection, however, results in more accurate predictions.

[U] 20 Estimation and postestimation commands
help — Display help in Stata

Syntax

\[ \text{help } [\text{command\_or\_topic\_name}] [\text{, new name(viewername)} \text{ marker(markername)}] \]

Menu

Help > Stata Command...

Description

The help command displays help information about the specified command or topic.

Stata for Mac, Stata for Unix(GUI), and Stata for Windows:
help launches a new Viewer to display help for the specified command or topic. If help is not followed by a command or a topic name, Stata launches the Viewer and displays help help\_advice, advice for using the help system and documentation.

Help may be accessed either by selecting Help > Stata Command... and filling in the desired command name or by typing help followed by a command or topic name.

Stata for Unix(console):
Typing help followed by a command name or a topic name will display help on the console.
If help is not followed by a command or a topic name, a description of how to use the help system is displayed.

Options

new specifies that a new Viewer window not be opened for the help topic if a Viewer window is already open. The default is for a new Viewer window to be opened each time help is typed so that multiple help files may be viewed at once. new causes the help file to be displayed in the topmost open Viewer.

name(viewername) specifies that help be displayed in a Viewer window named viewername. If the named window already exists, its contents will be replaced. If the named window does not exist, it will be created.

marker(markername) specifies that the help file be opened to the position of markername within the help file.

Remarks and examples

To obtain help for any Stata command, type help command or select Help > Stata Command... and fill in command.
help is best explained by examples.

To obtain help for ...

- `regress`  
  postestimation tools for `regress`  
  `graph option xlabel()`  
  `Stata function strpos()`  
  `Mata function optimize()`

Tips:

- `help` displays advice for using the help system and documentation.
- `help guide` displays a table of contents for basic Stata concepts.
- `help estimation commands` displays an alphabetical listing of all Stata estimation commands.
- `help functions` displays help on Stata functions by category.
- `help mata functions` displays a subject table of contents for Mata’s functions.
- `help ts glossary` displays the glossary for the time-series manual, and similarly for the other Stata specialty manuals.

If you type `help topic` and help for `topic` is not found, Stata will automatically perform a search for `topic`.

For instance, try typing `help forecasting`. A forecasting help file is not found, so Stata executes `search forecasting` and displays the results in the Viewer.

See [U] 4 Stata’s help and search facilities for a complete description of how to use `help`.

Technical note

When you type `help topic`, Stata first looks along the adopath for `topic.sthlp`; see [U] 17.5 Where does Stata look for ado-files?.

*het() is required. The full specification is `het(varlist [, offset(varname_o) ] )`.
`indepvars` and `varlist` may contain factor variables; see [U] 11.4.3 Factor variables.
`depvar`, `indepvars`, and `varlist` may contain time-series operators; see [U] 11.4.4 Time-series varlists.
`bootstrap`, `by`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] 11.1.10 Prefix commands.
Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap.
`vce()`, `noskip`, and weights are not allowed with the `svy` prefix; see [SVY] svy.
`fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 weight.
`coeflegend` does not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
hetprobit — Heteroskedastic probit model

Menu
Statistics > Binary outcomes > Heteroskedastic probit regression

Description

hetprobit fits a maximum-likelihood heteroskedastic probit model.
hetprob is a synonym for hetprobit.
See [R] logistic for a list of related estimation commands.

Options

Model

het(varlist [, offset(varname_o)]) specifies the independent variables and the offset variable, if there is one, in the variance function. het() is required.

offset(varname_o) specifies that selection offset varname_o be included in the model with the coefficient constrained to be 1.

noconstant, offset(varname): see [R] estimation options.

asis forces the retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see [R] probit.

constraints(constraints), collinear; see [R] estimation options.

SE/Robust

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting

level(#); see [R] estimation options.

noskip requests fitting of the constant-only model and calculation of the corresponding likelihood-ratio $\chi^2$ statistic for testing significance of the full model. By default, a Wald $\chi^2$ statistic is computed for testing the significance of the full model.

nolrtest specifies that a Wald test of whether $\ln\sigma^2 = 0$ be performed instead of the LR test.

nocnsreport; see [R] estimation options.

display_options: nomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).
The following option is available with `hetprobit` but is not shown in the dialog box: `coeflegend`; see \[R\] estimation options.

**Remarks and examples**

Remarks are presented under the following headings:

- Introduction
- Robust standard errors

**Introduction**

`hetprobit` fits a maximum-likelihood heteroskedastic probit model, which is a generalization of the probit model. Let \( y_j, j = 1, \ldots, N \), be a binary outcome variable taking on the value 0 (failure) or 1 (success). In the probit model, the probability that \( y_j \) takes on the value 1 is modeled as a nonlinear function of a linear combination of the \( k \) independent variables \( x_j = (x_{1j}, x_{2j}, \ldots, x_{kj}) \),

\[
\Pr(y_j = 1) = \Phi(x_j \beta)
\]

in which \( \Phi() \) is the cumulative distribution function (CDF) of a standard normal random variable, that is, a normally distributed (Gaussian) random variable with mean 0 and variance 1. The linear combination of the independent variables, \( x_j \beta \), is commonly called the index function, or index. Heteroskedastic probit generalizes the probit model by generalizing \( \Phi() \) to a normal CDF with a variance that is no longer fixed at 1 but can vary as a function of the independent variables. `hetprobit` models the variance as a multiplicative function of these \( m \) variables \( z_j = (z_{1j}, z_{2j}, \ldots, z_{mj}) \), following Harvey (1976):

\[
\sigma_j^2 = \{\exp(z_j \gamma)\}^2
\]

Thus the probability of success as a function of all the independent variables is

\[
\Pr(y_j = 1) = \Phi\left\{x_j \beta / \exp(z_j \gamma)\right\}
\]

From this expression, it is clear that, unlike the index \( x_j \beta \), no constant term can be present in \( z_j \gamma \) if the model is to be identifiable.

Suppose that the binary outcomes \( y_j \) are generated by thresholding an unobserved random variable, \( w \), which is normally distributed with mean \( x_j \beta \) and variance 1 such that

\[
y_j = \begin{cases} 
1 & \text{if } w_j > 0 \\
0 & \text{if } w_j \leq 0 
\end{cases}
\]

This process gives the probit model:

\[
\Pr(y_j = 1) = \Pr(w_j > 0) = \Phi(x_j \beta)
\]

Now suppose that the unobserved \( w_j \) are heteroskedastic with variance

\[
\sigma_j^2 = \{\exp(z_j \gamma)\}^2
\]

Relaxing the homoskedastic assumption of the probit model in this manner yields our multiplicative heteroskedastic probit model:

\[
\Pr(y_j = 1) = \Phi\left\{x_j \beta / \exp(z_j \gamma)\right\}
\]
Example 1

For this example, we generate simulated data for a simple heteroskedastic probit model and then estimate the coefficients with *hetprobit*:

```
. set obs 1000
obs was 0, now 1000
. set seed 1234567
. gen x = 1-2*runiform()
. gen xhet = runiform()
. gen sigma = exp(1.5*xhet)
. gen p = normal((0.3+2*x)/sigma)
. gen y = cond(runiform()<=p,1,0)
. hetprob y x, het(xhet)
```

Heteroskedastic probit model

Number of obs = 1000
Zero outcomes = 452
Nonzero outcomes = 548
Wald chi2(1) = 78.66
Log likelihood = -569.4783
Prob > chi2 = 0.0000

|       | Coef.   | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|-------|---------|-----------|-------|-----|----------------------|
| y     |         |           |       |     |                      |
| x     | 2.228031| 0.2512073 | 8.87  | 0.000| 1.735673 to 2.720388  |
| _cons| 0.2493822| 0.0862833 | 2.89  | 0.004| 0.08027 to 0.4184943  |
| lnsigma2 | 1.602537 | 0.2640131 | 6.07  | 0.000| 1.085081 to 2.119993  |

Likelihood-ratio test of lnsigma2=0: chi2(1) = 44.06
Prob > chi2 = 0.0000

Above we created two variables, x and xhet, and then simulated the model

\[
\Pr(y = 1) = F\left\{ \frac{(\beta_0 + \beta_1 x)}{\exp(\gamma_1 xhet)} \right\}
\]

for \(\beta_0 = 0.3, \beta_1 = 2, \) and \(\gamma_1 = 1.5\). According to *hetprobit*’s output, all coefficients are significant, and, as we would expect, the Wald test of the full model versus the constant-only model—for example, the index consisting of \(\beta_0 + \beta_1 x\) versus that of just \(\beta_0\)—is significant with \(\chi^2(1) = 79\). Likewise, the likelihood-ratio test of heteroskedasticity, which tests the full model with heteroskedasticity against the full model without, is significant with \(\chi^2(1) = 44\). See [R] maximize for more explanation of the output. For this simple model, *hetprobit* took five iterations to converge. As stated elsewhere (Greene 2012, 714), this is a difficult model to fit, and it is not uncommon for it to require many iterations or for the optimizer to print out warnings and informative messages during the optimization. Slow convergence is especially common for models in which one or more of the independent variables appear in both the index and variance functions.
Technical note

Stata interprets a value of 0 as a negative outcome (failure) and treats all other values (except missing) as positive outcomes (successes). Thus if your dependent variable takes on the values 0 and 1, then 0 is interpreted as failure and 1 as success. If your dependent variable takes on the values 0, 1, and 2, then 0 is still interpreted as failure, but both 1 and 2 are treated as successes.

Robust standard errors

If you specify the `vce(robust)` option, `hetprobit` reports robust standard errors as described in [U] 20.21 Obtaining robust variance estimates. To illustrate the effect of this option, we will reestimate our coefficients by using the same model and data in our example, this time adding `vce(robust)` to our `hetprobit` command.

Example 2

```
. hetprobit y x, het(xhet) vce(robust) nolog
Heteroskedastic probit model
Number of obs = 1000
Zero outcomes = 452
Nonzero outcomes = 548
Wald chi2(1) = 65.23
Log pseudolikelihood = -569.4783 Prob > chi2 = 0.0000
Robust
Coef. Std. Err. z P>|z| [95% Conf. Interval]
y  x  2.22803  .2758597  8.08 0.000 1.687355 2.768705
   _cons .2493821  .0843367  2.96 0.003  .0840853  .4146789
   lnsigma2 xhet 1.602537  .2671326  6.00 0.000  1.078967  2.126107
Wald test of lnsigma2=0:  chi2(1) = 35.99 Prob > chi2 = 0.0000
```

The `vce(robust)` standard errors for two of the three parameters are larger than the previously reported conventional standard errors. This is to be expected, even though (by construction) we have perfect model specification because this option trades off efficient estimation of the coefficient variance–covariance matrix for robustness against misspecification.

Specifying the `vce(cluster clustvar)` option relaxes the usual assumption of independence between observations to the weaker assumption of independence just between clusters; that is, `hetprobit, vce(cluster clustvar)` is robust with respect to within-cluster correlation. This option is less efficient than the `xtgee` population-averaged models because `hetprobit` inefficiently sums within cluster for the standard-error calculation rather than attempting to exploit what might be assumed about the within-cluster correlation.
hetprobit stores the following in e():

Scalars
- e(N) number of observations
- e(N_f) number of zero outcomes
- e(N_s) number of nonzero outcomes
- e(k) number of parameters
- e(k_eq) number of equations in e(b)
- e(k_eq_model) number of equations in overall model test
- e(k_dv) number of dependent variables
- e(df_m) model degrees of freedom
- e(ll) log likelihood
- e(ll_0) log likelihood, constant-only model
- e(ll_c) log likelihood, comparison model
- e(N_clust) number of clusters
- e(chi2) \(\chi^2\) for heteroskedasticity LR test
- e(chi2_c) \(\chi^2\) for heteroskedasticity LR test
- e(p_c) \(p\)-value for heteroskedasticity LR test
- e(df_m_c) degrees of freedom for heteroskedasticity LR test
- e(p) significance
- e(rank) rank of e(V)
- e(rank0) rank of e(V) for constant-only model
- e(ic) number of iterations
- e(rc) return code
- e(converged) 1 if converged, 0 otherwise

Macros
- e(cmd) hetprobit
- e(cmdline) command as typed
- e(depvar) name of dependent variable
- e(wtype) weight type
- e(wexp) weight expression
- e(title) title in estimation output
- e(clustvar) name of cluster variable
- e(offset1) offset for probit equation
- e(offset2) offset for variance equation
- e(chi2type) Wald or LR; type of model \(\chi^2\) test
- e(chi2_ct) Wald or LR; type of model \(\chi^2\) test corresponding to e(chi2_c)
- e(vcetype) vcetype specified in vce()
- e(vcetitle) title used to label Std. Err.
- e(opt) type of optimization
- e(which) max or min; whether optimizer is to perform maximization or minimization
- e(method) requested estimation method
- e(ml_method) type of ml method
- e(user) name of likelihood-evaluator
- e(technique) maximization technique
- e(properties) b V
- e(predict) program used to implement predict
- e(asbalanced) factor variables fvset as asbalanced
- e(asobserved) factor variables fvset as asobserved

Matrices
- e(b) coefficient vector
- e(Cns) constraints matrix
- e(ilog) iteration log (up to 20 iterations)
- e(gradient) gradient vector
- e(V) variance–covariance matrix of the estimators
- e(V_modelbased) model-based variance

Functions
- e(sample) marks estimation sample
Methods and formulas

The heteroskedastic probit model is a generalization of the probit model because it allows the scale of the inverse link function to vary from observation to observation as a function of the independent variables.

The log-likelihood function for the heteroskedastic probit model is

\[
\ln L = \sum_{j \in S} w_j \ln \Phi \left( \frac{x_j \beta}{\exp(z \gamma)} \right) + \sum_{j \notin S} w_j \ln \left[ 1 - \Phi \left( \frac{x_j \beta}{\exp(z \gamma)} \right) \right]
\]

where \( S \) is the set of all observations \( j \) such that \( y_j \neq 0 \) and \( w_j \) denotes the optional weights. \( \ln L \) is maximized as described in [R] maximize.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \( \text{vce(robust)} \) and \( \text{vce(cluster clustvar)} \), respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

hetprobit also supports estimation with survey data. For details on VCEs with survey data, see [SVY] variance estimation.

1. `forecast` is not appropriate with `svy` estimation results.
2. `lrtest` is not appropriate with `svy` estimation results.
Syntax for predict

```
predict [type] newvar [if] [in] [ , statistic nooffset ]
```

```
predict [type] { stub* | newvar | newvar | ln sigma2 } [if] [in] , scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Main</td>
<td></td>
</tr>
<tr>
<td>pr</td>
<td>probability of a positive outcome; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>sigma</td>
<td>standard deviation of the error term</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

- **Main**
  - `pr`, the default, calculates the probability of a positive outcome.
  - `xb` calculates the linear prediction.
  - `sigma` calculates the standard deviation of the error term.
  - `nooffset` is relevant only if you specified `offset(varname)` for `hetprobit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as \( x_j b \) rather than as \( x_j b + \text{offset}_j \).
  - `scores` calculates equation-level score variables.
    - The first new variable will contain \( \partial \ln L / \partial (x_j \beta) \).
    - The second new variable will contain \( \partial \ln L / \partial (z_j \gamma) \).

Remarks and examples

Once you have fit a model, you can use the `predict` command to obtain the predicted probabilities for both the estimation sample and other samples; see [U] Estimation and postestimation commands and [R] predict. `predict` without arguments calculates the predicted probability of a positive outcome. With the `xb` option, `predict` calculates the index function combination, \( x_j b \), where \( x_j \) are the independent variables in the \( j \)th observation and \( b \) is the estimated parameter vector. With the `sigma` option, `predict` calculates the predicted standard deviation, \( \sigma_j = \exp(z_j \gamma) \).

Example 1

We use `predict` to compute the predicted probabilities and standard deviations based on the model in example 2 in [R] `hetprobit` to compare these with the actual values:
. predict phat
   (option pr assumed; Pr(y))
. gen diff_p = phat - p
. summarize diff_p

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>diff_p</td>
<td>1000</td>
<td>-.0107081</td>
<td>.0131869</td>
<td>-.0466331</td>
<td>.010482</td>
</tr>
</tbody>
</table>

. predict sigmahat, sigma
. gen diff_s = sigmahat - sigma
. summarize diff_s

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>diff_s</td>
<td>1000</td>
<td>.1558882</td>
<td>.1363698</td>
<td>.0000417</td>
<td>.4819107</td>
</tr>
</tbody>
</table>

### Menu

Graphics > Histogram

### Description

`histogram` draws histograms of `varname`, which is assumed to be the name of a continuous variable unless the `discrete` option is specified.

### Options for use in the continuous case

`bin(#)` and `width(#)` are alternatives. They specify how the data are to be aggregated into bins: `bin()` by specifying the number of bins (from which the width can be derived) and `width()` by specifying the bin width (from which the number of bins can be derived).

If neither option is specified, results are the same as if `bin(k)` had been specified, where

\[
  k = \min\left\{ \sqrt{N}, 10 \ln(N) / \ln(10) \right\}
\]

and where `N` is the (weighted) number of observations.

`start(#)` specifies the theoretical minimum of `varname`. The default is `start(m)`, where `m` is the observed minimum value of `varname`.
Specify `start()` when you are concerned about sparse data, for instance, if you know that `varname` can have a value of 0, but you are concerned that 0 may not be observed.

`start(#)`, if specified, must be less than or equal to `m`, or else an error will be issued.

**Options for use in the discrete case**

- `discrete` specifies that `varname` is discrete and that you want each unique value of `varname` to have its own bin (bar of histogram).
- `width(#)` is rarely specified in the discrete case; it specifies the width of the bins. The default is `width(d)`, where `d` is the observed minimum difference between the unique values of `varname`. Specify `width()` if you are concerned that your data are sparse. For example, in theory `varname` could take on the values, say, 1, 2, 3, ..., 9, but because of the sparseness, perhaps only the values 2, 4, 7, and 8 are observed. Here the default width calculation would produce `width(2)`, and you would want to specify `width(1)`.
- `start(#)` is also rarely specified in the discrete case; it specifies the theoretical minimum value of `varname`. The default is `start(m)`, where `m` is the observed minimum value.

As with `width()`, specify `start(#)` if you are concerned that your data are sparse. In the previous example, you might also want to specify `start(1)`. `start()` does nothing more than add white space to the left side of the graph.

The value of `#` in `start()` must be less than or equal to `m`, or an error will be issued.

**Options for use in the continuous and discrete cases**

- `density`, `fraction`, `frequency`, and `percent` specify whether you want the histogram scaled to density units, fractional units, frequencies, or percentages. `density` is the default.
  - `density` scales the height of the bars so that the sum of their areas equals 1.
  - `fraction` scales the height of the bars so that the sum of their heights equals 1.
  - `frequency` scales the height of the bars so that each bar’s height is equal to the number of observations in the category. Thus the sum of the heights is equal to the total number of observations.
  - `percent` scales the height of the bars so that the sum of their heights equals 100.
- `bar_options` are any of the options allowed by `graph twoway bar`; see [G-2] graph twoway bar.
  
  One of the most useful `bar_options` is `barwidth(#)`, which specifies the width of the bars in `varname` units. By default, `histogram` draws the bars so that adjacent bars just touch. If you want gaps between the bars, do not specify `histogram`’s `width()` option—which would change how the histogram is calculated—but specify the `bar_option` `barwidth()` or the `histogram` option `gap`, both of which affect only how the bar is rendered.

  The `bar_option` `horizontal` cannot be used with the `addlabels` option.

`addlabels` specifies that the top of each bar be labeled with the density, fraction, or frequency, as determined by the `density`, `fraction`, and `frequency` options.
addlabopts(marker_label_options) specifies how to render the labels atop the bars. See [G-3] marker_label_options. Do not specify the marker_label_option mlabel(varname), which specifies the variable to be used; this is specified for you by histogram.

addlabopts() will accept more options than those documented in [G-3] marker_label_options. All options allowed by twoway scatter are also allowed by addlabopts(); see [G-2] graph twoway scatter. One particularly useful option is yvarformat(); see [G-3] advanced_options.

---

Density plots

normal specifies that the histogram be overlaid with an appropriately scaled normal density. The normal will have the same mean and standard deviation as the data.

normopts(line_options) specifies details about the rendition of the normal curve, such as the color and style of line used. See [G-2] graph twoway line.

kdensity specifies that the histogram be overlaid with an appropriately scaled kernel density estimate of the density. By default, the estimate will be produced using the Epanechnikov kernel with an “optimal” half-width. This default corresponds to the default of kdensity; see [R] kdensity. How the estimate is produced can be controlled using the kdenopts() option described below.

kdenopts(kdensity_options) specifies details about how the kernel density estimate is to be produced along with details about the rendition of the resulting curve, such as the color and style of line used. The kernel density estimate is described in [G-2] graph twoway kdensity. As an example, if you wanted to produce kernel density estimates by using the Gaussian kernel with optimal half-width, you would specify kdenopts(gauss) and if you also wanted a half-width of 5, you would specify kdenopts(gauss width(5)).

---

Add plots

addplot(plot) allows adding more graph twoway plots to the graph; see [G-3] addplot_option.

---

Y axis, X axis, Titles, Legend, Overall, By

twoway_options are any of the options documented in [G-3] twoway_options. This includes, most importantly, options for titling the graph (see [G-3] title_options), options for saving the graph to disk (see [G-3] saving_option), and the by() option, which will allow you to simultaneously graph histograms for different subsets of the data (see [G-3] by_option).

Remarks and examples

Remarks are presented under the following headings:

Histories of continuous variables
Overlaying normal and kernel density estimates
Histories of discrete variables
Use with by()
Video example

For an example of editing a histogram with the Graph Editor, see Pollock (2011, 29–31).
Histograms of continuous variables

*histogram* assumes that the variable is continuous, so you need type only *histogram* followed by the variable name:

```
. use http://www.stata-press.com/data/r13/sp500
(S&P 500)
. histogram volume
(bin=15, start=4103, width=1280.3533)
```

The small values reported for density on the *y* axis are correct; if you added up the area of the bars, you would get 1. Nevertheless, many people are used to seeing histograms scaled so that the bar heights sum to 1,
and others are used to seeing histograms so that the bar height reflects the number of observations,

```
. histogram volume, frequency
(bin=15, start=4103, width=1280.3533)
```

Regardless of the scale you prefer, you can specify other options to make the graph look more impressive:
. summarize volume

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>volume</td>
<td>248</td>
<td>12320.68</td>
<td>2585.929</td>
<td>4103</td>
<td>23308.3</td>
</tr>
</tbody>
</table>

. histogram volume, freq
  > xaxis(1 2)
  > ylabel(0(10)60, grid)
  > xlabel(12321 "mean"
  > 9735 "-1 s.d."
  > 14907 "+1 s.d."
  > 7149 "-2 s.d."
  > 17493 "+2 s.d."
  > 20078 "+3 s.d."
  > 22664 "+4 s.d.
  > , axis(2) grid gmax)
  > xtitle("", axis(2))
  > subtitle("S&P 500, January 2001 - December 2001")
  > note("Source: Yahoo! Finance and Commodity Systems, Inc.")
  (bin=15, start=4103, width=1280.3533)

For an explanation of the xaxis() option—it created the upper and lower x axis—see [G-3] axis_choice_options. For an explanation of the ylabel() and xlabel() options, see [G-3] axis_label_options. For an explanation of the subtitle() and note() options, see [G-3] title_options.

Overlaying normal and kernel density estimates

Specifying normal will overlay a normal density over the histogram. It would be enough to type

. histogram volume, normal

but we will add the option to our more impressive rendition:

. summarize volume

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>volume</td>
<td>248</td>
<td>12320.68</td>
<td>2585.929</td>
<td>4103</td>
<td>23308.3</td>
</tr>
</tbody>
</table>
. histogram volume, freq normal
>   xaxis(1 2)
>   ylabel(0(10)60, grid)
>   xlabel(12321 "mean"
>   9735 "-1 s.d."
>   14907 "+1 s.d."
>   7149 "-2 s.d."
>   17493 "+2 s.d."
>   20078 "+3 s.d."
>   22664 "+4 s.d."
>   , axis(2) grid gmax)
>   xtitle("", axis(2))
>   subtitle("S&P 500, January 2001 - December 2001")
>   note("Source: Yahoo! Finance and Commodity Systems, Inc.")
(bin=15, start=4103, width=1280.3533)

If we instead wanted to overlay a kernel density estimate, we could specify `kdensity` in place of `normal`.

**Histograms of discrete variables**

Specify `histogram`'s discrete option when you wish to treat the data as discrete—when you wish each unique value of the variable to be assigned its own bin. For instance, in the automobile data, `mpg` is a continuous variable, but the mileage ratings have been measured to integer precision. If we were to type

```
. use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
. histogram mpg
(bin=8, start=12, width=3.625)
```

`mpg` would be treated as continuous and categorized into eight bins by the default number-of-bins calculation, which is based on the number of observations, 74.
Adding the `discrete` option makes a histogram with a bin for each of the 21 unique values.

```
. histogram mpg, discrete
    (start=12, width=1)
```

Just as in the continuous case, the $y$ axis was reported in density, and we could specify the `fraction` or `frequency` options if we wanted it to be reported differently. Below we specify `frequency`, we specify `addlabels` to add a report of frequencies printed above the bars, we specify `ylabel(,grid)` to add horizontal grid lines, and we specify `xlabel(12(2)42)` to label the values 12, 14, ..., 42 on the $x$ axis:

```
. histogram mpg, discrete freq addlabels ylabel(,grid) xlabel(12(2)42)
    (start=12, width=1)
```
Use with by()

histogram may be used with graph twoway’s by(); for example,

```stata
use http://www.stata-press.com/data/r13/auto
(1978 Automobile Data)
histogram mpg, discrete by(foreign)
```

Here results would be easier to compare if the graphs were presented in one column:

```stata
histogram mpg, discrete by(foreign, col(1))
```

```
col(1) is a by() suboption—see [G-3] by_option—and there are other useful suboptions, such as total, which will add an overall total histogram. total is a suboption of by(), not an option of histogram, so you would type

```stata
histogram mpg, discrete by(foreign, total)
```

and not histogram mpg, discrete by(foreign) total.

```
. use http://www.stata-press.com/data/r13/voter
. histogram candi [freq=pop], discrete fraction by(inc, total)
> gap(40) xlabel(2 3 4, valuelabel)
```

We specified `gap(40)` to reduce the width of the bars by 40%. We also used `xlabel()`’s `valuelabel` suboption, which caused our bars to be labeled “Clinton”, “Bush”, and “Perot”, rather than 2, 3, and 4; see [G-3] `axis_label_options`.

**Menu**

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Intraclass correlations

**Description**

icc estimates intraclass correlations for one-way random-effects models, two-way random-effects models, or two-way mixed-effects models for both individual and average measurements. Intraclass correlations measuring consistency of agreement or absolute agreement of the measurements may be estimated.

**Options for one-way RE model**

- **Main**
  - absolute specifies that intraclass correlations measuring absolute agreement of the measurements be estimated. This is the default for random-effects models.
  - testvalue(#) tests whether intraclass correlations equal #. The default is testvalue(0).

- **Reporting**
  - level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [R] level.
  - format(%fmt) specifies how the intraclass correlation estimates and confidence intervals are to be formatted. The default is format(%9.0g).
Options for two-way RE and ME models

mixed is required to calculate two-way mixed-effects models. mixed specifies that intraclass correlations for a mixed-effects model be estimated.

absolute specifies that intraclass correlations measuring absolute agreement of the measurements be estimated. This is the default for random-effects models. Only one of absolute or consistency may be specified.

consistency specifies that intraclass correlations measuring consistency of agreement of the measurements be estimated. This is the default for mixed-effects models. Only one of absolute or consistency may be specified.

testvalue(#) tests whether intraclass correlations equal #. The default is testvalue(0).

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [R] level.

format(%,fmt) specifies how the intraclass correlation estimates and confidence intervals are to be formatted. The default is format(%,9.0g).

Remarks and examples

Remarks are presented under the following headings:

Introduction
One-way random effects
Two-way random effects
Two-way mixed effects
Adoption study
Relationship between ICCs
Tests against nonzero values

Introduction

In some disciplines, such as psychology and sociology, data are often measured with error that can seriously affect statistical interpretation of the results. Thus it is important to assess the amount of measurement error by evaluating the consistency or reliability of measurements. The intraclass correlation coefficient (ICC) is often used to measure the consistency or homogeneity of measurements.

Several versions of ICCs are introduced in the literature depending on the experimental design and goals of the study (see, for example, Shrout and Fleiss [1979] and McGraw and Wong [1996a]). Following Shrout and Fleiss (1979), we describe various forms of ICCs in the context of a reliability study of ratings of different targets (or objects of measurements) by several raters.

Consider \( n \) targets (for example, students, patients, athletes) that are randomly sampled from a population of interest. Each target is rated independently by a set of \( k \) raters (for example, teachers, doctors, judges). One rating per target and rater is obtained. It is of interest to determine the extent of the agreement of the ratings.

As noted by Shrout and Fleiss (1979) and McGraw and Wong (1996a), you need to answer several questions to decide what version of ICC is appropriate to measure the agreement in your study:
1. Is a one-way or two-way analysis-of-variance model appropriate for your study?

2. Are differences between raters’ mean ratings relevant to the reliability of interest?

3. Is the unit of analysis an individual rating or the mean rating over several raters?

4. Is the consistency of agreement or the absolute agreement of ratings of interest?

Three types of analysis-of-variance models are considered for the reliability study: one-way random effects, two-way random effects, and two-way mixed effects. Mixed models contain both fixed effects and random effects. In the one-way random-effects model, each target is rated by a different set of \( k \) independent raters, who are randomly drawn from the population of raters. The target is the only random effect in this model; the effects due to raters and possibly due to rater-and-target interaction cannot be separated from random error. In the two-way random-effects model, each target is rated by the same set of \( k \) independent raters, who are randomly drawn from the population of raters. The random effects in this model are target and rater and possibly their interaction, although in the absence of repeated measurements for each rater on each target, the effect of an interaction cannot be separated from random error. In the two-way mixed-effects model, each target is rated by the same set of \( k \) independent raters. Because they are the only raters of interest, rater is a fixed effect. The random effects are target and possibly target-and-rater interaction, but again the interaction effect cannot be separated from random error without repeated measurements for each rater and target. The definition of ICC depends on the chosen random-effects model; see Methods and formulas for details.

In summary, use a one-way model if there are no systematic differences in measurements due to raters and use a two-way model otherwise. If you want to generalize your results to a population of raters from which the observed raters are sampled, use a two-way random-effects model, treating raters as random. If you are only interested in the effects of the observed \( k \) raters, use a two-way mixed-effects model, treating raters as fixed. For example, suppose you compare judges’ ratings of targets from different groups. If you use the combined data from \( k \) judges to compare the groups, the random-effects model is appropriate. If you compare groups separately for each judge and then pool the differences, the mixed-effects model is appropriate.

The definition of ICC also depends on the unit of analysis in a study—whether the agreement is measured between individual ratings (individual ICC) or between the averages of ratings over several raters (average ICC). The data on individual ratings are more common. The data on average ratings are typically used when individual ratings are deemed unreliable. The average ICC can also be used when teams of raters are used to rate a target. For example, the ratings of teams of physicians may be evaluated in this manner. When the unit of analysis is an average rating, you should remember that the interpretation of ICC pertains to average ratings and not individual ratings.

Finally, depending on whether consistency of agreement or absolute agreement is of interest, two types of ICC are used: consistency-of-agreement ICC (CA-ICC) and absolute-agreement ICC (AA-ICC). Under consistency of agreement, the scores are considered consistent if the scores from any two raters differ by the same constant value for all targets. This implies that raters give the same ranking to all targets. Under absolute agreement, the scores are considered in absolute agreement if the scores from all raters match exactly.

For example, suppose we observe three targets and two raters. The ratings are \( (2,4) \), \( (4,6) \), and \( (6,8) \), with rater 1 giving the scores \( (2,4,6) \) and rater 2 giving the scores \( (4,6,8) \), two points higher than rater 1. The CA-ICC between individual ratings is 1 because the scores from rater 1 and rater 2 differ by a constant value (two points) for all targets. That rater 1 gives lower scores than rater 2 is deemed irrelevant under the consistency measure of agreement. The raters have the same difference of opinion on every target, and the variation between raters that is caused by this difference is not relevant. On the other hand, the AA-ICC between individual ratings is \( \frac{8}{12} = 0.67 \), where 8 is the estimated between-target variance and 12 is the estimated total variance of ratings.
Either CA-ICC or AA-ICC can serve as a useful measure of agreement depending on whether rater variability is relevant for determining the degree of agreement. As McGraw and Wong (1996a) point out, CA-ICC is useful when comparative judgments are made about objects of measurement. The CA-ICC represents correlation when the rater is fixed; the AA-ICC represents correlation when the rater is random.

See Shrout and Fleiss (1979) and McGraw and Wong (1996a) for more detailed guidelines about the choice of appropriate ICC.

Shrout and Fleiss (1979) and McGraw and Wong (1996a) describe 10 versions of ICCs based on the concepts above: individual and average AA-ICCs for a one-way model (consistency of agreement is not defined for this model); individual and average AA-ICCs and CA-ICCs for a two-way random-effects model; and individual and average AA-ICCs and CA-ICCs for a two-way mixed-effects model. Although each of these ICCs has its own definition and interpretation, the estimators for some are identical, leading to the same estimates of those ICCs; see Relationship between ICCs and Methods and formulas for details.

The icc command calculates ICCs for each of the three analysis-of-variance models. You can use option absolute to compute AA-ICCs or option consistency to compute CA-ICCs. By default, icc computes ICCs corresponding to the correlation between ratings and between average ratings made on the same target: AA-ICC for a random-effects model and CA-ICC for a mixed-effects model. As pointed out by Shrout and Fleiss (1979), although the data on average ratings might be needed for reliability, the generalization of interest might be individuals. For this reason, icc reports ICCs for both units, individual and average, for each model.

In addition to estimates of ICCs, icc provides confidence intervals and one-sided $F$ tests. The $F$ test of $H_0: \rho = 0$ versus $H_a: \rho > 0$ is the same for the individual and average ICCs, so icc reports one test. This is not true, however, for nonzero null hypotheses (see Tests against nonzero values for details), so icc reports a separate test in this case.

The icc command requires data in long form; see [D] reshape for how to convert data in wide form to long form. The data must also be balanced and contain one observation per target and rater. For unbalanced data, icc omits all targets with fewer than $k$ ratings from computation. Under one-way models, $k$ is determined as the largest number of observed ratings for a target. Under two-way models, $k$ is the number of unique raters. If multiple observations per target and rater are detected, icc issues an error.

We demonstrate the use of icc using datasets from Shrout and Fleiss (1979) and McGraw and Wong (1996a). In the next three sections, we use an example from table 2 of Shrout and Fleiss (1979) with six targets and four judges. For instructional purposes, we analyze these data under each of the three different models: one-way random effects, two-way random effects, and two-way mixed effects.

### One-way random effects

In the one-way random-effects model, we assume that the $n$ targets being rated are randomly selected from the population of potential targets. Each is rated by a different set of $k$ raters randomly drawn from the population of potential raters. McGraw and Wong (1996a) describe an example of this setting, where behavioral genetics data are used to assess familial resemblance. Family units can be viewed as “targets”, and children can be viewed as “raters”. By taking a measurement on a child of the family unit, we obtain the “rating” of the family unit by the “child-rater”. In this case, we can use ICC to assess similarity between children within a family or, in other words, assess if there is a family effect in these data.
As we mentioned in the introduction, only AA-ICC is defined for a one-way model. The consistency of agreement is not defined in this case, as each target is evaluated by a different set of raters. Thus there is no between-rater variability in this model.

In a one-way model, the AA-ICC corresponds to the correlation coefficient between ratings within a target. It is also a ratio of the between-target variance of ratings to the total variance of ratings, the sum of the between-target and error variances.

Example 1: One-way random-effects ICCs

Consider data from table 2 of Shrout and Fleiss (1979) stored in judges.dta. The data contain 24 ratings of $n = 6$ targets by $k = 4$ judges. We list the first eight observations:

```
. use http://www.stata-press.com/data/r13/judges
    (Ratings of targets by judges)
. list in 1/8, sepby(target)
```

<table>
<thead>
<tr>
<th>rating</th>
<th>target</th>
<th>judge</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>9</td>
<td>1</td>
</tr>
<tr>
<td>2.</td>
<td>2</td>
<td>1</td>
</tr>
<tr>
<td>3.</td>
<td>5</td>
<td>1</td>
</tr>
<tr>
<td>4.</td>
<td>8</td>
<td>1</td>
</tr>
<tr>
<td>5.</td>
<td>6</td>
<td>2</td>
</tr>
<tr>
<td>6.</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>7.</td>
<td>3</td>
<td>2</td>
</tr>
<tr>
<td>8.</td>
<td>2</td>
<td>2</td>
</tr>
</tbody>
</table>

For a moment, let’s ignore that targets are rated by the same set of judges. Instead, we assume that a different set of four judges is used to rate each target. In this case, the only systematic variation in the data is due to targets, so the one-way random-effects model is appropriate.

We use `icc` to estimate the intraclass correlations for these data. To compute ICCs for a one-way model, we specify the dependent variable `rating` followed by the target variable `target`:

```
. icc rating target
```

```
Intraclass correlations
One-way random-effects model
Absolute agreement
Random effects: target
Number of targets = 6
Number of raters = 4

<table>
<thead>
<tr>
<th>rating</th>
<th>ICC</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Individual</td>
<td>.1657418</td>
<td>-.1329323 - .7225601</td>
</tr>
<tr>
<td>Average</td>
<td>.4427971</td>
<td>-.8844422 - .9124154</td>
</tr>
</tbody>
</table>
```

F test that

\[
\text{ICC}=0.00: F(5.0, 18.0) = 1.79, \quad \text{Prob > F} = 0.165
\]

Note: ICCs estimate correlations between individual measurements and between average measurements made on the same target.

`icc` reports the AA-ICCs for both individual and average ratings. The individual AA-ICC corresponds to ICC(1) in McGraw and Wong (1996a) or ICC(1,1) in Shrout and Fleiss (1979). The average AA-ICC corresponds to ICC($k$) in McGraw and Wong (1996a) or ICC(1,$k$) in Shrout and Fleiss (1979).
The estimated correlation between individual ratings is 0.17, indicating little similarity between ratings within a target, low reliability of individual target ratings, or no target effect. The estimated intraclass correlation between ratings averaged over $k = 4$ judges is higher, 0.44. (The average ICC will typically be higher than the individual ICC.) The estimated intraclass correlation measures the similarity or reliability of mean ratings from groups of four judges. We do not have statistical evidence that either ICC is different from zero based on reported confidence intervals and the one-sided $F$ test.

Note that although the estimates of ICCs cannot be negative in this setting, the lower bound of the computed confidence interval may be negative. A common ad-hoc way of handling this is to truncate the lower bound at zero.

The estimates of both the individual and the average AA-ICC are also computed by the `loneway` command (see [R] loneway), which performs a one-way analysis of variance.

---

### Technical note

Mean rating is commonly used when individual rating is unreliable because the reliability of a mean rating is always higher than the reliability of the individual rating when the individual reliability is positive.

In the previous example, we estimated low reliability of the individual ratings of a target, 0.17. The reliability increased to 0.44 for the ratings averaged over four judges. What if we had more judges?

We can use the Spearman–Brown formula (Spearman 1910; Brown 1910) to compute the $m$-average ICC based on the individual ICC:

$$ICC(m) = \frac{m \cdot ICC(1)}{1 + (m - 1) \cdot ICC(1)}$$

Using this formula for the previous example, we find that the mean reliability over, say, 10 judges is $10 \times 0.17 / (1 + 9 \times 0.17) = 0.67$.

Alternatively, we can invert the Spearman–Brown formula to determine the number of judges (or the number of ratings of a target) we need to achieve the desired reliability. Suppose we would like an average reliability of 0.9, then

$$m = \frac{ICC(m) \cdot (1 - ICC(1))}{ICC(1) \cdot (1 - ICC(m))} = \frac{0.9 (1 - 0.17)}{0.17 (1 - 0.9)} = 44$$

See, for example, Bliese (2000) for other examples.

---

### Two-way random effects

As before, we assume that the targets being rated are randomly selected from the population of potential targets. We now also assume that each target is evaluated by the same set of $k$ raters, who have been randomly sampled from the population of raters. In this scenario, we want to generalize our findings to the population of raters from which the observed $k$ raters were sampled. For example, suppose we want to estimate the reliability of doctors’ evaluations of patients with a certain condition. Unless the reliability at a specific hospital is of interest, the doctors may be interchanged with others in the relevant population of doctors.
As for a one-way model, the AA-ICC corresponds to the correlation between measurements on the same target and is also a ratio of the between-target variance to the total variance of measurements in a two-way random-effects model. The total variance is now the sum of the between-target, between-rater, and error variances. Unlike a one-way model, the CA-ICC can be computed for a two-way random-effects model when the consistency of agreement is of interest rather than the absolute agreement. The CA-ICC is also the ratio of the between-target variance to the total variance, but the total variance does not include the between-rater variance because the between-rater variability is irrelevant for the consistency of agreement.

Again, the two versions, individual and average, are available for each ICC.

➢ Example 2: Two-way random-effects ICCs

Continuing with example 1, recall that we previously ignored that each target is rated by the same set of four judges and instead assumed different sets of judges. We return to the original data setting. We want to evaluate the agreement between judges’ ratings of targets in a population represented by the observed set of four judges.

In a two-way model, we must specify both the target and the rater variables. In icc, we now additionally specify the rater variable judge following the target variable target; the random-effects model is assumed by default.

```plaintext
. icc rating target judge
Intraclass correlations
Two-way random-effects model
Absolute agreement

<table>
<thead>
<tr>
<th>Random effects: target</th>
<th>Number of targets = 6</th>
</tr>
</thead>
<tbody>
<tr>
<td>Random effects: judge</td>
<td>Number of raters = 4</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>rating</th>
<th>ICC</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Individual</td>

<td>.0711368 .927232</td>
</tr>
</tbody>
</table>

F test that
ICC=0.00: F(5.0, 15.0) = 11.03 Prob > F = 0.000
Note: ICCs estimate correlations between individual measurements and between average measurements made on the same target.
```

As for a one-way random-effects model, icc by default reports AA-ICCs that correspond to the correlation between ratings on a target. Notice that both individual and average ICCs are larger in the two-way random-effects model than in the previous one-way model—0.29 versus 0.17 and 0.62 versus 0.44, respectively. We also have statistical evidence to reject the null hypothesis that neither ICC is zero based on confidence intervals and the \( F \) test. If a one-way model is used when a two-way model is appropriate, the true ICC will generally be underestimated.

Instead of the absolute agreement, we can also assess the consistency of agreement. The individual and average CA-ICCs are considered in McGraw and Wong (1996a) and denoted as ICC(\( C_1 \)) and ICC(\( C_2,k \)), respectively. These ICCs are not considered in Shrout and Fleiss (1979) because they are not correlations in the strict sense. Although CA-ICCs do not estimate correlation, they can provide useful information about the reliability of the raters. McGraw and Wong (1996a) note that the practical value of the individual and average CA-ICCs in the two-way random-effects model setting is well documented in measurement theory, citing Hartmann (1982) and Suen (1988).
To estimate the individual and average CA-ICCs, we specify the consistency option:

```
.icc rating target judge, consistency
```

Intraclass correlations
Two-way random-effects model
Consistency of agreement

<table>
<thead>
<tr>
<th>Random effects: target</th>
<th>Number of targets = 6</th>
</tr>
</thead>
<tbody>
<tr>
<td>Random effects: judge</td>
<td>Number of raters = 4</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>

<th>ICC</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Individual</td>
<td>.7148407</td>
<td>.3424648 .9458583</td>
</tr>
<tr>
<td>Average</td>
<td>.9093155</td>
<td>.6756747 .9855917</td>
</tr>
</tbody>
</table>

F test that ICC=0.00: F(5.0, 15.0) = 11.03 Prob > F = 0.000

We estimate that the consistency of agreement of ratings in the considered population of raters is high, 0.71, based on the individual CA-ICC. On the other hand, the absolute agreement of ratings is low, 0.29, based on the individual AA-ICC from the previous output.

The measure of consistency of agreement among means, the average CA-ICC, is equivalent to Cronbach’s alpha (Cronbach 1951); see [MV] `alpha`. The individual CA-ICC can also be equivalent to the Pearson’s correlation coefficient between raters when \( k = 2 \); see McGraw and Wong (1996a) for details.

In the next example, we will see that the actual estimates of the individual and average AA-ICCs and CA-ICCs are the same whether we examine a random-effects model or a mixed-effects model. The differences between these ICCs are in their definitions and interpretations.

**Two-way mixed effects**

As in a two-way random-effects model, we assume that the targets are randomly selected from the population of potential targets and that each is evaluated by the same set of \( k \) raters. In a mixed-effects model, however, we assume that these raters are the only raters of interest. So as before, the targets are random, but now the raters are fixed.

In the two-way mixed-effects model, the fixed effect of the rater does not contribute to the between-rater random variance component to the total variance. As such, the definitions and interpretations of ICCs are different in a mixed-effects model than in a random-effects model. However, the estimates of ICCs as well as test statistics and confidence intervals are the same. The only exceptions are average AA-ICCs and CA-ICCs. These are not estimable in a two-way mixed-effects model including an interaction term between target and rater; see *Relationship between ICCs* and *Methods and formulas* for details.

In a two-way mixed-effects model, the CA-ICC corresponds to the correlation between measurements on the same target. As pointed out by Shrout and Fleiss (1979), when the rater variance is ignored, the correlation coefficient is interpreted in terms of rater consistency rather than rater absolute agreement. Formally, the CA-ICC is the ratio of the covariance between measurements on the target to the total variance of the measurements. The AA-ICC corresponds to the same ratio, but includes a variance of the fixed factor, rater, in its denominator.
Example 3: Two-way mixed-effects ICCs

Continuing with example 2, suppose that we are now interested in assessing the agreement of ratings from only the observed four judges. The judges are now fixed effects, and the appropriate model is a two-way mixed-effects model.

To estimate ICCs for a two-way mixed-effects model, we specify the mixed option with `icc`:

```
. icc rating target judge, mixed
```

Intraclass correlations
Two-way mixed-effects model
Consistency of agreement

Random effects: target
Fixed effects: judge
Number of targets = 6
Number of raters = 4

<table>
<thead>
<tr>
<th>rating</th>
<th>ICC</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Individual</td>
<td>.7148407</td>
<td>.3424648 .9458583</td>
</tr>
<tr>
<td>Average</td>
<td>.9093155</td>
<td>.6756747 .9858917</td>
</tr>
</tbody>
</table>

F test that
ICC=0.00: F(5.0, 15.0) = 11.03 Prob > F = 0.000

Note: ICCs estimate correlations between individual measurements and between average measurements made on the same target.

As we described in the introduction, `icc` by default reports ICCs corresponding to the correlations. So, for a mixed-effects model, `icc` reports CA-ICCs by default. The individual and average CA-ICCs are denoted as ICC(3,1) and ICC(3,k) in Shrout and Fleiss (1979) and ICC(C,1) and ICC(C,k) in McGraw and Wong (1996a).

Our estimates of the individual and average CA-ICCs are identical to the CA-ICC estimates obtained under the two-way random-effects model in example 2, but our interpretation of the results is different. Under a mixed-effects model, 0.71 and 0.91 are the estimates, respectively, of the correlation between individual measurements and the correlation between average measurements made on the same target.

We can also estimate the AA-ICCs in this setting by specifying the absolute option:

```
. icc rating target judge, mixed absolute
```

Intraclass correlations
Two-way mixed-effects model
Absolute agreement

Random effects: target
Fixed effects: judge
Number of targets = 6
Number of raters = 4

<table>
<thead>
<tr>
<th>rating</th>
<th>ICC</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Individual</td>
<td>.2897638</td>
<td>.0187865 .7610844</td>
</tr>
<tr>
<td>Average</td>
<td>.6200505</td>
<td>.0711368 .927232</td>
</tr>
</tbody>
</table>

F test that
ICC=0.00: F(5.0, 15.0) = 11.03 Prob > F = 0.000

The intraclass correlation estimates match the individual and average AA-ICCs obtained under the two-way random-effects model in example 2; but in a mixed-effects model, they do not represent correlations. We demonstrate the use of an individual AA-ICC in a mixed-effects setting in the next example.

The AA-ICCs under a mixed-effects model are not considered by Shrout and Fleiss (1979). They are denoted as ICC(A,1) and ICC(A,k) in McGraw and Wong (1996a).
Adoption study

In this section, we consider the adoption study described in McGraw and Wong (1996a). Adoption studies commonly include two effects of interest. One is the mean difference between the adopted child and its biological parents. It is used to determine if characteristics of adopted children differ on average from those of their biological parents. Another effect of interest is the correlation between genetically paired individuals and genetically unrelated individuals who live together. This effect is used to evaluate the impact of genetic differences on individual differences.

As discussed in McGraw and Wong (1996a), a consistent finding from adoption research using IQ as a trait characteristic is that while adopted children typically have higher IQs than their biological parents, their IQs correlate better with those of their biological parents than with those of their adoptive parents. Both effects are important, and there is additional need to reconcile the two findings. McGraw and Wong (1996a) propose to use the individual AA-ICC for this purpose.

Example 4: Absolute-agreement ICC in a mixed-effects model

The adoption.dta dataset contains the data from table 6 of McGraw and Wong (1996a) on IQ scores:

```
. use http://www.stata-press.com/data/r13/adoption
(Biological mother and adopted child IQ scores)
. describe
Contains data from http://www.stata-press.com/data/r13/adoption.dta
    obs: 20 Biological mother and adopted child IQ scores
    vars: 5 15 May 2013 13:50
    size: 160 (_dta has notes)

storage  display value
variable name type format label variable label

family byte %9.0g Adoptive family ID
mc byte %9.0g mcvalues 1=Mother, 2=Child
iq3 int %9.0g IQ scores, mother-child difference of 3 pts
iq9 int %9.0g IQ scores, mother-child difference of 9 pts
iq15 int %9.0g IQ scores, mother-child difference of 15 pts
```

Sorted by:

The family variable contains adoptive family identifiers, the mc variable records a mother or a child, and the iq3, iq9, and iq15 variables record IQ scores with differences between mother and child mean IQ scores of 3, 9, and 15 points, respectively.
. by mc, sort: summarize iq*

</tbody>
</table>

The variances of the mother and child IQ scores are the same.

Children are fixed effects, so the mixed-effects model is appropriate for these data. We want to compare individual CA-ICC with individual AA-ICC for each of the three IQ variables. We could issue a separate `icc` command for each of the three IQ variables to obtain the intraclass correlations. Instead, we use `reshape` to convert our data to long form with one `iq` variable and the new `diff` variable recording mean differences:

```
. reshape long iq, i(family mc) j(diff)
   (note: j = 3 9 15)
```

We can now use the `by` prefix with `icc` to estimate intraclass correlations for the three groups of interest:
. by diff, sort: icc iq family mc, mixed

-> diff = 3
Intraclass correlations
Two-way mixed-effects model
Consistency of agreement
Random effects: family Number of targets = 10
Fixed effects: mc Number of raters = 2

<table>
<thead>
<tr>

</tr>
</thead>
<tbody>
<tr>
<td>Individual</td>
<td>.7142152</td>
<td>.1967504 .920474</td>
</tr>
<tr>
<td>Average</td>
<td>.8332853</td>
<td>.3288078 .9585904</td>
</tr>
</tbody>
</table>

F test that
ICC=0.00: F(9.0, 9.0) = 6.00 Prob > F = 0.007
Note: ICCs estimate correlations between individual measurements and between average measurements made on the same target.

-> diff = 15
(output omitted)

The estimated CA-ICCs are the same in all three groups and are equal to the corresponding estimates of the Pearson’s correlation coefficients because mothers’ and children’s IQ scores have the same variability. The scores differ only in means, and mean differences are irrelevant when measuring the consistency of agreement.
The AA-ICCs, however, differ across the three groups:

```

```

As the mean differences increase, the AA-ICCs decrease. Their attenuation reflects the difference in means between biological mother and child IQs while still measuring their agreement. Notice that for small mean differences, the estimates of AA-ICCs and CA-ICCs are very similar.

Note that our estimates match those given in McGraw and Wong (1996b), who correct the original table 6 of McGraw and Wong (1996a).
Relationship between ICCs

In examples 2 and 3, we saw that the estimates of AA-ICC and CA-ICC are the same for two-way random-effects and two-way mixed-effects models. In this section, we consider the relationship between various forms of ICCs in more detail; also see Methods and formulas.

There are 10 different versions of ICCs, but only six different estimators are needed to compute them. These estimators include the two estimators for the individual and average AA-ICC in a one-way model, the two estimators for the individual and average AA-ICC in two-way models, and the two estimators for the individual and average CA-ICC in two-way models.

Only individual and average AA-ICC are defined for the one-way model. The estimates of AA-ICC based on the one-way model will typically be smaller than individual and average estimates of AA-ICC and CA-ICC based on two-way models. The estimates of individual and average CA-ICC will typically be larger than the estimates of individual and average AA-ICC.

Although AA-ICC and CA-ICC have the same respective estimators in two-way random-effects and mixed-effects models, their definitions and interpretations are different. The AA-ICC based on a random-effects model contain the between-rater variance component in the denominator of the variance ratio. The CA-ICC based on a mixed-effects model contain the variance of the fixed-factor rater instead of the random between-rater variability. The AA-ICC in a random-effects model represent correlations between any two measurements made on a target. The CA-ICC in a mixed-effects model measure absolute agreement of measurements treating raters as fixed. The CA-ICC for random-effects and mixed-effects models have the same definition but different interpretations. The CA-ICC represent correlations between any two measurements made on a target in a mixed-effects model but estimate the degree of consistency among measurements treating raters as random in a random-effects model. The difference in the definitions of AA-ICC and CA-ICC is that CA-ICC do not contain the between-rater variance in the denominator of the variance ratio.

For two-way models, the definitions and interpretations (but not the estimators) of ICC also depend on whether the model contains an interaction between target and rater. For two-way models with interaction, ICCs include an additional variance component for the target-rater interaction in the denominator of the variance ratio. This component cannot be separated from random error because there is only one observation per target and rater.

Also, under a two-way mixed-effects model including interaction, the interaction components are not mutually independent, as they are in a two-way random-effects model. The considered version of the mixed-effects model places a constraint on the interaction effects—the sum of the interaction effects over levels of the fixed factor is zero; see, for example, chapter 7 in Kuehl (2000) for an introductory discussion of mixed models. In this version of the model, there is a correlation between the interaction effects. Specifically, the two interaction effects for the same target and two different raters are negatively correlated. As a result, the estimated intraclass correlation can be negative under a two-way mixed-effects model with interaction. Also, average AA-ICC and average CA-ICC cannot be estimated in a two-way mixed-effects model including interaction; see Methods and formulas and McGraw and Wong (1996a) for details.

Tests against nonzero values

It may be of interest to test whether the intraclass correlation is equal to a value other than zero. ICC supports testing against positive values through the use of the testvalue() option. Specifying testvalue(#) provides a one-sided hypothesis test of $H_0: \rho = # \text{ versus } H_a: \rho > #$. The test is provided separately for both individual and average ICCs.
Example 5: Testing ICC against a nonzero value

We return to the two-way random-effects model for the judge and target data from Shrout and Fleiss (1979). Suppose we want to test whether the individual and average AA-ICCs are each equal to 0.2. We specify the testvalue(0.2) option with `icc`:

```
. use http://www.stata-press.com/data/r13/judges, clear
   (Ratings of targets by judges)
. icc rating target judge, testvalue(0.2)
```

```
Intraclass correlations
Two-way random-effects model
Absolute agreement

<table>
<thead>
<tr>
<th>rating</th>
<th>ICC</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Individual</td>
<td>.2897638</td>
<td>.0187865 .7610844</td>
</tr>
<tr>
<td>Average</td>
<td>.6200505</td>
<td>.0711368 .927232</td>
</tr>
</tbody>
</table>
```

F test that

- ICC(1) = 0.20: F(5.0, 5.3) = 1.54 Prob > F = 0.317
- ICC(k) = 0.20: F(5.0, 9.4) = 4.35 Prob > F = 0.026

Note: ICCs estimate correlations between individual measurements and between average measurements made on the same target.

We reject the null hypothesis that the average AA-ICC, labeled as ICC(k) in the output, is equal to 0.2, but we do not have statistical evidence to reject the null hypothesis that the individual AA-ICC, labeled as ICC(1), is equal to 0.2.

Stored results

`icc` stores the following in `r()`:

Scalars

- `r(N_target)` number of targets
- `r(N_rater)` number of raters
- `r(icc_i)` intraclass correlation for individual measurements
- `r(icc_i_F)` $F$ test statistic for individual ICC
- `r(icc_i_df1)` numerator degrees of freedom for `r(icc_i_F)`
- `r(icc_i_df2)` denominator degrees of freedom for `r(icc_i_F)`
- `r(icc_i_p)` $p$-value for $F$ test of individual ICC
- `r(icc_i_lb)` lower endpoint for confidence intervals of individual ICC
- `r(icc_i_ub)` upper endpoint for confidence intervals of individual ICC
- `r(icc_avg)` intraclass correlation for average measurements
- `r(icc_avg_F)` $F$ test statistic for average ICC
- `r(icc_avg_df1)` numerator degrees of freedom for `r(icc_avg_F)`
- `r(icc_avg_df2)` denominator degrees of freedom for `r(icc_avg_F)`
- `r(icc_avg_p)` $p$-value for $F$ test of average ICC
- `r(icc_avg_lb)` lower endpoint for confidence intervals of average ICC
- `r(icc_avg_ub)` upper endpoint for confidence intervals of average ICC
- `r(testvalue)` null hypothesis value
- `r(level)` confidence level

Macros

- `r(model)` analysis-of-variance model
- `r(depvar)` name of dependent variable
- `r(target)` target variable
- `r(rater)` rater variable
- `r(type)` type of ICC estimated (absolute or consistency)
Methods and formulas

We observe \( y_{ij} \), where \( i = 1, \ldots, n \) and \( j = 1, \ldots, k \). \( y_{ij} \) is the \( j \)th rating on the \( i \)th target. Let \( \alpha = 1 - l/100 \), where \( l \) is the significance level specified by the user.

Methods and formulas are presented under the following headings:

- Mean squares
- One-way random effects
- Two-way random effects
- Two-way mixed effects

Mean squares

The mean squares within targets are

\[
W_{\text{MS}} = \sum_i \sum_j \frac{(y_{ij} - \bar{y}_i)^2}{n(k-1)}
\]

where \( \bar{y}_i = \sum_j y_{ij} / k \).

The mean squares between targets are

\[
B_{\text{MS}} = \sum_i \frac{(\bar{y}_i - \bar{\bar{y}})^2}{n-1}
\]

where \( \bar{\bar{y}} = \frac{\sum_i \bar{y}_i}{n} \).

These are the only mean squares needed to estimate ICC in the one-way random-effects model. For the two-way models, we need two additional mean squares.

The mean squares between raters are

\[
J_{\text{MS}} = \sum_j \frac{(\bar{y}_j - \bar{\bar{y}})^2}{k-1}
\]

where \( \bar{y}_j = \sum_i y_{ij} / n \) and \( \bar{\bar{y}} = \frac{\sum_j \bar{y}_j}{k} \).

The residual or error mean square is

\[
E_{\text{MS}} = \frac{\sum_i \sum_j (y_{ij} - \bar{y})^2 - (k-1)J_{\text{MS}} - (n-1)B_{\text{MS}}}{(n-1)(k-1)}
\]
One-way random effects

Under the one-way random-effects model, we observe

\[ y_{ij} = \mu + r_i + \epsilon_{ij} \tag{M1} \]

where \( \mu \) is the mean rating, \( r_i \) is the target random effect, and \( \epsilon_{ij} \) is random error. The \( r_i \)'s are i.i.d. \( N(0, \sigma_r^2) \); \( \epsilon_{ij} \)'s are i.i.d. \( N(0, \sigma_e^2) \) and are independent of \( r_i \)'s. There is no rater effect separate from the residual error because each target is evaluated by a different set of raters.

The individual AA-ICC is the correlation between individual measurements on the same target:

\[ \rho_1 = \text{ICC}(1) = \text{Corr}(y_{ij}, y_{ij}') = \frac{\sigma_r^2}{\sigma_r^2 + \sigma_e^2} \]

The average AA-ICC is the correlation between average measurements of size \( k \) made on the same target:

\[ \rho_k = \text{ICC}(k) = \text{Corr}(\bar{y}_i, \bar{y}_i') = \frac{\sigma_r^2}{\sigma_r^2 + \sigma_e^2 / k} \]

They are estimated by

\[ \hat{\rho}_1 = \widehat{\text{ICC}(1)} = \frac{\text{BMS} - \text{WMS}}{\text{BMS} + (k - 1)\text{WMS}} \]

\[ \hat{\rho}_k = \widehat{\text{ICC}(k)} = \frac{\text{BMS} - \text{WMS}}{\text{BMS}} \]

Confidence intervals. Let \( F_{\text{obs}} = \text{BMS}/\text{WMS} \), let \( F_l \) be the \((1 - \alpha/2) \times 100\)th percentile of the \( F_{n-1,n(k-1)} \) distribution, and let \( F_u \) be the \((1 - \alpha/2) \times 100\)th percentile of the \( F_{n(k-1),n-1} \) distribution. Let \( F_L = F_{\text{obs}}/F_l \) and \( F_U = F_{\text{obs}}F_u \).

A \((1 - \alpha) \times 100\%\) confidence interval for \( \rho_1 \) is

\[ \left( \frac{F_L - 1}{F_l + k - 1}, \frac{F_U - 1}{F_U + k - 1} \right) \tag{1} \]

A \((1 - \alpha) \times 100\%\) confidence interval for \( \rho_k \) is

\[ \left( 1 - \frac{1}{F_L}, 1 - \frac{1}{F_U} \right) \tag{2} \]

Hypothesis tests. Consider a one-sided hypothesis test of \( H_0: \text{ICC} = \rho_0 \) versus \( H_a: \text{ICC} > \rho_0 \).

The test statistic for \( \rho_1 \) is

\[ F_{\rho_1} = \frac{\text{BMS}}{\text{WMS}} \frac{1 - \rho_0}{1 + (k - 1)\rho_0} \tag{3} \]

The test statistic for \( \rho_k \) is

\[ F_{\rho_k} = \frac{\text{BMS}}{\text{WMS}}(1 - \rho_0) \tag{4} \]

Under the null hypothesis, both \( F_{\rho_1} \) and \( F_{\rho_k} \) have the \( F_{n-1,n(k-1)} \) distribution. When \( \rho_0 = 0 \), the two test statistics coincide.
Two-way random effects

In this setting, the target is evaluated by the same set of raters, who are randomly drawn from the population of raters. The underlying models with and without interaction are

\[ y_{ij} = \mu + r_i + c_j + (rc)_{ij} + \epsilon_{ij} \quad (M2) \]

\[ y_{ij} = \mu + r_i + c_j + \epsilon_{ij} \quad (M2A) \]

where \( y_{ij} \) is the rating of the \( i \)th target by the \( j \)th rater, \( \mu \) is the mean rating, \( r_i \) is the target random effect, \( c_j \) is the rater random effect, \((rc)_{ij}\) is the target-rater random effect, and \( \epsilon_{ij} \) is random error. The \( r_i \)s are i.i.d. \( N(0, \sigma_r^2) \), \( c_j \)s are i.i.d. \( N(0, \sigma_c^2) \), \((rc)_{ij}\)s are i.i.d. \( N(0, \sigma_{rc}^2) \), and \( \epsilon_{ij} \)s are i.i.d. \( N(0, \sigma_\epsilon^2) \). Each effect is mutually independent of the others.

Below we provide formulas for ICCs for model (M2). The corresponding ICCs for model (M2A) can be obtained by setting \( \sigma_{rc}^2 = 0 \).

The individual AA-ICC is the correlation between individual measurements on the same target:

\[
\rho_{A,1} = ICC(A,1) = \text{Corr}(y_{ij}, y_{ij'}) = \frac{\sigma_r^2}{\sigma_r^2 + \sigma_c^2 + (\sigma_{rc}^2 + \sigma_\epsilon^2)}
\]

The average AA-ICC is the correlation between average measurements of size \( k \) made on the same target:

\[
\rho_{A,k} = ICC(A,k) = \text{Corr}(\bar{y}_{i.}, \bar{y}_{i,.}') = \frac{\sigma_r^2}{\sigma_r^2 + (\sigma_c^2 + \sigma_{rc}^2 + \sigma_\epsilon^2)/k}
\]

The consistency-of-agreement intraclass correlation for individual measurements, individual CA-ICC, is

\[
\rho_{C,1} = ICC(C,1) = \frac{\sigma_r^2}{\sigma_r^2 + (\sigma_{rc}^2 + \sigma_\epsilon^2)}
\]

The consistency-of-agreement intraclass correlation for average measurements of size \( k \), average CA-ICC, is

\[
\rho_{C,k} = ICC(C,k) = \frac{\sigma_r^2}{\sigma_r^2 + (\sigma_{rc}^2 + \sigma_\epsilon^2)/k}
\]

With one observation per target and rater, \( \sigma_{rc}^2 \) and \( \sigma_\epsilon^2 \) cannot be estimated separately.

The estimators of intraclass correlations, confidence intervals, and test statistics are the same for models (M2) and (M2A). The estimators of ICCs are
Confidence intervals. Let 
\[ a = k\hat{\rho}_{A,1}/\{n(1 - \hat{\rho}_{A,1})\}, \quad b = 1 + k\hat{\rho}_{A,1}(n - 1)/\{n(1 - \hat{\rho}_{A,1})\}, \]
and
\[ v = \frac{(aJMS + bEMS)^2}{\frac{a^2JMS^2}{k-1} + \frac{b^2EMS^2}{(n-1)(k-1)}} \]  \hspace{1cm} (5) \]

Let \( F_l \) be the \((1 - \alpha/2) \times 100\)th percentile of the \( F_{n-1,v} \) distribution and \( F_u \) be the \((1 - \alpha/2) \times 100\)th percentile of the \( F_{v,n-1} \) distribution.

A \((1 - \alpha) \times 100\)% confidence interval for \( \rho_{A,1} \) is given by \((L, U)\), where
\[ L = \frac{n(BMS - F_lEMS)}{F_l\{kJMS + (kn - k - n)EMS\} + nBMS} \]
\[ U = \frac{n(F_uBMS - EMS)}{kJMS + (kn - k - n)EMS + nF_uBMS} \]  \hspace{1cm} (6) \]

A \((1 - \alpha) \times 100\)% confidence intervals for \( \rho_{A,k} \) is a special case of (6) with \( k = 1 \), where
\[ a = \hat{\rho}_{A,k}/\{n(1 - \hat{\rho}_{A,k})\}, \quad b = 1 + \hat{\rho}_{A,k}(n - 1)/\{n(1 - \hat{\rho}_{A,k})\}, \]
and \( v \) is defined in (5).

To define confidence intervals for \( \rho_{C,1} \) and \( \rho_{C,k} \), let \( F_{obs} = BMS/EMS \), \( F_l \) be the \((1 - \alpha/2) \times 100\)th percentile of the \( F_{n-1,(n-1)(k-1)} \) distribution, and \( F_u \) be the \((1 - \alpha/2) \times 100\)th percentile of the \( F_{(n-1)(k-1),n-1} \) distribution. Let \( F_L = F_{obs}/F_l \) and \( F_L = F_{obs}F_u \).

A \((1 - \alpha) \times 100\)% confidence intervals for \( \rho_{C,1} \) and \( \rho_{C,k} \) are then as given by (1) and (2) for model (M1).

Hypothesis tests. Consider a one-sided hypothesis test of \( H_a: ICC = \rho_0 \) versus \( H_a: ICC > \rho_0 \). Let
\[ a = k\rho_0/\{n(1 - \rho_0)\} \]  \quad and \quad \[ b = 1 + k\rho_0(n - 1)/\{n(1 - \rho_0)\} \].

The test statistic for \( \rho_{A,1} \) is
\[ F_{\rho_{A,1}} = \frac{BMS}{aJMS + bEMS} \]

Under the null hypothesis, \( F_{\rho_{A,1}} \) has the \( F_{n-1,v} \) distribution, where \( v \) is defined in (5).

The test statistic for \( \rho_{A,k} \) is defined similarly, except
\[ a = \rho_0/\{n(1 - \rho_0)\} \]  \quad and \quad \[ b = 1 + \rho_0(n - 1)/\{n(1 - \rho_0)\} \]. Under the null hypothesis, \( F_{\rho_{A,k}} \) has the \( F_{n-1,v} \) distribution, where \( v \) is defined in (5). When \( \rho_0 = 0 \), then \( a = 0 \), \( b = 1 \), and the two test statistics coincide.

The test statistics for \( \rho_{C,1} \) and \( \rho_{C,k} \) are defined by (3) and (4), respectively, with WMS replaced by EMS. Under the null hypothesis, both \( F_{\rho_{C,1}} \) and \( F_{\rho_{C,k}} \) have the \( F_{n-1,(n-1)(k-1)} \) distribution. They also both have the same value when \( \rho_0 = 0 \).
Two-way mixed effects

In this setting, every target is evaluated by the same set of judges, who are the only judges of interest. The underlying models with and without interaction are

\[ y_{ij} = \mu + r_i + c_j + (rc)_{ij} + \epsilon_{ij} \]  

(M3)

\[ y_{ij} = \mu + r_i + c_j + \epsilon_{ij} \]  

(M3A)

where \( y_{ij} \) is the rating of the \( i \)th target by the \( j \)th rater, \( \mu \) is the mean rating, \( r_i \) is the target random effect, \( c_j \) is the rater random effect, \( (rc)_{ij} \) is an interaction effect between target and rater, and \( \epsilon_{ij} \) is random error. The \( r_i \)s are i.i.d. \( N(0, \sigma_r^2) \), \( (rc)_{ij} \)s are \( N(0, \sigma_{rc}^2) \), and \( \epsilon_{ij} \)s are i.i.d. \( N(0, \sigma_\epsilon^2) \). Each random effect is mutually independent of the others. The \( c_j \)s are fixed such that \( \sum_j c_j = 0 \). The variance of \( c_j \)s is \( \theta_c^2 = \frac{\sum c_j^2}{k-1} \).

In the presence of an interaction, two versions of a mixed-effects model may be considered. One assumes that \( (rc)_{ij} \)s are i.i.d. \( N(0, \sigma_{rc}^2) \). Another assumes that \( (rc)_{ij} \)s are \( N(0, \sigma_{rc}^2) \) with an additional constraint that \( \sum_j (rc)_{ij} = 0 \) (for example, Kuehl [2000]), so only interaction terms involving different targets are independent. The latter model is considered here.

We now define the intraclass correlations for individual measurements for model (M3).

The individual CA-ICC, the correlation between individual measurements on the same target, is

\[ \rho_{C,1} = ICC(C,1) = Corr(y_{ij}, y_{ij'}) = \frac{\sigma_r^2 - \sigma_{rc}^2/(k-1)}{\sigma_r^2 + (\sigma_{rc}^2 + \sigma_\epsilon^2)} \]

The absolute-agreement intraclass correlation for individual measurements, individual AA-ICC, is

\[ \rho_{A,1} = ICC(A,1) = \frac{\sigma_r^2 - \sigma_{rc}^2/(k-1)}{\sigma_r^2 + \theta_c^2 + (\sigma_{rc}^2 + \sigma_\epsilon^2)} \]

Shrout and Fleiss (1979) show that the individual ICC could be negative in this case—a phenomenon first pointed out by Sitgreaves (1960). This can happen when the interaction term has a high variance relative to the targets and there are not many raters.

The individual intraclass correlations for model (M3A) have similar definitions with \( \sigma_{rc}^2 = 0 \). The individual CA-ICC is the correlation between individual measurements on the same target, \( Corr(y_{ij}, y_{ij'}) \).

We now discuss the intraclass correlations that correspond to average measurements. Neither average AA-ICC, \( \rho_{A,k} \), nor average CA-ICC, \( \rho_{C,k} \), can be estimated under model (M3) (Shrout and Fleiss 1979; McGraw and Wong 1996a). The problem is that in this model, \( \sigma_r^2 \), which is the covariance between two means based on \( k \) raters, cannot be estimated.

Specifically, the parameter \( \sigma_r^2 \) appears only in the expectation of the between-target mean squares BMS. Under the restriction \( \sum_j (rc)_{ij} = 0 \),

\[ E(BMS) = k\sigma_r^2 + \sigma_\epsilon^2 \]

Note that \( \sigma_{rc}^2 \) does not appear in the expectation of between-target mean squares. With one observation per target and rater, \( \sigma_{rc}^2 \) and \( \sigma_\epsilon^2 \) cannot be estimated separately (only their sum \( \sigma_{rc}^2 + \sigma_\epsilon^2 \) can be estimated), so BMS alone cannot be used to estimate \( \sigma_r^2 \).
Under model (M3A), however, there is no interaction (and thus no interaction variance component $\sigma^2_{rc}$), so $\rho_{A,k}$ or $\rho_{C,k}$ can be estimated.

The average AA-ICC, the absolute-agreement intraclass correlation for average measurements of size $k$, is

$$\rho_{A,k} = \text{ICC}(A,k) = \frac{\sigma^2_r}{\sigma^2_r + (\theta^2_c + \sigma^2_\epsilon)/k}$$

The average CA-ICC, the correlation between average measurements of size $k$ made on the same target, is

$$\rho_{C,k} = \text{ICC}(C,k) = \text{Corr}(\bar{y}_{i.}, \bar{y}'_{i.}) = \frac{\sigma^2_r}{\sigma^2_r + \sigma^2_\epsilon/k}$$

The estimators of ICCs, their confidence intervals, and hypothesis tests are as described for two-way random-effects models, except $\rho_{A,k}$ and $\rho_{C,k}$ are not defined under model (M3).

Remarks and examples

Stata does not have commands for inequality measures, except `roctab` has an option to report Gini and Pietra indices; see `[R] roctab`. Stata users, however, have developed an excellent suite of commands, many of which have been published in the *Stata Journal* (SJ) and in the *Stata Technical Bulletin* (STB).

Max Otto Lorenz (1876–1959) was born in Iowa and studied at the Universities of Iowa and Wisconsin. He proposed what is now known as the Lorenz curve in 1905. Lorenz worked for the Interstate Commerce Commission between 1911 and 1944, mainly with transportation data. His hobbies included calendar reform and Interlingua, a proposed international language.

To download and install the Jenkins and Van Kerm `g1curve` command from the Internet, for instance, you could

1. Select **Help > SJ and User-written Programs**.
2. Click on **Stata Journal**.
3. Click on `sj7-2`.
4. Click on `gr0001_3`.
5. Click on *click here to install*.

or you could instead do the following:

1. Navigate to the appropriate `SJ` issue:
   a. Type `net from http://www.stata-journal.com/software`  
      `Type net cd sj7-2`
   or
   b. Type `net from http://www.stata-journal.com/software/sj7-2`
2. Type `net describe gr0001_3`
3. Type `net install gr0001_3`

To download and install the Jenkins `sumdist` command from the Internet, for instance, you could

1. Select **Help > SJ and User-written Programs**.
2. Click on **STB**.
3. Click on `stb48`.
4. Click on `sg104`.
5. Click on *click here to install*.

or you could instead do the following:

1. Navigate to the appropriate `STB` issue:
   a. Type `net from http://www.stata.com`  
      `Type net cd stb`
      `Type net cd stb48`
   or
   b. Type `net from http://www.stata.com/stb/stb48`
2. Type `net describe sg104`
3. Type `net install sg104`

`indepvars` and `varlist` may contain factor variables; see [U] 11.4.3 Factor variables.

`depvar1`, `depvar2`, `indepvars`, and `varlist` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`bootstrap`, `by`, `fp`, `jackknife`, `mfp`, `nestreg`, `rolling`, `statsby`, `stepwise`, and `svy` are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

`aweights` are not allowed with the jackknife prefix; see [R] jackknife.

`vce()` and weights are not allowed with the svy prefix; see [SVY] svy.

`aweights`, `fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 weight.

`coeflegend` does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
**Description**

`intreg` fits a model of \( y = [\text{depvar}_1, \text{depvar}_2] \) on \( \text{indepvars} \), where \( y \) for each observation is point data, interval data, left-censored data, or right-censored data.

\( \text{depvar}_1 \) and \( \text{depvar}_2 \) should have the following form:

<table>
<thead>
<tr>
<th>Type of data</th>
<th>( \text{depvar}_1 )</th>
<th>( \text{depvar}_2 )</th>
</tr>
</thead>
<tbody>
<tr>
<td>point data</td>
<td>( a = [a, a] )</td>
<td>( a )</td>
</tr>
<tr>
<td>interval data</td>
<td>( [a, b] )</td>
<td>( a )</td>
</tr>
<tr>
<td>left-censored data</td>
<td>( (-\infty, b] )</td>
<td>( . )</td>
</tr>
<tr>
<td>right-censored data</td>
<td>( [a, +\infty) )</td>
<td>( . )</td>
</tr>
</tbody>
</table>

**Options**

- **Model**
  - `noconstant`; see [R] estimation options.
  - `het(\text{varlist} [, \text{noconstant}] )` specifies that \( \text{varlist} \) be included in the specification of the conditional variance. This \( \text{varlist} \) enters the variance specification collectively as multiplicative heteroskedasticity.
  - `offset(\text{varname})`, `constraints(\text{constraints})`, `collinear`; see [R] estimation options.

- **SE/Robust**
  - `vce(\text{vcetype})` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\text{oim}, \text{opg}), that are robust to some kinds of misspecification (\text{robust}), that allow for intragroup correlation (\text{cluster} \text{clustvar}), and that use bootstrap or jackknife methods (\text{bootstrap}, \text{jackknife}); see [R] vce_option.

- **Reporting**
  - `level(#)`; see [R] estimation options.
  - `nocnsreport`; see [R] estimation options.
  - `display_options`: `nolemit`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fwidth`, `fwidth(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] estimation options.

- **Maximization**
  - `maximize_options`: `difficult`, `technique(\text{algorithm_spec})`, `iterate(#)`, `[no]\text{log}`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] maximize. These options are seldom used.

Setting the optimization type to `technique(bhhh)` resets the default \text{vcetype} to `vce(opg).`
The following option is available with \texttt{intreg} but is not shown in the dialog box: \texttt{coeflegend}; see \cite{R} estimation options.

Remarks and examples

\texttt{intreg} is a generalization of the models fit by \texttt{tobit}. \citet*{cameron2010microeconomics} discuss the differences among censored, truncated, and interval data. If you know that the value for the \(j\)th individual is somewhere in the interval \([y_{1j}, y_{2j}]\), then the likelihood contribution from this individual is simply \(\Pr(y_{1j} \leq Y_j \leq y_{2j})\). For censored data, their likelihoods contain terms of the form \(\Pr(Y_j \leq y_j)\) for left-censored data and \(\Pr(Y_j \geq y_j)\) for right-censored data, where \(y_j\) is the observed censoring value and \(Y_j\) denotes the random variable representing the dependent variable in the model.

Hence, \texttt{intreg} can fit models for data where each observation represents interval data, left-censored data, right-censored data, or point data. Regardless of the type of observation, the data should be stored in the dataset as interval data; that is, two dependent variables, \texttt{depvar1} and \texttt{depvar2}, are used to hold the endpoints of the interval. If the data are left-censored, the lower endpoint is \(-\infty\) and is represented by a missing value, ‘.’, or an extended missing value, ‘.a, .b, …, .z’, in \texttt{depvar1}. If the data are right-censored, the upper endpoint is \(+\infty\) and is represented by a missing value, ‘.’ (or an extended missing value), in \texttt{depvar2}. Point data are represented by the two endpoints being equal.

<table>
<thead>
<tr>
<th>Type of data</th>
<th>\texttt{depvar1}</th>
<th>\texttt{depvar2}</th>
</tr>
</thead>
<tbody>
<tr>
<td>point data</td>
<td>(a = [a, a])</td>
<td>(a)</td>
</tr>
<tr>
<td>interval data</td>
<td>([a, b])</td>
<td>(a)</td>
</tr>
<tr>
<td>left-censored data</td>
<td>((-\infty, b])</td>
<td>(.)</td>
</tr>
<tr>
<td>right-censored data</td>
<td>([a, +\infty))</td>
<td>(a)</td>
</tr>
</tbody>
</table>

Truly missing values of the dependent variable must be represented by missing values in both \texttt{depvar1} and \texttt{depvar2}.

Interval data arise naturally in many contexts, such as wage data. Often you know only that, for example, a person’s salary is between $30,000 and $40,000. Below we give an example for wage data and show how to set up \texttt{depvar1} and \texttt{depvar2}.

\begin{itemize}
  \item \textbf{Example 1}
\end{itemize}

We have a dataset that contains the yearly wages of working women. Women were asked via a questionnaire to indicate a category for their yearly income from employment. The categories were less than 5,000, 5,001–10,000, \ldots, 25,001–30,000, 30,001–40,000, 40,001–50,000, and more than 50,000. The wage categories are stored in the \texttt{wagecat} variable.
. use http://www.stata-press.com/data/r13/womenwage
  (Wages of women)

</table>

A value of 5 for wagecat represents the category less than 5,000, a value of 10 represents 5,001–10,000, ..., and a value of 51 represents greater than 50,000.

To use intreg, we must create two variables, wage1 and wage2, containing the lower and upper endpoints of the wage categories. Here is one way to do it. We first create a dataset containing the nine wage categories, lag the wage categories into wage1, and match-merge this dataset with nine observations back into the main one.

. by wagecat: keep if _n==1
  (479 observations deleted)
. generate wage1 = wagecat[_n-1]
  (1 missing value generated)
. keep wagecat wage1
. save lagwage
  file lagwage.dta saved
. use http://www.stata-press.com/data/r13/womenwage
  (Wages of women)
. merge m:1 wagecat using lagwage
  Result # of obs.
  not matched 0
  matched 488 (_merge==3)

Now we create the upper endpoint and list the new variables:

. generate wage2 = wagecat
. replace wage2 = . if wagecat == 51
  (6 real changes made, 6 to missing)
. sort age, stable
We can now run `intreg`:

```
. intreg wage1 wage2 age c.age#c.age nev_mar rural school tenure
```

Fitting constant-only model:

Iteration 0: log likelihood = -967.24956  
Iteration 1: log likelihood = -967.1368  
Iteration 2: log likelihood = -967.1368

Fitting full model:

Iteration 0: log likelihood = -856.65324  
Iteration 1: log likelihood = -856.33294  
Iteration 2: log likelihood = -856.33293

Interval regression  
Number of obs = 488  
LR chi2(6) = 221.61  
Log likelihood = -856.33293  
Prob > chi2 = 0.0000

Observation summary:  
14 left-censored observations  
0 uncensored observations  
6 right-censored observations  
468 interval observations
We could also model these data by using an ordered probit model with `oprobit` (see \[R\] `oprobit`):

```
. oprobit wagecat age c.age#c.age nev_mar rural school tenure
```

Iteration 0: log likelihood = -881.1491
Iteration 1: log likelihood = -764.31729
Iteration 2: log likelihood = -763.31191
Iteration 3: log likelihood = -763.31049
Iteration 4: log likelihood = -763.31049

Ordered probit regression

```
Log likelihood = -763.31049
```

We can directly compare the log likelihoods for the `intreg` and `oprobit` models because both likelihoods are discrete. If we had point data in our `intreg` estimation, the likelihood would be a mixture of discrete and continuous terms, and we could not compare it directly with the `oprobit` likelihood.

Here the `oprobit` log likelihood is significantly larger (that is, less negative), so it fits better than the `intreg` model. The `intreg` model assumes normality, but the distribution of wages is skewed and definitely nonnormal. Normality is more closely approximated if we model the log of wages.
. generate logwage1 = log(wage1)
(14 missing values generated)
. generate logwage2 = log(wage2)
(6 missing values generated)
. intreg logwage1 logwage2 age c.age#c.age nev_mar rural school tenure

Fitting constant-only model:
Iteration 0:  log likelihood = -889.23647
Iteration 1:  log likelihood = -889.06346
Iteration 2:  log likelihood = -889.06346

Fitting full model:
Iteration 0:  log likelihood = -773.81968
Iteration 1:  log likelihood = -773.36566
Iteration 2:  log likelihood = -773.36563

Observation summary: 14 left-censored observations
0 uncensored observations
6 right-censored observations
468 interval observations

The log likelihood of this intreg model is close to the oprobit log likelihood, and the z statistics for both models are similar.

Technical note

intreg has two parameterizations for the log-likelihood function: the transformed parameterization ($\beta/\sigma, 1/\sigma$) and the untransformed parameterization ($\beta, \ln(\sigma)$). By default, the log likelihood for intreg is parameterized in the transformed parameter space. This parameterization tends to be more convergent, but it requires that any starting values and constraints have the same parameterization, and it prevents the estimation with multiplicative heteroskedasticity. Therefore, when the het() option is specified, intreg switches to the untransformed log likelihood for the fit of the conditional-variance model. Similarly, specifying from() or constraints() causes the optimization in the untransformed parameter space to allow constraints on (and starting values for) the coefficients on the covariates without reference to $\sigma$.

The estimation results are all stored in the ($\beta, \ln(\sigma)$) metric.
intreg stores the following in \texttt{e()}: 

**Scalars**
- \texttt{e(N)}: number of observations
- \texttt{e(N_unc)}: number of uncensored observations
- \texttt{e(N_lc)}: number of left-censored observations
- \texttt{e(N_rc)}: number of right-censored observations
- \texttt{e(N_int)}: number of interval observations
- \texttt{e(k)}: number of parameters
- \texttt{e(k_aux)}: number of auxiliary parameters
- \texttt{e(k_eq)}: number of equations in \texttt{e(b)}
- \texttt{e(k_eq_model)}: number of equations in overall model test
- \texttt{e(df_m)}: model degrees of freedom
- \texttt{e(ll)}: log likelihood
- \texttt{e(ll_0)}: log likelihood, constant-only model
- \texttt{e(ll_c)}: log likelihood, comparison model
- \texttt{e(N_clust)}: number of clusters
- \texttt{e(chi2)}: \(\chi^2\)
- \texttt{e(p)}: \(p\)-value for model \(\chi^2\) test
- \texttt{e(sigma)}: \(\sigma\)
- \texttt{e(se_sigma)}: standard error of \(\sigma\)
- \texttt{e(rank)}: rank of \texttt{e(V)}
- \texttt{e(rank0)}: rank of \texttt{e(V)} for constant-only model
- \texttt{e(ic)}: number of iterations
- \texttt{e(rc)}: return code
- \texttt{e(converged)}: 1 if converged, 0 otherwise

**Macros**
- \texttt{e(cmd)}: \texttt{intreg}
- \texttt{e(cmdline)}: command as typed
- \texttt{e(depvar)}: names of dependent variables
- \texttt{e(wtype)}: weight type
- \texttt{e(wexp)}: weight expression
- \texttt{e(title)}: title in estimation output
- \texttt{e(clustvar)}: name of cluster variable
- \texttt{e(offset)}: linear offset variable
- \texttt{e(chi2type)}: Wald or LR; type of model \(\chi^2\) test
- \texttt{e(vc)}: \texttt{vcetype} specified in \texttt{vce()}
- \texttt{e(vcetype)}: title used to label Std. Err.
- \texttt{e(het)}: heteroskedasticity, if \texttt{het()} specified
- \texttt{e(ml_score)}: program used to implement scores
- \texttt{e(opt)}: type of optimization
- \texttt{e(which)}: \texttt{max} or \texttt{min}; whether optimizer is to perform maximization or minimization
- \texttt{e(ml_method)}: type of \texttt{ml} method
- \texttt{e(user)}: name of likelihood-evaluator program
- \texttt{e(technique)}: maximization technique
- \texttt{e(properties)}: \texttt{b \ V}
- \texttt{e(predict)}: program used to implement \texttt{predict}
- \texttt{e(footnote)}: program and arguments to display footnote
- \texttt{e(asbalanced)}: factor variables \texttt{fvset} as \texttt{asbalanced}
- \texttt{e(asobserved)}: factor variables \texttt{fvset} as \texttt{asobserved}

**Matrices**
- \texttt{e(b)}: coefficient vector
- \texttt{e(Cns)}: constraints matrix
- \texttt{e(ilog)}: iteration log (up to 20 iterations)
- \texttt{e(gradient)}: gradient vector
- \texttt{e(V)}: variance–covariance matrix of the estimators
- \texttt{e(V_modelbased)}: model-based variance

**Functions**
- \texttt{e(sample)}: marks estimation sample
Methods and formulas

See Wooldridge (2013, sec. 17.4) or Davidson and MacKinnon (2004, sec. 11.6) for an introduction to censored and truncated regression models.

The likelihood for \texttt{intreg} subsumes that of the \texttt{tobit} models.

Let \( y = X\beta + \epsilon \) be the model. \( y \) represents continuous outcomes—either observed or not observed. Our model assumes \( \epsilon \sim \mathcal{N}(0, \sigma^2 I) \).

For observations \( j \in \mathcal{C} \), we observe \( y_j \), that is, point data. Observations \( j \in \mathcal{L} \) are left-censored; we know only that the unobserved \( y_j \) is less than or equal to \( y_{\mathcal{L}j} \), a censoring value that we do know. Similarly, observations \( j \in \mathcal{R} \) are right-censored; we know only that the unobserved \( y_j \) is greater than or equal to \( y_{\mathcal{R}j} \). Observations \( j \in \mathcal{I} \) are intervals; we know only that the unobserved \( y_j \) is in the interval \([ y_{1j}, y_{2j} ]\).

The log likelihood is

\[
\ln L = -\frac{1}{2} \sum_{j \in \mathcal{C}} w_j \left\{ \left( \frac{y_j - x\beta}{\sigma} \right)^2 + \log 2\pi \sigma^2 \right\} \\
+ \sum_{j \in \mathcal{L}} w_j \log \Phi\left( \frac{y_{\mathcal{L}j} - x\beta}{\sigma} \right) \\
+ \sum_{j \in \mathcal{R}} w_j \log \left\{ 1 - \Phi\left( \frac{y_{\mathcal{R}j} - x\beta}{\sigma} \right) \right\} \\
+ \sum_{j \in \mathcal{I}} w_j \log \left\{ \Phi\left( \frac{y_{2j} - x\beta}{\sigma} \right) - \Phi\left( \frac{y_{1j} - x\beta}{\sigma} \right) \right\}
\]

where \( \Phi() \) is the standard cumulative normal and \( w_j \) is the weight for the \( j \)th observation. If no weights are specified, \( w_j = 1 \). If \texttt{aweights} are specified, \( w_j = 1 \), and \( \sigma \) is replaced by \( \sigma/\sqrt{a_j} \) in the above, where \( a_j \) are the \texttt{aweights} normalized to sum to \( N \).

Maximization is as described in \texttt{[R] maximize}; the estimate reported as \_sigma is \( \hat{\sigma} \).

See Amemiya (1973) for a generalization of the tobit model to variable, but known, cutoffs.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \texttt{[P] _robust}, particularly \texttt{Maximum likelihood estimators} and \texttt{Methods and formulas}.

\texttt{intreg} also supports estimation with survey data. For details on VCEs with survey data, see \texttt{[SVY] variance estimation}.

intreg postestimation — Postestimation tools for intreg

Description

The following postestimation commands are available after `intreg`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>contrast</code></td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td><code>estat ic</code></td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td><code>estat summarize</code></td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>lincom</code></td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td><code>lrtest¹</code></td>
<td>likelihood-ratio test</td>
</tr>
<tr>
<td><code>margins</code></td>
<td>marginal means, predictive margins, marginal effects, and average marginal effects</td>
</tr>
<tr>
<td><code>marginsplot</code></td>
<td>graph the results from margins (profile plots, interaction plots, etc.)</td>
</tr>
<tr>
<td><code>nlcom</code></td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td><code>predict</code></td>
<td>predictions, residuals, influence statistics, and other diagnostic measures</td>
</tr>
<tr>
<td><code>predictnl</code></td>
<td>point estimates, standard errors, testing, and inference for generalized predictions</td>
</tr>
<tr>
<td><code>pwcompare</code></td>
<td>pairwise comparisons of estimates</td>
</tr>
<tr>
<td><code>suest</code></td>
<td>seemingly unrelated estimation</td>
</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

¹ `lrtest` is not appropriate with `svy` estimation results.
Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
predict [type] { stub*| newvar_reg newvar_insigma } [if] [in], scores
```

**statistic**

<table>
<thead>
<tr>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Main</strong></td>
</tr>
<tr>
<td><strong>xb</strong></td>
</tr>
<tr>
<td><strong>stdp</strong></td>
</tr>
<tr>
<td><strong>stdf</strong></td>
</tr>
<tr>
<td><strong>pr(a,b)</strong></td>
</tr>
<tr>
<td><strong>e(a,b)</strong></td>
</tr>
<tr>
<td><strong>ystar(a,b)</strong></td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

`stdf` is not allowed with `svy` postestimation results.

where `a` and `b` may be numbers or variables; `a` missing \((a \geq .)\) means \(-\infty\), and `b` missing \((b \geq .)\) means \(+\infty\); see [U] 12.2.1 Missing values.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

---

- **Main**: `xb`, the default, calculates the linear prediction.
- **stdp** calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.
- **stdf** calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by `stdf` are always larger than those produced by `stdp`; see Methods and formulas in [R] regress postestimation.
- **pr(a,b)** calculates \( Pr(a < x_j b + u_j < b) \), the probability that \( y_j | x_j \) would be observed in the interval \((a, b)\).
- `a` and `b` may be specified as numbers or variable names; `lb` and `ub` are variable names;
- `pr(20,30)` calculates \( Pr(20 < x_j b + u_j < 30) \);
- `pr(lb,ub)` calculates \( Pr(lb < x_j b + u_j < ub) \) and `pr(20,ub)` calculates \( Pr(20 < x_j b + u_j < ub) \).
- `a` missing \((a \geq .)\) means \(-\infty\); `pr(.,30)` calculates \( Pr(-\infty < x_j b + u_j < 30) \);
- `pr(lb,30)` calculates \( Pr(-\infty < x_j b + u_j < 30) \) in observations for which `lb` \(\geq .\) and calculates \( Pr(lb < x_j b + u_j < 30) \) elsewhere.
b missing \( (b \geq .) \) means \(+\infty\); \( \text{pr}(20, .) \) calculates \( \Pr(\, +\infty > x_j b + u_j > 20) \);
\( \text{pr}(20, ub) \) calculates \( \Pr(\, +\infty > x_j b + u_j > 20) \) in observations for which \( ub \geq . \)
and calculates \( \Pr(20 < x_j b + u_j < ub) \) elsewhere.

\( \text{e}(a, b) \) calculates \( E(x_j b + u_j \mid a < x_j b + u_j < b) \), the expected value of \( y_j \mid x_j \) conditional on \( y_j \mid x_j \) being in the interval \((a, b)\), meaning that \( y_j \mid x_j \) is truncated.

\( a \) and \( b \) are specified as they are for \( \text{pr}() \).

\( \text{ystar}(a, b) \) calculates \( E(y_j^\ast) \), where
\( y_j^\ast = a \) if \( x_j b + u_j \leq a \),
\( y_j^\ast = b \) if \( x_j b + u_j \geq b \), and
\( y_j^\ast = x_j b + u_j \) otherwise, meaning that \( y_j^\ast \) is censored. \( a \) and \( b \) are specified as they are for \( \text{pr}() \).

\text{nooffset} is relevant only if you specified \text{offset}(\text{varname})\. It modifies the calculations made by \text{predict} so that they ignore the offset variable; the linear prediction is treated as \( x_j b \) rather than as \( x_j b + \text{offset}_j \).

\text{scores} calculates equation-level score variables.

The first new variable will contain \( \partial \ln L/\partial(x_j \beta) \).

The second new variable will contain \( \partial \ln L/\partial \ln \sigma \).

## Remarks and examples

### Example 1

We continue with example 1 of [R] \texttt{intreg}.

```
. use http://www.stata-press.com/data/r13/intregxmpl
. intreg wage1 wage2 age c.age#c.age nev_mar rural school tenure
(output omitted)
```

By default, the \texttt{predict} command produces the linear prediction, which in this case is the expected wage for each individual.

```
. predict w1
   (option xb assumed; fitted values)
```

We can use the \( \text{e}(a, b) \) option to compute the expected wage, conditional on it being larger than \$5,000:

```
. predict w2, e(5,.)
```

The probability of earning more than \$5,000 might vary with age. We can use \texttt{margins} to compute the marginal means for those probabilities for different ages.
```stata
. margins, predict(pr(5,.)) at(age=(20(5)50))

Predictive margins                  Number of obs = 488
Model VCE : OIM                      Number of obs = 488
Expression : Pr(y>5), predict(pr(5,.))

options

Model

noconstant
suppress constant term

exposure(varname)
include ln(varname) in model with coefficient constrained to 1

offset(varname)
include varname in model with coefficient constrained to 1

*twostep
use two-step GMM estimator; the default for ivpoisson gmm

*onestep
use one-step GMM estimator; the default for ivpoisson cfunction

*i
use iterative GMM estimator

Weight matrix

wmatrix(wmttype)
specify weight matrix; wmttype may be robust, cluster clustvar, or unadjusted

center
center moments in weight-matrix computation

winitial(iwtype[, independent])
specify initial weight matrix; iwtype may be unadjusted, identity, or the name of a Stata matrix

SE/Robust

vce(vcetype)
vcetype may be robust, cluster clustvar, bootstrap, jackknife, or unadjusted

Reporting

level(#)set confidence level; default is level(95)

irr
report incidence-rate ratios

display_options
control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

Optimization

from(initial_values)
specify initial values for parameters

†igmmiterate(#)specify maximum number of iterations for iterated GMM estimator

†igmmeps(#)specify # for iterated GMM parameter convergence criterion; default is igmmeps(1e-6)

†igmmweps(#)specify # for iterated GMM weight-matrix convergence criterion; default is igmmweps(1e-6)

optimization_options
control the optimization process; seldom used

* You can specify at most one of these options.
† These options may be specified only when igmm is specified.

varlist and varlist1v may contain factor variables; see [U] 11.4.3 Factor variables.
depvar, varlist1, varlist2, and varlist1v may contain time-series operators; see [U] 11.4.4 Time-series varlists.
bootstrap, by, jackknife, rolling, and statsby are allowed; see [U] 11.1.10 Prefix commands.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
aweights are not allowed with the jackknife prefix; see [R] jackknife.
aweights, fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
ivpoisson estimates the parameters of a Poisson regression model in which some of the regressors are endogenous. The model is also known as an exponential conditional mean model in which some of the regressors are endogenous. The model may be specified using either additive or multiplicative error terms. The model is frequently used to model count outcomes and is also used to model nonnegative outcome variables.

### Options

| Model | noconstant, exposure(varname$_e$), offset(varname$_o$); see [R] estimation options. |

- **additive**, the default, specifies that the regression errors be added to the conditional mean term and have mean 0.
- **multiplicative** specifies that the regression errors be multiplied by the conditional mean term and have mean 1.

- **twostep**, **onestep**, and **igmm** specify which estimator is to be used.
  - **twostep** requests the two-step GMM estimator. **gmm** obtains parameter estimates based on the initial weight matrix, computes a new weight matrix based on those estimates, and then reestimates the parameters based on that weight matrix. **twostep** is the default for ivpoisson **gmm**.
  - **onestep** requests the one-step GMM estimator. The parameters are estimated based on an initial weight matrix, and no updating of the weight matrix is performed except when calculating the appropriate variance–covariance (VCE) matrix. **onestep** is the default for ivpoisson **cfunction**.
  - **igmm** requests the iterative GMM estimator. **gmm** obtains parameter estimates based on the initial weight matrix, computes a new weight matrix based on those estimates, reestimates the parameters based on that weight matrix, computes a new weight matrix, and so on, to convergence. Convergence is declared when the relative change in the parameter vector is less than **igmmweps()**, the relative change in the weight matrix is less than **igmmweps()**, or **igmmiterate()** iterations have been completed. **Hall (2005, sec. 2.4 and 3.6)** mentions that there may be gains to finite-sample efficiency from using the iterative estimator.

| Weight matrix | wmatrix(wmtype) specifies the type of weight matrix to be used in conjunction with the two-step and iterated GMM estimators. |

- Specifying **wmatrix(robust)** requests a weight matrix that is appropriate when the errors are independent but not necessarily identically distributed. **wmatrix(robust)** is the default.
- Specifying **wmatrix(cluster clustvar)** requests a weight matrix that accounts for arbitrary correlation among observations within clusters identified by **clustvar**.
- Specifying **wmatrix(unadjusted)** requests a weight matrix that is suitable when the errors are homoskedastic.

**wmatrix()** cannot be specified if **onestep** is also specified.
center requests that the sample moments be centered (demeaned) when computing GMM weight matrices. By default, centering is not done.

`winitial(wmtype[, independent])` specifies the weight matrix to use to obtain the first-step parameter estimates.

Specifying `winitial(unadjusted)` requests a weighting matrix that assumes the error functions are independent and identically distributed. This matrix is of the form $(Z'Z)^{-1}$, where $Z$ represents all the exogenous and instrumental variables.

`winitial(identity)` requests that the identity matrix be used.

`winitial(matname)` requests that Stata matrix `matname` be used.

Including the `independent` suboption creates a weight matrix that assumes error functions are independent. Elements of the weight matrix corresponding to covariances between any two error functions are set equal to zero. This suboption only applies to `ivpoisson cfunction`.

`winitial(unadjusted)` is the default for `ivpoisson gmm`.

`winitial(unadjusted, independent)` is the default for `ivpoisson cfunction`.

---

`vce(vcetype)` specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] `vce_option`.

`vce(unadjusted)` specifies that an unadjusted (nonrobust) VCE matrix be used; this, along with the `twostep` option, results in the “optimal two-step GMM” estimates often discussed in textbooks. `vce(unadjusted)` may not be set in `ivpoisson cfunction`.

The default `vcetype` is based on the `wmtype` specified in the `wmatrix()` option. If `wmatrix()` is specified but `vce()` is not, then `vcetype` is set equal to `wmtype`. To override this behavior in `ivpoisson gmm` and obtain an unadjusted (nonrobust) VCE matrix, specify `vce(unadjusted)`. The default `vcetype` for `ivpoisson cfunction` is `robust`.

Specifying `vce(bootstrap)` or `vce(jackknife)` results in standard errors based on the bootstrap or jackknife, respectively. See [R] `vce_option`, [R] `bootstrap`, and [R] `jackknife` for more information on these VCEs.

The syntax for `vcetypess` is identical to those for `wmatrix()`.

---

`level(#); see [R] estimation options.`

`irr` reports estimated coefficients transformed to incidence-rate ratios, that is, $e^{\beta_i}$ rather than $\beta_i$.

Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. `irr` may be specified at estimation or when replaying previously estimated results. `irr` is not allowed with `additive`.

`display_options: nomitted, vsquish, noemptycells, baselevels, allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.`

---

`from(initial_values)` specifies the initial values to begin the estimation. You can specify a $1 \times k$ matrix, where $k$ is the number of parameters in the model, or you can specify a parameter name,
ivpoisson estimates the parameters of a Poisson regression model in which some of the regressors are endogenous. A regressor is endogenous if it is related to the unobserved error term. The model is also known as an exponential conditional mean model in which some of the regressors are endogenous. The model may be specified using either additive or multiplicative error terms.

The model is frequently used to model count outcomes and is also used to model nonnegative outcome variables. Poisson regression is a special exponential conditional mean model. See [R] poisson for more information on Poisson regression.

The exponential conditional mean model has an error form representation in which the dependent variable \( y \) is a function of the exogenous regressors \( x \), endogenous regressors \( y_2 \), and an error \( \epsilon \). The regressors \( x \) are independent of \( \epsilon \), while \( y_2 \) are not.

ivpoisson allows \( \epsilon \) to enter either additively,

\[
y_i = \exp(x_i'\beta_1 + y_2,i\beta_2) + \epsilon_i
\]

or multiplicatively,

\[
y_i = \exp(x_i'\beta_1 + y_2,i\beta_2)\epsilon_i
\]
Mullahy (1997), Cameron and Trivedi (2013), Windmeijer and Santos Silva (1997), and Wooldridge (2010) discuss the generalized method of moments (GMM) estimators implemented in `ivpoisson`. GMM is frequently used in modern econometrics. Many econometric and statistical models can be expressed as conditions on the population moments. The parameter estimates produced by GMM estimators make the sample-moment conditions as true as possible given the data. See [R] `gmm` for further information on GMM estimation and how Stata performs it.

The rest of the discussion is presented under the following headings:

- **GMM estimator for additive model**
- **GMM estimator for multiplicative model**
- **CF estimator for multiplicative model**

### GMM estimator for additive model

The GMM estimator uses additional variables, known as instruments and denoted by $z_i$, to specify moment conditions that hold in the population. The GMM parameter estimates make the sample versions of these population-moment conditions as close to true as possible. The instrumental variables are assumed to be correlated with the endogenous regressors $y_{2,i}$ but independent of the errors $\epsilon_i$.

Under additive errors, the dependent variable $y_i$ is determined by exogenous regressors $x_i$, endogenous regressors $y_{2,i}$, and zero-mean error $\epsilon_i$ as

$$y_i = \exp(x_i'\beta_1 + y_{2,i}'\beta_2) + \epsilon_i$$

This leads to the following error function

$$u(y_i, x_i, y_{2,i}, \beta_1, \beta_2) = y_i - \exp(x_i'\beta_1 + y_{2,i}'\beta_2)$$

The population-moment conditions for GMM estimation are $E \{ \tilde{z}_i u(y_i, x_i, y_{2,i}, \beta_1, \beta_2) \} = 0$, where the vector $\tilde{z}_i$ is partitioned as $(x_i', z_i')$. The sample-moment conditions are formed by replacing the expectation with the corresponding sample mean. The GMM estimator solves a minimization problem to make the sample-moment conditions as close to zero as possible. Details on how estimation is performed are given in *Methods and formulas*.

Now we will demonstrate how `ivpoisson gmm` works in the additive error setting with an example.

#### Example 1: ivpoisson gmm with additive errors

This example uses simulated data based on the following story. A news website randomly samples 500 young adults in a major city. The website wants to model the number of times the sampled individuals visit its website (`visits`) based on their overall time spent on the Internet (`time`) and the number of times they receive an ad for the website through email or viewing another website (`ad`). The website also suspects the gender of the individual may matter, so an exogenous dummy variable, `female`, is included in the model.

We suspect time spent on the Internet is correlated with unobserved factors that additively affect the number of times an individual visits the website. So we treat `time` as an endogenous regressor. Two instruments are used for this variable. The time spent on the phone (`phone`) is one instrument. The other instrument is the time spent interacting with friends and family that live out of town (`frfam`).

We model the number of visits the website receives using an exponential conditional mean model with additive errors and use `ivpoisson gmm` to estimate the parameters of the regression in the output below. To allow for heteroskedasticity of the errors, we use robust standard errors, which is the default; see *Obtaining standard errors* in [R] `gmm` for a discussion of why robust standard errors is the default.
. use http://www.stata-press.com/data/r13/website
  (Visits to website)
  . ivpoisson gmm visits ad female (time = phone frfam)

Step 1
Iteration 0:  GMM criterion Q(b) = .33829416
Iteration 1:  GMM criterion Q(b) = .00362656
Iteration 2:  GMM criterion Q(b) = .00131886
Iteration 3:  GMM criterion Q(b) = .00131876
Step 2
Iteration 0:  GMM criterion Q(b) = .00027102
Iteration 1:  GMM criterion Q(b) = .00025811
Iteration 2:  GMM criterion Q(b) = .00025811

Exponential mean model with endogenous regressors
Number of parameters = 4  Number of obs = 500
Number of moments = 5
Initial weight matrix: Unadjusted
GMM weight matrix:   Robust

visits  Robust
       |   Coef. Std. Err.      z    P>|z|   [95% Conf. Interval]
---|----------------------|----------------------|-------|-------|----------------------|----------------------|----------------------|
  time |  .0589294  .0107942  5.46  0.000    .0377732   .0800857
  ad   |  .137344   .010157  13.52  0.000    .1174366   .1572515
female| -.0247707  .0376218 -0.66  0.510   -.098508   .0489666
_cons |  1.041505  .0385848  26.99  0.000   .9658807  1.117130

Instrumented:  time
Instruments:   ad female phone frfam

We find significant coefficients for all regressors but female. At fixed values of the other regressors, increased time spent on the Internet will raise the expected number of website visits. Receiving additional advertisements will also cause an increase in the expected number of website visits.

GMM estimator for multiplicative model

Under multiplicative errors, the dependent variable $y_i$ is determined by exogenous regressors $x_i$, endogenous regressors $y_{2,i}$, and unit-mean errors $\epsilon_i$ as

$$y_i = \exp(x'_i \beta_1 + y'_{2,i} \beta_2) \epsilon_i$$

This setting yields a different error function than the additive error case. This ratio formulation is

$$u(y_i, x_i, y_{2,i}, \beta_1, \beta_2) = y_i / \exp(x'_i \beta_1 + y'_{2,i} \beta_2) - 1$$

Given the instrumental variables $z$, the population-moment conditions for GMM estimation are $E \{Z_i u(y_i, x_i, y_{2,i}, \beta_1, \beta_2)\} = 0$. The vector $Z_i$ is partitioned as $(x'_i, z'_i)$. As above, the sample-moment conditions are the sample analogs of the population-moment conditions, and the GMM estimator solves a minimization problem to make the sample-moment conditions as close to zero as possible. Details on how estimation is performed are given in Methods and formulas.
Example 2: ivpoisson gmm with multiplicative errors

In this example, we observe a simulated random sample of 5,000 households. We model the number of trips taken by members of the household in the 24-hour period immediately prior to the interview time by using an exponential conditional mean model with multiplicative errors. Exogenous regressors include the distance to the central business district from the household (cbd), the distance from the household to a public transit node (ptn), whether there is a full-time worker in the household (worker), and whether the examined period is on a weekend (weekend). We suspect that the endogenous regressor, the transportation cost of the household in the prior week (tcost), is correlated with unobserved factors that affect the number of trips taken. This transportation cost includes gasoline and bus, train tickets, etc.

The ratio of the cost of a public transit day pass in the sampled area to the national average cost of such a pass (pt) is also observed. This is used as an instrument for transportation cost.

In the output below, we estimate the parameters of the regression with ivpoisson gmm. To allow for heteroskedasticity of the errors, we use robust standard errors, which is the default.

```
. use http://www.stata-press.com/data/r13/trip
  (Household trips)
. ivpoisson gmm trips cbd ptn worker weekend (tcost = pt), multiplicative
```

```
Step 1
Iteration 0:  GMM criterion Q(b) = 0.04949852
Iteration 1:  GMM criterion Q(b) = 0.00011194
Iteration 2:  GMM criterion Q(b) = 1.563e-08
Iteration 3:  GMM criterion Q(b) = 3.685e-16

Step 2
Iteration 0:  GMM criterion Q(b) = 2.287e-16
Iteration 1:  GMM criterion Q(b) = 1.413e-31

Exponential mean model with endogenous regressors
Number of parameters = 6  Number of obs = 5000
Number of moments = 6

```

We find that all coefficients are significant. At fixed values of the other regressors, we see that additional mileage from the central business district and public transit nodes reduces the expected number of trips taken. Individuals who live farther away from the central business district may still be out of the house the same amount of time, but they will take fewer trips because the transit time has increased. The situation is similar for those who live farther from public transit.

To interpret the other parameters, we will look at the partial effects of their respective independent variables. The partial effects of a change in an independent variable on the modeled conditional expectation function vary over the data because the model is nonlinear. However, under the multiplicative
error model, the ratio of the new value to the old value after a discrete change in an independent variable is constant over the data.

Let \( w = (x', y_2')' \). If we add 1 to the \( j \)th independent variable in \( w \), the functional form of the model implies that

\[
\frac{E(y|w, w_j + 1, \epsilon)}{E(y|w, w_j, \epsilon)} = \frac{E(y|w_1, \ldots, w_j + 1, \ldots, w_k, \epsilon)}{E(y|w_1, \ldots, w_j, \ldots, w_k, \epsilon)} = e^{\beta_j}
\]

When \( y \) is a count variable, this normalized effect is called the incidence-rate ratio (IRR) for a one-unit change in \( w_j \).

More generally, the IRR for a \( \Delta w_j \) change in \( w_j \) is \( e^{\beta_j \Delta w_j} \) under a multiplicative-error exponential conditional mean model. We can calculate incidence-rate ratios for different changes in the regressors by using \( \text{lincom} \); see \[R\] \( \text{lincom} \).

Here we replay the \( \text{ivpoisson} \) results by typing the command name and we specify the \( \text{irr} \) option to get the incidence-rate ratios. Each significance test for a coefficient equaling zero becomes a test for the incidence-rate ratio equaling one.

Instrumented: tcost

Instruments: cbd ptn worker weekend pt

Holding other regressors and the error constant, the expected number of trips made from houses with a full-time worker is nearly twice that of those houses without a full-time worker. Similarly, the expected number of trips made during a weekend day is close to 35% higher than the expected number of trips made on other days. For each additional dollar of weekly transportation cost, the expected number of household trips is increased by approximately 3.6%.

**CF estimator for multiplicative model**

Control-function (CF) estimators can be used to account for endogenous regressors. As Wooldridge (2010, sec. 18.5) describes, CF estimators assume a certain structural relationship between the endogenous regressors and the exogenous regressors and use functions of first-stage parameter estimates to control for the endogeneity in the second stage.
Wooldridge (2010, sec. 18.5) notes that the VCE of the second-stage estimator must be adjusted to account for estimates from the first stage. *ivpoisson cfunction* solves this problem by stacking the moment conditions that define each stage and applying a single GMM estimator. See Newey (1984) and Wooldridge (2010, sec. 14.2) for a description of this technique. No adjustment to the VCE is necessary because there is only one stage.

The CF estimator augments the original multiplicative model with an estimated term that controls for the endogeneity of \( y_{2,i} \). When \( y_{2,i} \) is exogenous, the coefficient on this control term is zero. Let \( z \) be instrumental variables, and the vector \( \tilde{z}_i \) be \((x'_i, z'_i)\).

The augmented model is

\[
y_i = \exp(x'_i\beta_1 + y'_i\beta_2 + v'_i\rho + c_i)
\]

where

\[
y_{2,i} = B\tilde{z}'_i + v_i
\]

The term \( v'_i\rho \) controls for the endogeneity of \( y_{2,i} \), and we normalize \( E\{\exp(c_i)\} = 1 \). The coefficient vector \( \rho \) measures the strength of the endogeneity of \( y_{2,i} \); \( y_{2,i} \) is exogenous when \( \rho = 0 \).

*ivpoisson cfunction* estimates \( \beta_1 \) and \( \beta_2 \) and the auxiliary parameters \( \rho \) and \( B \) by GMM; see *Methods and formulas* for details.

**Example 3: Control-function estimator**

We return to the previous example, where we estimated the parameters of an exponential conditional mean model for the number of trips taken by a household in a 24-hour period. We will estimate the parameters of the regression with the CF estimator method and compare our results with those obtained with the GMM estimator in example 2.

In the output below, we estimate the parameters of the regression with the *ivpoisson cfunction* command.
. ivpoisson cfunction trips cbd ptn worker weekend (tcost = pt)

Instrumented: tcost

Instrument:   cbd ptn worker weekend pt

The output table presents results for the estimated coefficients in each of three equations. First, in the trips equation, we see the results for the estimated coefficients in the equation for the dependent variable trips. Second, in the tcost equation, we see the estimated coefficients in the regression of tcost on the instrumental and exogenous variables. Third, the /c_tcost ancillary parameter corresponds to the estimate of $\rho$, the coefficient on the residual variable included to control for the endogeneity of tcost.

We find that all coefficients are significant in the exponential conditional mean equation, trips. The coefficient estimates in the trips equation are similar to the estimates obtained by the GMM estimator in example 2. That the estimated coefficient on the tcost control variable is significantly different from zero suggests that tcost is endogenous.

Methods and formulas

The estimators in ivpoisson are GMM estimators that can be expressed in terms of error functions and the instruments that are used to form the moment conditions. When offsets $o_j^\beta$ are used in the outcome variable equation, the following formulas apply with $x'_j \beta_1$ changed to $x'_j \beta_1 + o_j^\beta$.

The error functions for the GMM estimators are given in the text.

Here we provide some details about the form of the error function used by the CF estimator.

Recall that the multiplicative model is

$$ y_i = \exp(x'_i \beta_1 + y'_2, i \beta_2) \epsilon_i $$

We parameterize the endogenous variables in the form

$$ y_{2, i} = B \tilde{z}'_i + v_i $$

This allows us to decompose $\epsilon_i$ as

$$ \epsilon_i = \exp(v'_i \rho + c_i) $$

Given this setup, we obtain the following conditional mean:

$$ E(y|x_i, z_i, y_{2, i}, v_i) = \exp(x'_i \beta_1 + y'_2, i \beta_2 + v'_i \rho) $$

We estimate $v_i$ as the residuals of the linear regression of $y_{2, i}$ on $\tilde{z}_i$. The estimates of $v_i$ are used as additional regressors in the exponential conditional mean model for $y$ to estimate $\beta_1$, $\beta_2$, and $\rho$. In essence, the estimates of $v_i$ control for the endogeneity.

The error functions for the endogenous regressors are defined as

$$ u_{en,i}(y_{2, i}, \tilde{z}_i, B) = y_{2, i} - B \tilde{z}'_i $$

Now we define the error function for the dependent variable as

$$ u_y(y_i, x_i, y_{2, i}, u_{en,i}, \beta_1, \beta_2, \rho) = y_i/\exp(x'_i \beta_1 + y'_2, i \beta_2 + u'_{en,i} \rho) - 1 $$

$u_{en,i}$ will be vector valued if we have multiple endogenous regressors $y_{2, i}$. Call the dimension of $y_{2, i}$ $g$. $u_{en,i}$ and $u_{y,i}$ define $g + 1$ separate error functions. We will use variables $\tilde{z}_i$ to instrument each error function in $u_{en,i}$. So for error function $j = 1, \ldots, g$, we have the error function $u_{en,i,j}$ and the population-moment conditions $E(\tilde{z}_i u_{en,i,j}) = 0$.

We calculate $\tilde{v}_{o,i}$ previous to estimation as the residuals of the linear regression of $y_{2, i}$ on $\tilde{z}_i$. We use variables $x_i$, $y_{2, i}$, and $\tilde{v}_{o,i}$ to instrument the error function $u_y$. This leads to the population-moment conditions $E\{ (x'_i, y'_2, i, \tilde{v}_{o,i}) u_{y,i} \} = 0$

Details of GMM estimation can be found in Methods and formulas of [R] gmm. Determination of the weight matrix $W_N$ is discussed there.

Under the GMM estimation, the GMM estimators $\hat{\beta}_1$ and $\hat{\beta}_2$ are the values of $\beta_1$ and $\beta_2$ that minimize

$$ Q(\beta_1, \beta_2) = \left\{ \frac{1}{N} \sum_i \tilde{z}_i u_i (y_i, x_i, y_{2, i}, \beta_1, \beta_2) \right\}' W_N \left\{ \frac{1}{N} \sum_i \tilde{z}_i u_i (y_i, x_i, y_{2, i}, \beta_1, \beta_2) \right\} $$

(1)
for \( q \times q \) weight matrix \( W_N \), where \( q \) is the dimension of \( \tilde{z}_i \). The error functions \( u_i \) were defined in the text.

In the CF method, we have multiple error functions as defined above. We can stack the moment conditions and write them more compactly as \( Z_i' u_i(B, \beta_1, \beta_2, \rho) \), where

\[
Z_i = \begin{bmatrix}
x_i' & 0 & 0 & \cdots & 0 \\
0 & y_2,i' & 0 & \cdots & 0 \\
0 & 0 & \tilde{z}_i & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & \tilde{z}_i
\end{bmatrix}
\]

and

\[
u_i(B, \beta_1, \beta_2) = \begin{bmatrix} u_y(y_i, x_i, y_2,i, u_{en,i}, \beta_1, \beta_2, \rho) \\ u_{en}(y_2,i, \tilde{z}_i, B) \end{bmatrix}
\]

The matrix \( Z_i \) has \( g + 1 \) rows and \( k + gz \) columns, where \( k \) is the number of regressors for \( y_i \) and \( z \) is the number of exogenous regressors in \( \tilde{z}_i \).

The GMM estimators \( \hat{B}, \hat{\beta}_1, \hat{\beta}_2, \) and \( \hat{\rho} \) are the values of \( B, \beta_1, \beta_2, \) and \( \rho \) that minimize

\[
Q(B, \beta_1, \beta_2, \rho) = \left\{ N^{-1} \sum_{i=1}^{N} Z_i' u_i(B, \beta_1, \beta_2, \rho) \right\}' W_N \left\{ N^{-1} \sum_{i=1}^{N} Z_i' u_i(B, \beta_1, \beta_2, \rho) \right\}
\]

for \( (k + gz) \times (k + gz) \) weight matrix \( W_N \).

By default, \texttt{ivpoisson} minimizes (1) and (2) using the Gauss–Newton method. See Hayashi (2000, 498) for a derivation. This technique is typically faster than quasi-Newton methods and does not require second-order derivatives.

## Special-interest postestimation command

`estat overid` reports Hansen’s $J$ statistic, which is used to determine the validity of the overidentifying restrictions in a GMM model. `ivpoisson gmm` uses GMM estimation to obtain parameter estimates. Under additive and multiplicative errors, Hansen’s $J$ statistic can be accurately reported when more instruments than endogenous regressors are specified. It is not appropriate to report the $J$ statistic after `ivpoisson cfunction`, because a just-identified model is fit.
If the model is correctly specified in the sense that \( E \{ \tilde{z}_i u(y_i, x_i, y_{2,i}, \beta) \} = 0 \), then the sample analog to that condition should hold at the estimated value of \( \beta_1 \) and \( \beta_2 \). The \( \tilde{z}_i \) variables are the exogenous regressors \( x_i \) and instrumental variables \( z_i \) used in \( \text{ivpoisson gmm} \). The \( y_{2,i} \) are the endogenous regressors. The \( u \) function is the error function, which will have a different form for multiplicative and additive errors in the regression.

Hansen’s \( J \) statistic is valid only if the weight matrix is optimal, meaning that it equals the inverse of the covariance matrix of the moment conditions. Therefore, \( \text{estat overid} \) only reports Hansen’s \( J \) statistic after two-step or iterated estimation or if you specified \( \text{winitial(matname)} \) when calling \( \text{ivpoisson gmm} \). In the latter case, it is your responsibility to determine the validity of the \( J \) statistic.

Syntax for predict

These statistics are available both in and out of sample; type \text{predict ... if e(sample) ... if wanted only for the estimation sample.}

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

\( \text{n} \), the default, calculates the predicted number of events via the exponential-form estimate. This is \( \exp(x'_j \beta_1 + y'_{2,j} \beta_2) \) if neither \( \text{offset()} \) nor \( \text{exposure()} \) was specified, \( \exp(x'_j \beta_1 + y'_{2,j} \beta_2 + \text{offset}_j) \) if \( \text{offset()} \) was specified, or \( \exp(x'_j \beta_1 + y'_{2,j} \beta_2) \times \text{exposure}_j \) if \( \text{exposure()} \) was specified.

After generalized method of moments estimation, the exponential-form estimate is not a consistent estimate of the conditional mean of \( y_j \), because it is not corrected for \( E(\epsilon_j|y_{2,j}) \). More details are found in \textit{Methods and formulas}.

After control-function estimation, we correct the exponential-form estimate for \( E(\epsilon_j|y_{2,j}) \) by using the estimated residuals of \( y_{2,j} \) and the \( c_\cdot \) auxiliary parameters. This supplements the direct effect of \( y_{2,j} \) and \( x_j \) through \( \beta_1 \) and \( \beta_2 \) with the indirect effects of \( y_{2,j} \), \( x_j \), and the instruments \( z_j \) through the endogenous error \( \epsilon_j \). Thus the exponential-form estimate consistently estimates the conditional mean of \( y_j \).

\text{xbtotal} calculates the linear prediction, which is \( x'_j \beta_1 + y'_{2,j} \beta_2 \) if neither \( \text{offset()} \) nor \( \text{exposure()} \) was specified, \( x'_j \beta_1 + y'_{2,j} \beta_2 + \text{offset}_j \) if \( \text{offset()} \) was specified, or \( x'_j \beta_1 + y'_{2,j} \beta_2 + \ln(\text{exposure}_j) \) if \( \text{exposure()} \) was specified.
After control-function estimation, the estimate of the linear form \( x_j' \beta_1 \) includes the estimated residuals of the endogenous regressors with coefficients from the \( c_* \) auxiliary parameters.

\( \text{xb} \) calculates the linear prediction, which is \( x_j' \beta_1 + y_2, j \beta_2 \) if neither \( \text{offset()} \) nor \( \text{exposure()} \) was specified, \( x_j' \beta_1 + y_2, j \beta_2 + \text{offset}_j \) if \( \text{offset()} \) was specified, or \( x_j' \beta_1 + y_2, j \beta_2 + \ln(\text{exposure}_j) \) if \( \text{exposure()} \) was specified.

\( \text{residuals} \) calculates the residuals. Under additive errors, these are calculated as \( y_j - \exp(x_j' \beta_1 + y_2, j \beta_2) \). Under multiplicative errors, they are calculated as \( y_j / \exp(x_j' \beta_1 + y_2, j \beta_2) - 1 \).

When \( \text{offset()} \) or \( \text{exposure()} \) is specified, \( x_j' \beta_1 \) is not used directly in the residuals. \( x_j' \beta_1 + \text{offset}_j \) is used if \( \text{offset()} \) was specified. \( x_j' \beta_1 + \ln(\text{exposure}_j) \) is used if \( \text{exposure()} \) was specified. See \( \text{nooffset} \) below.

After control-function estimation, the estimate of the linear form \( x_j' \beta_1 \) includes the estimated residuals of the endogenous regressors with coefficients from the \( c_* \) auxiliary parameters.

\( \text{nooffset} \) is relevant only if you specified \( \text{offset()} \) or \( \text{exposure()} \) when you fit the model. It modifies the calculations made by \( \text{predict} \) so that they ignore the offset or exposure variable. \( \text{nooffset} \) removes the offset from calculations involving both the \( \text{treat()} \) equation and the dependent count variable.

**Syntax for estat overid**

\[ \text{estat overid} \]

**Menu for estat**

Statistics > Postestimation > Reports and statistics

**Remarks and examples**

\( \text{estat overid} \) reports Hansen’s \( J \) statistic, which is used to determine the validity of the overidentifying restrictions in a GMM model. It is not appropriate to use it after \( \text{ivpoisson cf} \) function, because a just-identified model is fit.

Recall that the GMM criterion function is

\[
Q(\beta) = \left\{ \frac{1}{N} \sum_i \tilde{z}_i u(y_i, x_i, y_{2,i}, \beta_1, \beta_2) \right\}' W_N \left\{ \frac{1}{N} \sum_i \tilde{z}_i u(y_i, x_i, y_{2,i}, \beta_1, \beta_2) \right\}
\]

(A1)

Our \( u \) function within this formula will change depending on whether we use additive or multiplicative errors. The \( \tilde{z} \) vector contains the exogenous regressors and instrumental variables used. \( \text{ivpoisson gmm} \) estimates regression coefficients to minimize \( Q \).

Let \( l \) be the dimension of \( \tilde{z} \) and \( k \) the number of regressors. If \( W_N \) is an optimal weight matrix, under the null hypothesis \( H_0: E \{ \tilde{z}_i u(y_i, x_i, y_{2,i}, \beta_1, \beta_2) \} = 0 \), the test statistic \( J = N \times Q \sim \chi^2(l - k) \). A large test statistic casts doubt on the null hypothesis.

Because the weight matrix \( W_N \) must be optimal, \( \text{estat overid} \) works only after the two-step and iterated estimation or if you supplied your own initial weight matrix by using the \( \text{winitial(matname)} \) option of \( \text{ivpoisson gmm} \) and used the one-step estimator.
Often the overidentifying restrictions test is interpreted as a test of the validity of the instruments \( z \). However, other forms of model misspecification can sometimes lead to a significant test statistic. See Hall (2005, sec. 5.1) for a discussion of the overidentifying restrictions test and its behavior in correctly specified and misspecified models.

Note that \texttt{ivpoisson gmm} defaults to the two-step estimator when other options are not specified to override the default. Thus it is appropriate to perform the \( J \) test after the regression of example 1 in \texttt{[R] ivpoisson}.

Example 1: Specification test

Recall example 1 of \texttt{[R] ivpoisson}. We estimated the parameters of an exponential conditional mean model for the number of visits to a website. Additive errors were used. Exogenous regressors included the gender of an individual and the number of ads received from the website.

An endogenous regressor, time spent on the Internet, was also included in the model. Two instruments were used. One of the instruments measured the time spent interacting with friends and out-of-town family. The other measured the time spent on the phone.

We will reestimate the parameters of the regression here and then test the specification.

```stata
. use http://www.stata-press.com/data/r13/website
(Visits to website)
. ivpoisson gmm visits ad female (time = phone frfam)
(output omitted)
. estat overid
Test of overidentifying restriction:
    Hansen’s J chi2(1) = .129055 (p = 0.7194)
```

We have two instruments for one endogenous variable, so the \( J \) statistic has one degree of freedom. The \( J \) statistic is not significant. We fail to reject the null hypothesis that the model is correctly specified.

\[ E(y_i|y_{2,i}, \tilde{z}_i) = E\{E(y_i|x_i,y_{2,i},\epsilon_i)|y_{2,i},\tilde{z}_i\} \\
= E\{\exp(x_i'\beta_1 + y_{2,i}'\beta_2) \epsilon_i|y_{2,i},\tilde{z}_i\} \\
= \exp(x_i'\beta_1 + y_{2,i}'\beta_2) E(\epsilon_i|y_{2,i},\tilde{z}_i) \]

Stored results

\texttt{estat overid} stores the following in \texttt{r()}:

Scalars

- \texttt{r(J)}: Hansen’s \( J \) statistic
- \texttt{r(J_df)}: \( J \) statistic degrees of freedom
- \texttt{r(J_p)}: \( J \) statistic \( p \)-value

Methods and formulas

The vector \( x_i \) contains the exogenous regressors, and \( z_i \) the instruments. The vector \( \tilde{z}_i \) is partitioned as \( (x_i, z_i) \). The vector \( y_{2,i} \) contains the endogenous regressors.

Under multiplicative errors, the conditional mean of \( y_i \) is

\[ E(y_i|y_{2,i}, \tilde{z}_i) = E\{E(y_i|x_i,y_{2,i},\epsilon_i)|y_{2,i},\tilde{z}_i\} \\
= E\{\exp(x_i'\beta_1 + y_{2,i}'\beta_2) \epsilon_i|y_{2,i},\tilde{z}_i\} \\
= \exp(x_i'\beta_1 + y_{2,i}'\beta_2) E(\epsilon_i|y_{2,i},\tilde{z}_i) \]
Under the CF estimator,

\[
E(\epsilon_i | y_{2,i}, \tilde{z}_i) = E \{E(\epsilon_i | v_i, c_i) | y_{2,i}, \tilde{z}_i\}
\]
\[
= E \{\exp(v_i' \rho + c_i) | y_{2,i}, \tilde{z}_i\}
\]
\[
= \exp \{ (y_{2,i} - B\tilde{z}_i') \rho \} E(c_i | y_{2,i}, \tilde{z}_i)
\]
\[
= \exp \{ (y_{2,i} - B\tilde{z}_i') \rho \}
\]

Thus under the CF estimator, we estimate the conditional mean of \(y_i\) as

\[
E(y_i | y_{2,i}, \tilde{z}_i) = \exp(x_i' \beta_1 + y_{2,i}' \beta_2 + (y_{2,i} - B\tilde{z}_i') \rho)
\]

The CF estimator explicitly models the functional form of the endogeneity of \(y_{2,i}\) and \(\epsilon_i\) with the instruments and exogenous regressors \(\tilde{z}_i\). This allows it to correct the exponential-form estimator for the \(E(\epsilon_i | y_{2,i}, \tilde{z}_i)\) term.

In contrast, the GMM estimator does not model the functional form of the endogeneity of \(y_{2,i}\) and \(\epsilon_i\). Therefore, \(E(\epsilon_i | y_{2,i}, \tilde{z}_i)\) is not estimated, and the exponential-form estimator under GMM estimation simply ignores this term. Noting that because \(\tilde{z}_i\) and \(\epsilon_i\) are independent, \(E(\epsilon_i | y_{2,i}, \tilde{z}_i) = E(\epsilon_i | y_{2,i})\), we can obviously see that ignoring the term will lead to inconsistent estimation of the conditional mean of \(y_i\). \(y_{2,i}\) and \(\epsilon_i\) are not independent, so \(E(\epsilon_i | y_{2,i})\) may vary based on \(y_{2,i}\).

In the additive errors setting, a similar derivation will show that the exponential-form estimator obtained from GMM estimation is inconsistent for the conditional mean of \(y_i\).

\section*{Remarks and examples}

Remarks are presented under the following headings:

\begin{itemize}
  \item \textit{Model setup}
  \item \textit{Model identification}
\end{itemize}

\section*{Model setup}

\texttt{ivprobit} fits models with dichotomous dependent variables and endogenous regressors. You can use it to fit a probit model when you suspect that one or more of the regressors are correlated with the error term. \texttt{ivprobit} is to probit modeling what \texttt{ivregress} is to linear regression analysis; see [R] \texttt{ivregress} for more information.

Formally, the model is

\[ y_{1i}^* = y_{2i} \beta + x_{1i} \gamma + u_i \]
\[ y_{2i} = x_{1i} \Pi_1 + x_{2i} \Pi_2 + v_i \]

where \( i = 1, \ldots, N \), \( y_{2i} \) is a \( 1 \times p \) vector of endogenous variables, \( x_{1i} \) is a \( 1 \times k_1 \) vector of exogenous variables, \( x_{2i} \) is a \( 1 \times k_2 \) vector of additional instruments, and the equation for \( y_{2i} \) is written in reduced form. By assumption, \((u_i, v_i) \sim N(0, \Sigma)\), where \( \sigma_{11} \) is normalized to one to identify the model. \( \beta \) and \( \gamma \) are vectors of structural parameters, and \( \Pi_1 \) and \( \Pi_2 \) are matrices of reduced-form parameters. This is a recursive model: \( y_{2i} \) appears in the equation for \( y_{1i}^* \), but \( y_{1i}^* \) does not appear in the equation for \( y_{2i} \). We do not observe \( y_{1i}^* \); instead, we observe

\[ y_{1i} = \begin{cases} 0 & y_{1i}^* < 0 \\ 1 & y_{1i}^* \geq 0 \end{cases} \]

The order condition for identification of the structural parameters requires that \( k_2 \geq p \). Presumably, \( \Sigma \) is not block diagonal between \( u_i \) and \( v_i \); otherwise, \( y_{2i} \) would not be endogenous.
# Technical note

This model is derived under the assumption that \((u_i, v_i)\) is independent and identically distributed multivariate normal for all \(i\). The `vce(cluster clustvar)` option can be used to control for a lack of independence. As with most probit models, if \(u_i\) is heteroskedastic, point estimates will be inconsistent.

## Example 1

We have hypothetical data on 500 two-parent households, and we wish to model whether the woman is employed. We have a variable, `fem_work`, that is equal to one if she has a job and zero otherwise. Her decision to work is a function of the number of children at home (`kids`), number of years of schooling completed (`fem_educ`), and other household income measured in thousands of dollars (`other_inc`). We suspect that unobservable shocks affecting the woman’s decision to hold a job also affect the household’s other income. Therefore, we treat `other_inc` as endogenous. As an instrument, we use the number of years of schooling completed by the man (`male_educ`).

The syntax for specifying the exogenous, endogenous, and instrumental variables is identical to that used in `ivregress`; see [R] `ivregress` for details.

```
use http://www.stata-press.com/data/r13/laborsup
ivprobit fem_work fem_educ kids (other_inc = male_educ)
```

Wald test of exogeneity (`'/athrho' = 0`): chi2(1) = 6.70 Prob > chi2 = 0.0096
```

Because we did not specify `mle` or `twostep`, `ivprobit` used the maximum likelihood estimator by default. At the top of the output, we see the iteration log. `ivprobit` fits a probit model ignoring
endogeneity to obtain starting values for the endogenous model. The header of the output contains the sample size as well as a Wald statistic and $p$-value for the test of the hypothesis that all the slope coefficients are jointly zero. Below the table of coefficients, Stata reminds us that the endogenous variable is `other_inc` and that `femEduc`, `kids`, and `maleEduc` were used as instruments.

At the bottom of the output is a Wald test of the exogeneity of the instrumented variables. We reject the null hypothesis of no endogeneity. However, if the test statistic is not significant, there is not sufficient information in the sample to reject the null, so a regular probit regression may be appropriate. The point estimates from `ivprobit` are still consistent, though those from `probit` (see [R] `probit`) are likely to have smaller standard errors.

Various two-step estimators have also been proposed for the endogenous probit model, and Newey’s (1987) minimum chi-squared estimator is available with the `twostep` option.

Example 2

Refitting our labor-supply model with the two-step estimator yields

```
    . ivprobit fem_work fem_educ kids (other_inc = male_educ), twostep
    Checking reduced-form model...
    Two-step probit with endogenous regressors
    Number of obs = 500
    Wald chi2(3) = 93.97
    Prob > chi2 = 0.0000

                      Coef.  Std. Err.      z    P>|z|     [95% Conf. Interval]
    other_inc       -.058473   .0093364    -6.26   0.000    -.0767719   -.040174
    fem_educ        .227437    .0281628     8.08   0.000     .1722389    .282635
    kids           -.1961748   .0496323    -3.95   0.000    -.2934522   -.0988973
    _cons          .3956061   .4982649     0.79   0.427    -.5809752    1.372187

Instrumented:  other_inc
Instruments:   fem_educ kids male_educ

    Wald test of exogeneity:  chi2(1) = 6.50   Prob > chi2 = 0.0108
```

All the coefficients have the same signs as their counterparts in the maximum likelihood model. The Wald test at the bottom of the output confirms our earlier finding of endogeneity.

Technical note

In a standard probit model, the error term is assumed to have a variance of one. In the probit model with endogenous regressors, we assume that $(u_i, v_i)$ is multivariate normal with covariance matrix

$$
    \text{Var}(u_i, v_i) = \Sigma = \begin{bmatrix} 1 & \Sigma'_{21} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}
$$

With the properties of the multivariate normal distribution, $\text{Var}(u_i | v_i) = 1 - \Sigma_{21} \Sigma_{22}^{-1} \Sigma_{21}$. As a result, Newey’s estimator and other two-step probit estimators do not yield estimates of $\beta$ and $\gamma$ but rather $\beta/\sigma$ and $\gamma/\sigma$, where $\sigma$ is the square root of $\text{Var}(u_i | v_i)$. Hence, we cannot directly compare the estimates obtained from Newey’s estimator with those obtained via maximum likelihood or with those obtained from `probit`. See Wooldridge (2010, 585–594) for a discussion of Rivers and Vuong’s (1988) two-step estimator. The issues raised pertaining to the interpretation of the coefficients of that
 estimator are identical to those that arise with Newey’s estimator. Wooldridge also discusses ways to obtain marginal effects from two-step estimators.

Despite the coefficients not being directly comparable to their maximum likelihood counterparts, the two-step estimator is nevertheless useful. The maximum likelihood estimator may have difficulty converging, especially with multiple endogenous variables. The two-step estimator, consisting of nothing more complicated than a probit regression, will almost certainly converge. Moreover, although the coefficients from the two models are not directly comparable, the two-step estimates can still be used to test for statistically significant relationships.

Model identification

As in the linear simultaneous-equation model, the order condition for identification requires that the number of excluded exogenous variables (that is, the additional instruments) be at least as great as the number of included endogenous variables. *ivprobit* checks this for you and issues an error message if the order condition is not met.

Like *probit*, *logit*, and *logistic*, *ivprobit* checks the exogenous and endogenous variables to see if any of them predict the outcome variable perfectly. It will then drop offending variables and observations and fit the model on the remaining data. Instruments that are perfect predictors do not affect estimation, so they are not checked. See *Model identification* in [R] *probit* for more information.

*ivprobit* will also occasionally display messages such as

Note: 4 failures and 0 successes completely determined.

For an explanation of this message, see [R] *logit*.

Stored results

*ivprobit*, mle stores the following in *e()*:

Scalars

- `e(N)` number of observations

Methods and formulas

Fitting limited-dependent variable models with endogenous regressors has received considerable attention in the econometrics literature. Building on the results of Amemiya (1978, 1979), Newey (1987) developed an efficient method of estimation that encompasses both Rivers and Vuong’s (1988) simultaneous-equations probit model and Smith and Blundell’s (1986) simultaneous-equations tobit model. With modern computers, maximum likelihood estimation is feasible as well. For compactness, we write the model as

\[ y_{1i}^* = z_i^* \delta + u_i \]  \hspace{1cm} (1a)
\[ y_{2i} = x_i \Pi + v_i \]  \hspace{1cm} (1b)

where \( z_i = (y_{2i}, x_{1i}) \), \( x_i = (x_{1i}, x_{2i}) \), \( \delta = (\beta', \gamma')' \), and \( \Pi = (\Pi_1', \Pi_2')' \).

Deriving the likelihood function is straightforward because we can write the joint density \( f(y_{1i}, y_{2i} | x_i) \) as \( f(y_{1i} | y_{2i}, x_i) f(y_{2i} | x_i) \). When there is an endogenous regressor, the log likelihood for observation \( i \) is
\[
\ln L_i = w_i \left[ y_{1i} \ln \Phi (m_i) + (1 - y_{1i}) \ln \left\{ 1 - \Phi (m_i) \right\} + \ln \phi \left( \frac{y_{2i} - x_i \Pi}{\sigma} \right) \right] - \ln \sigma \]
\]

where
\[
m_i = \frac{z_i \delta + \rho (y_{2i} - x_i \Pi)}{(1 - \rho^2)^{\frac{1}{2}}} \]

\(\Phi(\cdot)\) and \(\phi(\cdot)\) are the standard normal distribution and density functions, respectively; \(\sigma\) is the standard deviation of \(v_i\); \(\rho\) is the correlation coefficient between \(u_i\) and \(v_i\); and \(w_i\) is the weight for observation \(i\) or one if no weights were specified. Instead of estimating \(\sigma\) and \(\rho\), we estimate \(\ln \sigma\) and \(\text{atanh} \ \rho\), where
\[
\text{atanh} \ \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)
\]

For multiple endogenous regressors, let
\[
\text{Var}(u_i, v_i) = \Sigma = \begin{bmatrix} 1 & \Sigma'_{21} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}
\]

As in any probit model, we have imposed the normalization \(\text{Var}(u_i) = 1\) to identify the model. The log likelihood for observation \(i\) is
\[
\ln L_i = w_i \left[ y_{1i} \ln \Phi (m_i) + (1 - y_{1i}) \ln \left\{ 1 - \Phi (m_i) \right\} + \ln f(y_{2i}|x_i) \right]
\]

where
\[
\ln f(y_{2i}|x_i) = -\frac{p}{2} \ln 2\pi - \frac{1}{2} \ln |\Sigma_{22}| - \frac{1}{2} (y_{2i} - x_i \Pi) \Sigma_{22}^{-1} (y_{2i} - x_i \Pi)'
\]

and
\[
m_i = (1 - \Sigma'_{21} \Sigma_{22}^{-1} \Sigma_{21})^{-\frac{1}{2}} \left\{ z_i \delta + (y_{2i} - x_i \Pi) \Sigma_{22}^{-1} \Sigma_{21} \right\}
\]

Instead of maximizing the log-likelihood function with respect to \(\Sigma\), we maximize with respect to the Cholesky decomposition \(S\) of \(\Sigma\); that is, there exists a lower triangular matrix, \(S\), such that \(SS' = \Sigma\). This maximization ensures that \(\Sigma\) is positive definite, as a covariance matrix must be. Let
With maximum likelihood estimation, this command supports the Huber/White/sandwich estimator of the variance and its clustered version using vce(robust) and vce(cluster clustvar), respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

The maximum likelihood version of ivprobit also supports estimation with survey data. For details on VCEs with survey data, see [SVY] variance estimation.

The two-step estimates are obtained using Newey’s (1987) minimum chi-squared estimator. The reduced-form equation for \( y_{1i}^* \) is

\[
y_{1i}^* = (x_i^\Pi + v_i)\beta + x_{1i}\gamma + u_i
\]

where \( \nu_i = v_i\beta + u_i \). Because \( u_i \) and \( v_i \) are jointly normal, \( \nu_i \) is also normal. Note that

\[
\alpha = \begin{bmatrix} \Pi_1 \\ \Pi_2 \end{bmatrix} \beta + \begin{bmatrix} I \\ 0 \end{bmatrix} \gamma = D(\Pi)\delta
\]

where \( D(\Pi) = (\Pi, I_1) \) and \( I_1 \) is defined such that \( x_i I_1 = x_{1i} \). Letting \( \hat{z}_i = (x_i \hat{\Pi}, x_{1i}) \), \( \hat{z}_i \delta = x_i D(\hat{\Pi})\delta \), where \( D(\hat{\Pi}) = (\hat{\Pi}, I_1) \). Thus one estimator of \( \alpha \) is \( D(\hat{\Pi})\delta \); denote this estimator by \( \hat{\alpha} \).

\( \alpha \) could also be estimated directly as the solution to

\[
\max_{\alpha, \lambda} \sum_{i=1}^{N} l(y_{1i}, x_i\alpha + \hat{v}_i\lambda)
\]

where \( l(\cdot) \) is the log likelihood for probit. Denote this estimator by \( \tilde{\alpha} \). The inclusion of the \( \hat{v}_i\lambda \) term follows because the multivariate normality of \( (u_i, v_i) \) implies that, conditional on \( y_{2i} \), the expected value of \( u_i \) is nonzero. Because \( v_i \) is unobservable, the least-squares residuals from fitting \( (1b) \) are used.

Amemiya (1978) shows that the estimator of \( \delta \) defined by

\[
\max_{\delta} (\hat{\alpha} - \hat{D}\delta)\hat{\Omega}^{-1}(\hat{\alpha} - \hat{D}\delta)
\]

where \( \hat{\Omega} \) is a consistent estimator of the covariance of \( \sqrt{N}(\hat{\alpha} - \hat{D}\delta) \), is asymptotically efficient relative to all other estimators that minimize the distance between \( \hat{\alpha} \) and \( D(\hat{\Pi})\delta \). Thus an efficient estimator of \( \delta \) is

\[
\hat{\delta} = (\hat{D}'\hat{\Omega}^{-1}\hat{D})^{-1}\hat{D}'\hat{\Omega}^{-1}\hat{\alpha}
\]

and

\[
\Var(\hat{\delta}) = (\hat{D}'\hat{\Omega}^{-1}\hat{D})^{-1}
\]

To implement this estimator, we need \( \hat{\Omega}^{-1} \).

Consider the two-step maximum likelihood estimator that results from first fitting \( (1b) \) by OLS and computing the residuals \( \hat{v}_i = y_{2i} - x_i\hat{\Pi} \). The estimator is then obtained by solving

\[
\max_{\delta, \lambda} \sum_{i=1}^{N} l(y_{1i}, z_i\delta + \hat{v}_i\lambda)
\]
This is the two-step instrumental variables (2SIV) estimator proposed by Rivers and Vuong (1988), and its role will become apparent shortly.

From Proposition 5 of Newey (1987), \( \sqrt{N}(\tilde{\alpha} - \hat{D}\delta) \overset{d}{\longrightarrow} N(0, \Omega) \), where
\[
\Omega = J^{-1}_{\alpha\alpha} + (\lambda - \beta)'\Sigma_{22}(\lambda - \beta)Q^{-1}
\]
and \( \Sigma_{22} = E\{v'_i v_i\} \). \( J^{-1}_{\alpha\alpha} \) is simply the covariance matrix of \( \tilde{\alpha} \), ignoring that \( \hat{\Pi} \) is an estimated parameter matrix. Moreover, Newey shows that the covariance matrix from an OLS regression of \( y_{2i}(\hat{\lambda} - \hat{\beta}) \) on \( x_i \) is a consistent estimator of the second term. \( \hat{\lambda} \) can be obtained from solving (2), and the 2SIV estimator yields a consistent estimate, \( \hat{\beta} \).

Mechanically, estimation proceeds in several steps.
1. Each of the endogenous right-hand-side variables is regressed on all the exogenous variables, and the fitted values and residuals are calculated. The matrix \( \hat{D} = D(\hat{\Pi}) \) is assembled from the estimated coefficients.
2. \texttt{probit} is used to solve (2) and obtain \( \tilde{\alpha} \) and \( \hat{\lambda} \). The portion of the covariance matrix corresponding to \( \alpha \), \( J^{-1}_{\alpha\alpha} \), is also saved.
3. The 2SIV estimator is evaluated, and the parameters \( \hat{\beta} \) corresponding to \( y_{2i} \) are collected.
4. \( y_{2i}(\hat{\lambda} - \hat{\beta}) \) is regressed on \( x_i \). The covariance matrix of the parameters from this regression is added to \( J^{-1}_{\alpha\alpha} \), yielding \( \hat{\Omega} \).
5. Evaluating (3) and (4) yields the estimates \( \hat{\delta} \) and \( \text{Var}(\hat{\delta}) \).
6. A Wald test of the null hypothesis \( H_0: \lambda = 0 \), using the 2SIV estimates, serves as our test of exogeneity.

The two-step estimates are not directly comparable to those obtained from the maximum likelihood estimator or from \texttt{probit}. The argument is the same for Newey’s efficient estimator as for Rivers and Vuong’s (1988) 2SIV estimator, so we consider the simpler 2SIV estimator. From the properties of the normal distribution,
\[
E(u_i|v_i) = v_i\Sigma_{22}^{-1}\Sigma_{21} \quad \text{and} \quad \text{Var}(u_i|v_i) = 1 - \Sigma_{21}'\Sigma_{22}^{-1}\Sigma_{21}
\]
We write \( u_i = v_i\Sigma_{22}^{-1}\Sigma_{21} + e_i = v_i\lambda + e_i \), where \( e_i \sim N(0, 1 - \rho^2) \), \( \rho^2 = \Sigma_{21}'\Sigma_{22}^{-1}\Sigma_{21} \), and \( e_i \) is independent of \( v_i \). In the second stage of 2SIV, we use a probit regression to estimate the parameters of
\[
y_{1i} = z_i\delta + v_i\lambda + e_i
\]
Because \( v_i \) is unobservable, we use the sample residuals from the first-stage regressions.
\[
\Pr(y_{1i} = 1|z_i, v_i) = \Pr(z_i\delta + v_i\lambda + e_i > 0|z_i, v_i) = \Phi\left\{ (1 - \rho^2)^{-\frac{1}{2}}(z_i\delta + v_i\lambda) \right\}
\]
Hence, as mentioned previously, 2SIV and Newey’s estimator do not estimate \( \delta \) and \( \lambda \) but rather
\[
\delta_\rho = \frac{1}{(1 - \rho^2)^{\frac{1}{2}}} \delta \quad \text{and} \quad \lambda_\rho = \frac{1}{(1 - \rho^2)^{\frac{1}{2}}} \lambda
\]
Acknowledgments

The two-step estimator is based on the \texttt{probitiv} command written by Jonah Gelbach of the Department of Economics at Yale University and the \texttt{ivprob} command written by Joe Harkness of the Institute of Policy Studies at Johns Hopkins University.

These statistics are available both in and out of sample; type \text{predict} \ldots \text{if} \ e(\text{sample}) \ldots \text{if} \ wanted \ only \ for \ the \ estimation \ sample.

Menu for predict

Statistics > Postestimation > Predictions, residuals, etc.

Options for predict

|xbox| Main\]
---|---|
|xb, the default, calculates the linear prediction.|
|stdep| calculates the standard error of the linear prediction.|
|pr| calculates the probability of a positive outcome. pr is not available with the two-step estimator.|
|rules| requests that Stata use any rules that were used to identify the model when making the prediction. By default, Stata calculates missing for excluded observations. rules is not available with the two-step estimator.|
|asif| requests that Stata ignore the rules and the exclusion criteria and calculate predictions for all observations possible using the estimated parameters from the model. asif is not available with the two-step estimator.|
|scores|, not available with twostep, calculates equation-level score variables.|

For models with one endogenous regressor, four new variables are created.

The first new variable will contain \( \partial \ln L/\partial (z_i \delta) \).

The second new variable will contain \( \partial \ln L/\partial (x_i \Pi) \).

The third new variable will contain \( \partial \ln L/\partial \ \text{atanh} \ \rho \).

The fourth new variable will contain \( \partial \ln L/\partial \ln \sigma \).

For models with \( p \) endogenous regressors, \( p + \{(p + 1)(p + 2)\}/2 \) new variables are created.

The first new variable will contain \( \partial \ln L/\partial (z_i \delta) \).
The second through \((p + 1)\)th new variables will contain \(\partial \ln L / \partial (x_i \Pi_k)\), \(k = 1, \ldots, p\), where \(\Pi_k\) is the \(k\)th column of \(\Pi\).

The remaining score variables will contain the partial derivatives of \(\ln L\) with respect to \(s_{21}, s_{31}, \ldots, s_{p+1,1}, s_{22}, \ldots, s_{p+1,2}, \ldots, s_{p+1,p+1}\), where \(s_{m,n}\) denotes the \((m, n)\) element of the Cholesky decomposition of the error covariance matrix.

## Remarks and examples

Remarks are presented under the following headings:

- **Marginal effects**
- **Obtaining predicted values**

### Marginal effects

#### Example 1

We can obtain marginal effects by using the `margins` command after `ivprobit`. We will calculate average marginal effects by using the labor-supply model of example 1 in [R] `ivprobit`.

```stata
. use http://www.stata-press.com/data/r13/laborsup
. ivprobit fem_work fem_educ kids (other_inc = male_educ)
   (output omitted)
. margins, dydx(*) predict(pr)
```

Average marginal effects

<table>
<thead>
<tr>
<th>Expression :</th>
<th>Probability of positive outcome, predict(pr)</th>
</tr>
</thead>
<tbody>
<tr>
<td>dy/dx w.r.t. :</td>
<td>other_inc fem_educ kids male_educ</td>
</tr>
</tbody>
</table>

| Delta-method | dy/dx | Std. Err. | z | P>|z| | [95% Conf. Interval] |
|-------------|-------|-----------|---|------|----------------------|
| other_inc   | -.014015 | .0009836 | -14.25 | 0.000 | -.0159428 -.0120872 |
| fem_educ    | .0545129 | .0066007 | 8.26 | 0.000 | .0415758 .06745 |
| kids        | -.0470199 | .0123397 | -3.81 | 0.000 | -.0712052 -.0228346 |
| male_educ   | 0 | (omitted) | | | |

Here we see that a $1,000 increase in `other_inc` leads to an average decrease of 0.014 in the probability that the woman has a job. `male_edu` has no effect because it appears only as an instrument.

### Obtaining predicted values

After fitting your model with `ivprobit`, you can obtain the linear prediction and its standard error for both the estimation sample and other samples by using the `predict` command; see [U] 20 `Estimation and postestimation commands` and [R] `predict`. If you had used the maximum likelihood estimator, you could also obtain the probability of a positive outcome.
predict’s \texttt{pr} option calculates the probability of a positive outcome, remembering any rules used to identify the model, and calculates missing for excluded observations. \texttt{predict’s rules} option uses the rules in predicting probabilities, whereas \texttt{predict’s asif} option ignores both the rules and the exclusion criteria and calculates probabilities for all possible observations by using the estimated parameters from the model. See \textit{Obtaining predicted values} in [R] \texttt{probit postestimation} for an example.

\section*{Methods and formulas}

The linear prediction is calculated as $z_i \hat{\delta}$, where $\hat{\delta}$ is the estimated value of $\delta$, and $z_i$ and $\delta$ are defined in (1a) of [R] \texttt{ivprobit}. The probability of a positive outcome is $\Phi(z_i \hat{\delta})$, where $\Phi(\cdot)$ is the standard normal distribution function.

Menu
Statistics > Endogenous covariates > Single-equation instrumental-variables regression

Description

ivregress fits a linear regression of depvar on varlist1 and varlist2, using varlistiv (along with varlist1) as instruments for varlist2. ivregress supports estimation via two-stage least squares (2SLS), limited-information maximum likelihood (LIML), and generalized method of moments (GMM).

In the language of instrumental variables, varlist1 and varlistiv are the exogenous variables, and varlist2 are the endogenous variables.

Options

Model

noconstant; see [R] estimation options.

hascons indicates that a user-defined constant or its equivalent is specified among the independent variables.

GMM

wmatrix(wmtype) specifies the type of weighting matrix to be used in conjunction with the GMM estimator.

Specifying wmatrix(robust) requests a weighting matrix that is optimal when the error term is heteroskedastic. wmatrix(robust) is the default.

Specifying wmatrix(cluster clustvar) requests a weighting matrix that accounts for arbitrary correlation among observations within clusters identified by clustvar.

Specifying wmatrix(hac kernel #) requests a heteroskedasticity- and autocorrelation-consistent (HAC) weighting matrix using the specified kernel (see below) with # lags. The bandwidth of a kernel is equal to # + 1.
Specifying `wmatrix(hac kernel opt)` requests an HAC weighting matrix using the specified kernel, and the lag order is selected using Newey and West’s (1994) optimal lag-selection algorithm.

Specifying `wmatrix(hac kernel)` requests an HAC weighting matrix using the specified kernel and \( N - 2 \) lags, where \( N \) is the sample size.

There are three kernels available for HAC weighting matrices, and you may request each one by using the name used by statisticians or the name perhaps more familiar to economists:

- `bartlett` or `newest` requests the Bartlett (Newey–West) kernel;
- `parzen` or `gallant` requests the Parzen (Gallant 1987) kernel; and
- `quadraticspectral` or `andrews` requests the quadratic spectral (Andrews 1991) kernel.

Specifying `wmatrix(unadjusted)` requests a weighting matrix that is suitable when the errors are homoskedastic. The GMM estimator with this weighting matrix is equivalent to the 2SLS estimator.

center requests that the sample moments be centered (demeaned) when computing GMM weight matrices. By default, centering is not done.

`igmm` requests that the iterative GMM estimator be used instead of the default two-step GMM estimator. Convergence is declared when the relative change in the parameter vector from one iteration to the next is less than `eps()` or the relative change in the weight matrix is less than `weps()`.

`eps(#)` specifies the convergence criterion for successive parameter estimates when the iterative GMM estimator is used. The default is `eps(1e-6)`. Convergence is declared when the relative difference between successive parameter estimates is less than `eps()` and the relative difference between successive estimates of the weighting matrix is less than `weps()`.

`weps(#)` specifies the convergence criterion for successive estimates of the weighting matrix when the iterative GMM estimator is used. The default is `weps(1e-6)`. Convergence is declared when the relative difference between successive parameter estimates is less than `eps()` and the relative difference between successive estimates of the weighting matrix is less than `weps()`.

`optimization_options`: `iterate(#)`, `[no]log`. `iterate()` specifies the maximum number of iterations to perform in conjunction with the iterative GMM estimator. The default is 16,000 or the number set using `set maxiter` (see [R] `maximize`). `log/nolog` specifies whether to show the iteration log. These options are seldom used.

`vce(vcetype)` specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap, jackknife`); see [R] `vce_option`.

`vce(unadjusted)`, the default for `2sls` and `liml`, specifies that an unadjusted (nonrobust) VCE matrix be used. The default for `gmm` is based on the `wmtype` specified in the `wmatrix()` option; see `wmatrix(wmtype)` above. If `wmatrix()` is specified with `gmm` but `vce()` is not, then `vcetype` is set equal to `wmtype`. To override this behavior and obtain an unadjusted (nonrobust) VCE matrix, specify `vce(unadjusted)`.

`ivregress` also allows the following:

`vce(hac kernel [#|opt])` specifies that an HAC covariance matrix be used. The syntax used with `vce(hac kernel ...)` is identical to that used with `wmatrix(hac kernel ...)`; see `wmatrix(wmtype)` above.

`level(#)`; see [R] `estimation options`. 

---

**ivregress** — Single-equation instrumental-variables regression

929
first requests that the first-stage regression results be displayed. small requests that the degrees-of-freedom adjustment \( N/(N-k) \) be made to the variance–covariance matrix of parameters and that small-sample \( F \) and \( t \) statistics be reported, where \( N \) is the sample size and \( k \) is the number of parameters estimated. By default, no degrees-of-freedom adjustment is made, and Wald and \( z \) statistics are reported. Even with this option, no degrees-of-freedom adjustment is made to the weighting matrix when the GMM estimator is used.

noheader suppresses the display of the summary statistics at the top of the output, displaying only the coefficient table.

depname(\textit{depname}) is used only in programs and ado-files that use \texttt{ivregress} to fit models other than instrumental-variables regression. \textit{depname()} may be specified only at estimation time. \textit{depname} is recorded as the identity of the dependent variable, even though the estimates are calculated using \textit{depvar}. This method affects the labeling of the output—not the results calculated—but could affect later calculations made by \texttt{predict}, where the residual would be calculated as deviations from \textit{depname} rather than \textit{depvar}. \textit{depname()} is most typically used when \textit{depvar} is a temporary variable (see \texttt{[P] macro}) used as a proxy for \textit{depname}.

eform(\textit{string}) is used only in programs and ado-files that use \texttt{ivregress} to fit models other than instrumental-variables regression. \textit{eform()} specifies that the coefficient table be displayed in “exponentiated form”, as defined in \texttt{[R] maximize}, and that \textit{string} be used to label the exponentiated coefficients in the table.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels,nofvlabel, fvwrap(#), fvwrappon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see \texttt{[R] estimation options}.

The following options are available with \texttt{ivregress} but are not shown in the dialog box:

perfect requests that \texttt{ivregress} not check for collinearity between the endogenous regressors and excluded instruments, allowing one to specify “perfect” instruments. This option cannot be used with the LIML estimator. This option may be required when using \texttt{ivregress} to implement other estimators.

coefflegend; see \texttt{[R] estimation options}.

Remarks and examples

\texttt{ivregress} performs instrumental-variables regression and weighted instrumental-variables regression. For a general discussion of instrumental variables, see Baum (2006), Cameron and Trivedi (2005; 2010, chap. 6) Davidson and MacKinnon (1993, 2004), Greene (2012, chap. 8), and Wooldridge (2010, 2013). See Hall (2005) for a lucid presentation of GMM estimation. Angrist and Pischke (2009, chap. 4) offer a casual yet thorough introduction to instrumental-variables estimators, including their use in estimating treatment effects. Some of the earliest work on simultaneous systems can be found in Cowles Commission monographs—Koopmans and Marschak (1950) and Koopmans and Hood (1953)—with the first developments of 2SLS appearing in Theil (1953) and Basmann (1957). However, Stock and Watson (2011, 422–424) present an example of the method of instrumental variables that was first published in 1928 by Philip Wright.

The syntax for \texttt{ivregress} assumes that you want to fit one equation from a system of equations or an equation for which you do not want to specify the functional form for the remaining equations of the system. To fit a full system of equations, using either 2SLS equation-by-equation or three-stage least squares, see \texttt{[R] reg3}. An advantage of \texttt{ivregress} is that you can fit one equation of a multiple-equation system without specifying the functional form of the remaining equations.
Formally, the model fit by \texttt{ivregress} is

\begin{align}
  y_i &= y_i \beta_1 + x_{1i} \beta_2 + u_i \tag{1} \\
  y_i &= x_{1i} \Pi_1 + x_{2i} \Pi_2 + v_i \tag{2}
\end{align}

Here \( y_i \) is the dependent variable for the \( i \)th observation, \( y_i \) represents the endogenous regressors (\texttt{varlist2} in the syntax diagram), \( x_{1i} \) represents the included exogenous regressors (\texttt{varlist1} in the syntax diagram), and \( x_{2i} \) represents the excluded exogenous regressors (\texttt{varlistiv} in the syntax diagram). \( x_{1i} \) and \( x_{2i} \) are collectively called the instruments. \( u_i \) and \( v_i \) are zero-mean error terms, and the correlations between \( u_i \) and the elements of \( v_i \) are presumably nonzero.

The rest of the discussion is presented under the following headings:

\textit{2SLS and LIML estimators}

\textit{GMM estimator}

\section*{2SLS and LIML estimators}

The most common instrumental-variables estimator is 2SLS.

\subsection*{Example 1: 2SLS estimator}

We have state data from the 1980 census on the median dollar value of owner-occupied housing (\texttt{hsngval}) and the median monthly gross rent (\texttt{rent}). We want to model \texttt{rent} as a function of \texttt{hsngval} and the percentage of the population living in urban areas (\texttt{pcturban}):

\begin{equation}
  \texttt{rent}_i = \beta_0 + \beta_1 \texttt{hsngval}_i + \beta_2 \texttt{pcturban}_i + u_i
\end{equation}

where \( i \) indexes states and \( u_i \) is an error term.

Because random shocks that affect rental rates in a state probably also affect housing values, we treat \texttt{hsngval} as endogenous. We believe that the correlation between \texttt{hsngval} and \( u \) is not equal to zero. On the other hand, we have no reason to believe that the correlation between \texttt{pcturban} and \( u \) is nonzero, so we assume that \texttt{pcturban} is exogenous.

Because we are treating \texttt{hsngval} as an endogenous regressor, we must have one or more additional variables available that are correlated with \texttt{hsngval} but uncorrelated with \( u \). Moreover, these excluded exogenous variables must not affect \texttt{rent} directly, because if they do then they should be included in the regression equation we specified above. In our dataset, we have a variable for family income (\texttt{faminc}) and for region of the country (\texttt{region}) that we believe are correlated with \texttt{hsngval} but not the error term. Together, \texttt{pcturban}, \texttt{faminc}, and factor variables 2.\texttt{region}, 3.\texttt{region}, and 4.\texttt{region} constitute our set of instruments.

To fit the equation in Stata, we specify the dependent variable and the list of included exogenous variables. In parentheses, we specify the endogenous regressors, an equal sign, and the excluded exogenous variables. Only the additional exogenous variables must be specified to the right of the equal sign; the exogenous variables that appear in the regression equation are automatically included as instruments.
Here we fit our model with the 2SLS estimator:

```
. ivregress 2sls rent pcturban (hsngval = faminc i.region)
```

Instrumental variables (2SLS) regression

|      | Coef. | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|------|-------|-----------|------|------|---------------------|
| rent |        |           |      |      |                     |
| hsngval | .0022398 | .0003284 | 6.82 | 0.000 | .0015961 – .0028836 |
| pcturban | .081516 | .2987652 | 0.27 | 0.785 | -.504053 – .667085  |
| _cons | 120.7065 | 15.22839 | 7.93 | 0.000 | 90.85942 – 150.5536 |

Instrumented: hsngval
Instruments: pcturban faminc 2.region 3.region 4.region

As we would expect, states with higher housing values have higher rental rates. The proportion of a state’s population that is urban does not have a significant effect on rents.

Technical note

In a simultaneous-equations framework, we could write the model we just fit as

\[ hsngval_i = \pi_0 + \pi_1faminc_i + \pi_22.region_i + \pi_33.region_i + \pi_44.region_i + v_i \]
\[ rent_i = \beta_0 + \beta_1hsngval_i + \beta_2pcturban_i + u_i \]

which here happens to be recursive (triangular), because hsngval appears in the equation for rent but rent does not appear in the equation for hsngval. In general, however, systems of simultaneous equations are not recursive. Because this system is recursive, we could fit the two equations individually via OLS if we were willing to assume that \(u\) and \(v\) were independent. For a more detailed discussion of triangular systems, see Kmenta (1997, 719–720).

Historically, instrumental-variables estimation and systems of simultaneous equations were taught concurrently, and older textbooks describe instrumental-variables estimation solely in the context of simultaneous equations. However, in recent decades, the treatment of endogeneity and instrumental-variables estimation has taken on a much broader scope, while interest in the specification of complete systems of simultaneous equations has waned. Most recent textbooks, such as Cameron and Trivedi (2005), Davidson and MacKinnon (1993, 2004), and Wooldridge (2010, 2013), treat instrumental-variables estimation as an integral part of the modern economists’ toolkit and introduce it long before shorter discussions on simultaneous equations.

In addition to the 2SLS member of the \(\kappa\)-class estimators, ivregress implements the LIML estimator. Both theoretical and Monte Carlo exercises indicate that the LIML estimator may yield less bias and confidence intervals with better coverage rates than the 2SLS estimator. See Poi (2006) and Stock, Wright, and Yogo (2002) (and the papers cited therein) for Monte Carlo evidence.
Example 2: LIML estimator

Here we refit our model with the LIML estimator:

```
. ivregress liml rent pcturban (hsngval = faminc i.region)
Instrumental variables (LIML) regression
```

|            | Coef.  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|------------|--------|-----------|-------|------|----------------------|
| rent       | 0.0026686 | 0.0004173 | 6.39  | 0.000 | 0.0018507 0.0034865 |
| hsngval    | -0.1827391 | 0.3571132 | -0.51 | 0.609 | -0.8826681 0.5171899 |
| _cons      | 117.6087   | 17.22625  | 6.83  | 0.000 | 83.84587 151.3715 |

Instrumented: hsngval
Instruments: pcturban faminc 2.region 3.region 4.region

These results are qualitatively similar to the 2SLS results, although the coefficient on hsngval is about 19% higher.

---

**GMM estimator**

Since the celebrated paper of Hansen (1982), the GMM has been a popular method of estimation in economics and finance, and it lends itself well to instrumental-variables estimation. The basic principle is that we have some moment or orthogonality conditions of the form

\[ E(z_i u_i) = 0 \]  

(3)

From (1), we have \( u_i = y_i - y_i \beta_1 - x_{1i} \beta_2 \). What are the elements of the instrument vector \( z_i \)? By assumption, \( x_{1i} \) is uncorrelated with \( u_i \), as are the excluded exogenous variables \( x_{2i} \), and so we use \( z_i = [x_{1i}, x_{2i}] \). The moment conditions are simply the mathematical representation of the assumption that the instruments are exogenous—that is, the instruments are orthogonal to (uncorrelated with) \( u_i \).

If the number of elements in \( z_i \) is just equal to the number of unknown parameters, then we can apply the analogy principle to (3) and solve

\[
\frac{1}{N} \sum_i z_i u_i = \frac{1}{N} \sum_i z_i (y_i - y_i \beta_1 - x_{1i} \beta_2) = 0
\]  

(4)

This equation is known as the method of moments estimator. Here where the number of instruments equals the number of parameters, the method of moments estimator coincides with the 2SLS estimator, which also coincides with what has historically been called the indirect least-squares estimator (Judge et al. 1985, 595).

The “generalized” in GMM addresses the case in which the number of instruments (columns of \( z_i \)) exceeds the number of parameters to be estimated. Here there is no unique solution to the population moment conditions defined in (3), so we cannot use (4). Instead, we define the objective function

\[
Q(\beta_1, \beta_2) = \left( \frac{1}{N} \sum_i z_i u_i \right)' W \left( \frac{1}{N} \sum_i z_i u_i \right)
\]  

(5)
where \(W\) is a positive-definite matrix with the same number of rows and columns as the number of columns of \(z_i\). \(W\) is known as the weighting matrix, and we specify its structure with the \(\text{wmatrix()}\) option. The GMM estimator of \((\beta_1, \beta_2)\) minimizes \(Q(\beta_1, \beta_2)\); that is, the GMM estimator chooses \(\beta_1\) and \(\beta_2\) to make the moment conditions as close to zero as possible for a given \(W\). For a more general GMM estimator, see [R] \text{gmm}. \text{gmm} does not restrict you to fitting a single linear equation, though the syntax is more complex.
