Syntax

Random-effects (RE) model

xtprobit depvar [indepvars] [if] [in] [weight] [, re RE_options]

Population-averaged (PA) model

xtprobit depvar [indepvars] [if] [in] [weight], pa [PA_options]

RE_options Description

Model

<u>nocon</u>stant suppress constant term

re use random-effects estimator; the default

offset (varname) include varname in model with coefficient constrained to 1

constraints (constraints) apply specified linear constraints

<u>col</u>linear keep collinear variables

asis retain perfect predictor variables

SE/Robust

vce(vcetype) vcetype may be oim, robust, cluster clustvar, bootstrap, or

jackknife

Reporting

<u>level(#)</u> set confidence level; default is level(95)

noskip perform overall model test as a likelihood-ratio test

<u>nocnsr</u>eport do not display constraints

display_options control column formats, row spacing, line width, display of omitted

variables and base and empty cells, and factor-variable labeling

Integration

intmethod(intmethod) integration method; intmethod may be mvaghermite (the default) or

ghermite

intpoints(#) use # quadrature points; default is intpoints(12)

Maximization

maximize_options control the maximization process; seldom used

coeflegend display legend instead of statistics

2 xtprobit — Random-effects and population-averaged probit models

PA_options	Description
Model	
<u>nocon</u> stant	suppress constant term
pa	use population-averaged estimator
<pre>offset(varname)</pre>	include varname in model with coefficient constrained to 1
asis	retain perfect predictor variables
Correlation	
$\underline{\mathbf{c}}$ orr $(correlation)$	within-panel correlation structure
force	estimate even if observations unequally spaced in time
SE/Robust	
vce(<i>vcetype</i>)	vcetype may be conventional, robust, bootstrap, or jackknife
nmp	use divisor $N-P$ instead of the default N
<u>s</u> cale(<i>parm</i>)	overrides the default scale parameter; parm may be x2, dev, phi, or #
Reporting	
<u>l</u> evel(#)	set confidence level; default is level(95)
display_options	control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
Optimization	
optimize_options	control the optimization process; seldom used
<u>coefl</u> egend	display legend instead of statistics
correlation	Description
<u>exc</u> hangeable	exchangeable
independent	independent
<u>uns</u> tructured	unstructured
<u>fix</u> ed matname	user-specified
ar#	autoregressive of order #
<u>sta</u> tionary#	stationary of order #
<pre>nonstationary #</pre>	nonstationary of order #

A panel variable must be specified. For xtprobit, pa, correlation structures other than exchangeable and independent require that a time variable also be specified. Use xtset; see [XT] xtset.

indepvars may contain factor variables; see [U] 11.4.3 Factor variables.

depvar and indepvars may contain time-series operators; see [U] 11.4.4 Time-series varlists.

by, mi estimate, and statsby are allowed; see [U] 11.1.10 Prefix commands. fp is allowed for the random-effects model.

vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate.

iweights, fweights, and pweights are allowed for the population-averaged model, and iweights are allowed for the random-effects model; see [U] 11.1.6 weight. Weights must be constant within panel.

coeflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Menu

Statistics > Longitudinal/panel data > Binary outcomes > Probit regression (RE, PA)

Description

xtprobit fits random-effects and population-averaged probit models. There is no command for a conditional fixed-effects model, as there does not exist a sufficient statistic allowing the fixed effects to be conditioned out of the likelihood. Unconditional fixed-effects probit models may be fit with the probit command with indicator variables for the panels. However, unconditional fixed-effects estimates are biased.

By default, the population-averaged model is an equal-correlation model; xtprobit, pa assumes corr(exchangeable). See [XT] xtgee for information about how to fit other population-averaged models.

See [R] logistic for a list of related estimation commands.

Options for RE model

Model

noconstant; see [R] estimation options.

re requests the random-effects estimator. re is the default if neither re nor pa is specified.

offset(varname), constraints(constraints), collinear; see [R] estimation options.

asis forces retention of perfect predictor variables and their associated, perfectly predicted observations and may produce instabilities in maximization; see [R] probit.

SE/Robust

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [XT] vce_options.

Specifying vce(robust) is equivalent to specifying vce(cluster panelvar); see xtprobit, re and the robust VCE estimator in Methods and formulas.

Reporting

level(#), noskip; see [R] estimation options.

nocnsreport; see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

Integration

intmethod(intmethod), intpoints(#); see [R] estimation options.

4 xtprobit — Random-effects and population-averaged probit models

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no] log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] maximize. These options are seldom used.

The following option is available with xtprobit but is not shown in the dialog box:

coeflegend; see [R] estimation options.

Options for PA model

Model

noconstant; see [R] estimation options.

pa requests the population-averaged estimator.

offset(varname); see [R] estimation options.

asis forces retention of perfect predictor variables and their associated, perfectly predicted observations and may produce instabilities in maximization; see [R] probit.

Correlation

corr(correlation) specifies the within-panel correlation structure; the default corresponds to the equal-correlation model, corr(exchangeable).

When you specify a correlation structure that requires a lag, you indicate the lag after the structure's name with or without a blank; for example, corr(ar 1) or corr(ar1).

If you specify the fixed correlation structure, you specify the name of the matrix containing the assumed correlations following the word fixed, for example, corr(fixed myr).

force specifies that estimation be forced even though the time variable is not equally spaced. This is relevant only for correlation structures that require knowledge of the time variable. These correlation structures require that observations be equally spaced so that calculations based on lags correspond to a constant time change. If you specify a time variable indicating that observations are not equally spaced, the (time dependent) model will not be fit. If you also specify force, the model will be fit, and it will be assumed that the lags based on the data ordered by the time variable are appropriate.

SE/Robust

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (conventional), that are robust to some kinds of misspecification (robust), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [XT] vce_options.

vce(conventional), the default, uses the conventionally derived variance estimator for generalized least-squares regression.

nmp, scale(x2 | dev | phi | #); see [XT] vce_options.

Reporting

level(#); see [R] estimation options.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] estimation options.

Optimization)

optimize_options control the iterative optimization process. These options are seldom used.

iterate(#) specifies the maximum number of iterations. When the number of iterations equals #, the optimization stops and presents the current results, even if convergence has not been reached. The default is iterate(100).

tolerance (#) specifies the tolerance for the coefficient vector. When the relative change in the coefficient vector from one iteration to the next is less than or equal to #, the optimization process is stopped. tolerance(1e-6) is the default.

nolog suppresses display of the iteration log.

trace specifies that the current estimates be printed at each iteration.

The following option is available with xtprobit but is not shown in the dialog box:

coeflegend; see [R] estimation options.

Remarks and examples

stata.com

xtprobit is a convenience command for obtaining the population-averaged model. Typing

. xtprobit ..., pa ...

is equivalent to typing

. xtgee ..., ... family(binomial) link(probit) corr(exchangeable)

See also [XT] **xtgee** for information about xtprobit.

By default or when re is specified, xtprobit fits via maximum likelihood the random-effects model

$$\Pr(y_{it} \neq 0 | \mathbf{x}_{it}) = \Phi(\mathbf{x}_{it}\boldsymbol{\beta} + \nu_i)$$

for $i=1,\ldots,n$ panels, where $t=1,\ldots,n_i,\nu_i$ are i.i.d., $N(0,\sigma_{\nu}^2)$, and Φ is the standard normal cumulative distribution function.

Underlying this model is the variance components model

$$y_{it} \neq 0 \iff \mathbf{x}_{it}\boldsymbol{\beta} + \nu_i + \epsilon_{it} > 0$$

where ϵ_{it} are i.i.d. Gaussian distributed with mean zero and variance $\sigma_{\epsilon}^2 = 1$, independently of ν_i .

Example 1: Random-effects model

We are studying unionization of women in the United States and are using the union dataset; see [XT] **xt**. We wish to fit a random-effects model of union membership:

Likelihood-ratio test of rho=0: chibar2(01) = 5984.32 Prob >= chibar2 = 0.000

The output includes the additional panel-level variance component, which is parameterized as the log of the variance $\ln(\sigma_{\nu}^2)$ (labeled lnsig2u in the output). The standard deviation σ_{ν} is also included in the output (labeled sigma_u) together with ρ (labeled rho), where

$$\rho = \frac{\sigma_{\nu}^2}{\sigma_{\nu}^2 + 1}$$

4

which is the proportion of the total variance contributed by the panel-level variance component.

When rho is zero, the panel-level variance component is unimportant, and the panel estimator is not different from the pooled estimator. A likelihood-ratio test of this is included at the bottom of the output. This test formally compares the pooled estimator (probit) with the panel estimator.

□ Technical note

The random-effects model is calculated using quadrature, which is an approximation whose accuracy depends partially on the number of integration points used. We can use the quadchk command to see if changing the number of integration points affects the results. If the results change, the quadrature approximation is not accurate given the number of integration points. Try increasing the number of integration points using the intpoints() option and run quadchk again. Do not attempt to interpret the results of estimates when the coefficients reported by quadchk differ substantially.

. quadchk, nooutput

Refitting model intpoints() = 8 Refitting model intpoints() = 16

The results obtained for 12 quadrature points were closer to the results for 16 points than to the results for eight points. Although the relative and absolute differences are a bit larger than we would like, they are not large. We can increase the number of quadrature points with the intpoints() option; if we choose intpoints(20) and do another quadchk we will get acceptable results, with relative differences around 0.01%.

This is not the case if we use nonadaptive quadrature. Then the results we obtain are

Once again, the results obtained for 12 quadrature points were closer to the results for 16 points than to the results for eight points. However, here the convergence point seems to be sensitive to the number of quadrature points, so we should not trust these results. We should increase the number of quadrature points with the intpoints() option and then use quadchk again. We should not use the results of a random-effects specification when there is evidence that the numeric technique for calculating the model is not stable (as shown by quadchk).

Generally, the relative differences in the coefficients should not change by more than 1% if the quadrature technique is stable. See [XT] quadchk for details. Increasing the number of quadrature points can often improve the stability, and for models with high rho we may need many. We can also switch between adaptive and nonadaptive quadrature. As a rule, adaptive quadrature, which is the default integration method, is much more flexible and robust.

. xtprobit union age grade i.not_smsa south##c.year, pa

Because the xtprobit, re likelihood function is calculated by Gauss-Hermite quadrature, on large problems the computations can be slow. Computation time is roughly proportional to the number of points used for the quadrature.

Example 2: Equal-correlation model

As an alternative to the random-effects specification, we can fit an equal-correlation probit model:

Iteration 1: tolerance = .12544249
Iteration 2: tolerance = .0034686
Iteration 3: tolerance = .00017448
Iteration 4: tolerance = 8.382e-06
Iteration 5: tolerance = 3.997e-07

GEE population-averaged model 26200 Number of obs Number of groups Group variable: 4434 idcode Link: probit Obs per group: min = 1 Family: binomial avg = 5.9 Correlation: exchangeable max = 12 Wald chi2(6) 242.57 Scale parameter: 1 Prob > chi2 0.0000

Example 3: Population-averaged model

In example 3 of [R] **probit**, we showed the above results and compared them with probit, vce(cluster id). xtprobit with the pa option allows a vce(robust) option (the random-effects estimator does not allow the vce(robust) specification), so we can obtain the population-averaged probit estimator with the robust variance calculation by typing

4

These standard errors are similar to those shown for probit, vce(cluster id) in [R] probit.

Example 4: Random-effects model with stable guadrature

In a previous example, we showed how quadchk indicated that the quadrature technique was numerically unstable. Here we present an example in which the quadrature is stable.

In this example, we have (synthetic) data on whether workers complain to managers at fast-food restaurants. The covariates are age (in years of the worker), grade (years of schooling completed by the worker), south (equal to 1 if the restaurant is located in the South), tenure (the number of years spent on the job by the worker), gender (of the worker), race (of the worker), income (in thousands of dollars by the restaurant), genderm (gender of the manager), burger (equal to 1 if the restaurant specializes in hamburgers), and chicken (equal to 1 if the restaurant specializes in chicken). The model is given by

Likelihood-ratio test of rho=0: chibar2(01) = 29.91 Prob >= chibar2 = 0.000

Again we would like to check the stability of the quadrature technique of the model before interpreting the results. Given the estimate of ρ and the small size of the panels (between 3 and 8), we should find that the quadrature technique is numerically stable.

The relative and absolute differences are all small between the default 12 quadrature points and the result with 16 points. We do not have any coefficients that have a large difference between the default 12 quadrature points and eight quadrature points.

We conclude that the quadrature technique is stable. Because the differences here are so small, we would plan on using and interpreting these results rather than trying to rerun with more quadrature points.

Methods and formulas

xtprobit reports the population-averaged results obtained by using xtgee, family(binomial) link(probit) to obtain estimates.

Assuming a normal distribution, $N(0, \sigma_{\nu}^2)$, for the random effects ν_i

$$\Pr(y_{i1}, \dots, y_{in_i} | \mathbf{x}_{i1}, \dots, \mathbf{x}_{in_i}) = \int_{-\infty}^{\infty} \frac{e^{-\nu_i^2/2\sigma_{\nu}^2}}{\sqrt{2\pi}\sigma_{\nu}} \left\{ \prod_{t=1}^{n_i} F(y_{it}, \mathbf{x}_{it}\boldsymbol{\beta} + \nu_i) \right\} d\nu_i$$

where

$$F(y,z) = \begin{cases} \Phi(z) & \text{if } y \neq 0 \\ 1 - \Phi(z) & \text{otherwise} \end{cases}$$

where Φ is the cumulative normal distribution.

The panel-level likelihood l_i is given by

$$l_{i} = \int_{-\infty}^{\infty} \frac{e^{-\nu_{i}^{2}/2\sigma_{\nu}^{2}}}{\sqrt{2\pi}\sigma_{\nu}} \left\{ \prod_{t=1}^{n_{i}} F(y_{it}, \mathbf{x}_{it}\boldsymbol{\beta} + \nu_{i}) \right\} d\nu_{i}$$
$$\equiv \int_{-\infty}^{\infty} g(y_{it}, x_{it}, \nu_{i}) d\nu_{i}$$

This integral can be approximated with M-point Gauss-Hermite quadrature

$$\int_{-\infty}^{\infty} e^{-x^2} h(x) dx \approx \sum_{m=1}^{M} w_m^* h(a_m^*)$$

This is equivalent to

$$\int_{-\infty}^{\infty} f(x)dx \approx \sum_{m=1}^{M} w_m^* \exp\left\{(a_m^*)^2\right\} f(a_m^*)$$

where the w_m^* denote the quadrature weights and the a_m^* denote the quadrature abscissas. The log likelihood, L, is the sum of the logs of the panel-level likelihoods l_i .

The default approximation of the log likelihood is by adaptive Gauss-Hermite quadrature, which approximates the panel-level likelihood with

$$l_i \approx \sqrt{2}\widehat{\sigma}_i \sum_{m=1}^M w_m^* \exp\left\{ (a_m^*)^2 \right\} g(y_{it}, x_{it}, \sqrt{2}\widehat{\sigma}_i a_m^* + \widehat{\mu}_i)$$

where $\hat{\sigma}_i$ and $\hat{\mu}_i$ are the adaptive parameters for panel i. Therefore, with the definition of $g(y_{it}, x_{it}, \nu_i)$, the total log likelihood is approximated by

$$L \approx \sum_{i=1}^{n} w_i \log \left[\sqrt{2} \widehat{\sigma}_i \sum_{m=1}^{M} w_m^* \exp\left\{ (a_m^*)^2 \right\} \frac{\exp\left\{ -(\sqrt{2} \widehat{\sigma}_i a_m^* + \widehat{\mu}_i)^2 / 2\sigma_\nu^2 \right\}}{\sqrt{2\pi} \sigma_\nu} \right]$$
$$\prod_{i=1}^{n_i} F(y_{it}, x_{it} \beta + \sqrt{2} \widehat{\sigma}_i a_m^* + \widehat{\mu}_i)$$

where w_i is the user-specified weight for panel i; if no weights are specified, $w_i = 1$.

The default method of adaptive Gauss-Hermite quadrature is to calculate the posterior mean and variance and use those parameters for $\widehat{\mu}_i$ and $\widehat{\sigma}_i$ by following the method of Naylor and Smith (1982), further discussed in Skrondal and Rabe-Hesketh (2004). We start with $\widehat{\sigma}_{i,0}=1$ and $\widehat{\mu}_{i,0}=0$, and the posterior means and variances are updated in the kth iteration. That is, at the kth iteration of the optimization for l_i , we use

$$l_{i,k} \approx \sum_{m=1}^{M} \sqrt{2} \widehat{\sigma}_{i,k-1} w_m^* \exp\{a_m^*\}^2 g(y_{it}, x_{it}, \sqrt{2} \widehat{\sigma}_{i,k-1} a_m^* + \widehat{\mu}_{i,k-1})$$

Letting

$$\tau_{i,m,k-1} = \sqrt{2}\widehat{\sigma}_{i,k-1}a_m^* + \widehat{\mu}_{i,k-1}$$

$$\widehat{\mu}_{i,k} = \sum_{m=1}^{M} (\tau_{i,m,k-1}) \frac{\sqrt{2} \widehat{\sigma}_{i,k-1} w_m^* \exp\{(a_m^*)^2\} g(y_{it}, x_{it}, \tau_{i,m,k-1})}{l_{i,k}}$$

and

$$\widehat{\sigma}_{i,k} = \sum_{m=1}^{M} (\tau_{i,m,k-1})^2 \frac{\sqrt{2}\widehat{\sigma}_{i,k-1} w_m^* \exp\{(a_m^*)^2\} g(y_{it}, x_{it}, \tau_{i,m,k-1})}{l_{i,k}} - (\widehat{\mu}_{i,k})^2$$

and this is repeated until $\widehat{\mu}_{i,k}$ and $\widehat{\sigma}_{i,k}$ have converged for this iteration of the maximization algorithm. This adaptation is applied on every iteration until the log-likelihood change from the preceding iteration is less than a relative difference of 1e–6; after this, the quadrature parameters are fixed.

The log likelihood can also be calculated by nonadaptive Gauss-Hermite quadrature, the intmethod(ghermite) option, where $\rho=\sigma_{\nu}^2/(\sigma_{\nu}^2+1)$:

$$L = \sum_{i=1}^{n} w_i \log \left\{ \Pr(y_{i1}, \dots, y_{in_i} | \mathbf{x}_{i1}, \dots, \mathbf{x}_{in_i}) \right\}$$

$$\approx \sum_{i=1}^{n} w_i \log \left[\frac{1}{\sqrt{\pi}} \sum_{m=1}^{M} w_m^* \prod_{t=1}^{n_i} F\left\{ y_{it}, \mathbf{x}_{it} \boldsymbol{\beta} + a_m^* \left(\frac{2\rho}{1-\rho} \right)^{1/2} \right\} \right]$$

Both quadrature formulas require that the integrated function be well approximated by a polynomial of degree equal to the number of quadrature points. The number of periods (panel size) can affect whether

$$\prod_{t=1}^{n_i} F(y_{it}, \mathbf{x}_{it}\boldsymbol{\beta} + \nu_i)$$

is well approximated by a polynomial. As panel size and ρ increase, the quadrature approximation can become less accurate. For large ρ , the random-effects model can also become unidentified. Adaptive quadrature gives better results for correlated data and large panels than nonadaptive quadrature; however, we recommend that you use the quadchk command (see [XT] quadchk) to verify the quadrature approximation used in this command, whichever approximation you choose.

xtprobit, re and the robust VCE estimator

Specifying vce(robust) or vce(cluster clustvar) causes the Huber/White/sandwich VCE estimator to be calculated for the coefficients estimated in this regression. See [P] _robust, particularly Introduction and Methods and formulas. Wooldridge (2013) and Arellano (2003) discuss this application of the Huber/White/sandwich VCE estimator. As discussed by Wooldridge (2013), Stock and Watson (2008), and Arellano (2003), specifying vce(robust) is equivalent to specifying vce(cluster panelvar), where panelvar is the variable that identifies the panels.

Clustering on the panel variable produces a consistent VCE estimator when the disturbances are not identically distributed over the panels or there is serial correlation in ϵ_{it} .

The cluster-robust VCE estimator requires that there are many clusters and the disturbances are uncorrelated across the clusters. The panel variable must be nested within the cluster variable because of the within-panel correlation that is generally induced by the random-effects transform when there is heteroskedasticity or within-panel serial correlation in the idiosyncratic errors.
