## How our work fits in to Stata conference

- I direct UCSF Statistical Laboratory for Aging Research (10 full time statisticians; based out of Pepper Center and Division of Geriatrics)
- Team-science framework with emphasis on deep, longitudinal collaboration with clinical researchers
- We are not currently Stata programming experts at level of others in this conference
- ▶ Historically, users of Stata, and users/programmers in SAS/R
- Stata-specific tools have become incredibly useful for our research in general (e.g. margins, svy, mi) and specifically for today's topic (e.g. ipdfc, meta, bayes:streg, bayesmh)
- Have end-to-end Stata script for this project; hope to create proper Stata command in near future
- Stata potentially better fit at UCSF (e.g. training in clinical research is Stata-centric from Vittinghoff et al. textbook)

## Topics for today

- Reconstruction of individual patient survival data from Kaplan-Meier figures in publications of clinical trials
- Alternatives to hazard ratios (time to benefit; difference in restricted mean survival)

▲□▶ ▲□▶ ▲□▶ ▲□▶ ▲□ ● ● ●

- Estimation of these with Bayesian parametric survival
- Combining across multiple studies (meta-analysis)

#### Meta-analysis worksheet

◆□▶ ◆□▶ ◆ 臣▶ ◆ 臣▶ ○ 臣 ○ の Q @

## Reconstruction of individual patient data

- Clinical trials often publish Kaplan-Meier curves for each arm and hazard ratio with 95% CI
- If want to look at other metrics, would be great if had the individual patient data
- Turns out this can be reconstructed from the Kaplan-Meier curves with high fidelity (Guyot 2012; Parmar 1998; Earle 2002)
- First step: extract the coordinates of the steps on the figure and number at risk information
- Second step: use this info to figure out number of events and censored at each jump in curve; this allows creation of a standard individual patient dataset

#### First step: a picture worth a thousand numbers

- Numerous packages and methods to turn a figure from a published paper back into the underlying numbers
- Raster figures: ycasd (Gross 2013), g3plot, WebPlotDigitizer, Engauge, Digitizelt
- Vector figures: exact numbers are computable from file and can be extracted (Liu 2015)

#### Second step: infer the individual patient data

- ipdfc package (Wei and Royston, 2017)
- Start with the sheet created by digital extraction (one line per step in the KM curve)
- Convert to one line per patient data with a time variable and event indicator (event vs. censored)

Many options to improve fidelity of reconstruction

#### Working with ipdfc in Stata

#### Example 2: ICON7 trial

This example is from ICON7, a two-arm randomized controlled trial of bevacizumab in advanced ovarian cancer (Perren et a probabilities instead of percentages were extracted across 30 months of follow up. The following code shows how to use extracted survival probabilities to time-to-event data.

- . local tot0=464
- . local tot1=470
- . import delimited using "ICON7\_data\_arm0.txt", clear
- . ipdfc, surv(s) tstart(ts) trisk(trisk) nrisk(nrisk) generate(t\_ipd event\_ipd) saving(temp0, replace) probability i totevents(`tot0')
- . import delimited using "ICON7\_data\_arm1.txt", clear
- . ipdfc, surv(s) tstart(ts) trisk(trisk) nrisk(nrisk) generate(t\_ipd event\_ipd) saving(temp1, replace) probability i
  totevents(`tot1')

The following code amalgamates the data from both arms and then conducts survival analysis.

- . use temp0, clear
- . generate byte arm = 0
- . append using temp1
- . replace arm = 1 if missing(arm)
- . stset t\_ipd, failure(event\_ipd)
- . stcox arm
- . sts graph, by(arm) xlabel(0(3)30) ylabel(0(0.2)1) risktable(0(6)30, order(1 "Bevacizumab" 2 "Standard chemo-")) le xtitle("Months since randomization") l2title("Alive without progression") plotlopts(lpattern(solid) lcolor(gs12) plot2opts(lpattern(solid) lcolor(black)) text(-0.38 -3.2 "therapy") text(0.75 14 "Bevacizumab", place(e)) text(0 chemotherapy")

#### The reconstructed KM curves for the inferred data

◆□▶ ◆□▶ ◆臣▶ ◆臣▶ 三臣 - のへで

## Summary of reconstructing IPD

- Clinical trials often publish Kaplan-Meier curves for each arm and hazard ratio with 95% CI
- Use specialized software to digitally extract the underlying coordinates of the Kaplan-Meier curves
- Run ipdfc to create a one line per participant version of the original survival data
- Why go to this trouble? Lots of things we can do with these data (e.g fit our own survival models, calculate other metrics besides hazard ratio)

## Metrics of interest

- Hazard ratio is useful for comparing survival curves, but there are other quantities of interest
- Difference in Restricted Mean Survival Time (RMST; Royston & Parmar, 2013) is popular with statisticians and is clinically interpretable
- Time to Benefit (TTB) less well known but extremely appealing to clinical researchers to weigh risks and benefits (Lee, 2013)

▲□▶ ▲□▶ ▲□▶ ▲□▶ ■ ●の00

## Restricted Mean Survival Time (RMST)

- For one arm,  $RMST(t) = \int_0^t S(u) du$  is the area under the survival curve out to some given time t
- Difference in RMST, dRMST(t) = RMST<sup>1</sup>(t) RMST<sup>0</sup>(t), is the area between the survival curves out to that time
- Interpreted as average gain in life from intervention over a t-year period
- Can compute this using non-parametric Kaplan Meier curves or by fitting a parametric model
- We use parametric models (e.g. Weibull or Gompertz) for simplicity/stability of estimation
- Bayesian estimation of the parametric survival curves makes computation of both estimate and CI straightforward

#### Time to Benefit

- TTB(r) is the amount of time until the survival curves are separated by an absolute amount of risk r; TTB(r) = smallest t such that S<sup>1</sup>(t) − S<sup>0</sup>(t) ≥ r
- Suppose survival curves are separated by r = 0.01 at 3 years
- Then the number needed to treat (NNT) to save one life with the intervention is 100 patients after 3 years
- Can compare this to life expectancy of patient to aid in decision-making
- And/or can contrast with the expected number out of 100 that will be harmed over 3 years (NNH)
- This framework is very natural for clinicians
- We again use parametric models and Bayesian estimation to make computation straightforward (so can do both TTB(r) and dRMST(t) for same price!)

#### Time to Benefit examples in literature

- Statins for primary prevention of ASCVD (Yourman 2021): 30 months needed to avoid 1 MACE for 100 patients (r = 0.01)
- Intensive blood pressure treatment (Chen 2022): 19.1 months needed to avoid 1 MACE per 200 patients (r = 0.005)
- Mammography for breast cancer (Lee 2013): 10.7 years needed to avoid 1 breast cancer death per 1000 women screened (r = 0.001)
- Bisphosphonates in osteoporosis (Deardorff 2020): 12.4 months to prevent 1 fracture in 100 women treated (r = 0.01)

# TTB figure (Deardorff, 2020)

▲□▶ ▲□▶ ▲三▶ ▲三▶ 三三 のへ(で)

Bayesian analysis of TTB, RMST, etc. in a single study

- Weibull or Gompertz provide excellent fit in our settings
- We allow both parameters (shape and scale for Weibull) to be different for two arms of study (4 parameters)
- We start with the data set reconstructed from ipdfc and then use bayes:streg to generate large number of MCMC realizations from the posterior distribution of the four parameters
- For each realization, we can create the Weibull survival curve given those 4 parameters. RMST(t) and TTB(r) then numerically evaluated
- Use posterior quantiles across the set of realizations to get estimate and CI for RMST(t) and TTB(r)

## Bayesian TTB(r) in more detail

- Have simulations θ<sub>1</sub>,...,θ<sub>M</sub> from the posterior distribution of the survival curve parameters
- For each simulated parameter vector θ<sub>m</sub>, create the survival curves and solve for the first time they are more than r apart (TTB(r)<sub>m</sub>)

- Take TTB(r) as median of  $TTB(r)_1, \ldots, TTB(r)_M$
- Take the 2.5th and 97.5th percentiles as a 95% credible interval

## Bayesian dRMST(t) in more detail

- Have simulations θ<sub>1</sub>,...,θ<sub>M</sub> from the posterior distribution of the survival curve parameters
- For each simulated parameter vector θ<sub>m</sub>, create survival curves and take difference when numerically integrate them from 0 to t (dRMSTt<sub>m</sub>)
- Take dRMST(t) as median of the M values
- Take the 2.5th and 97.5th percentiles as a 95% credible interval (or other methods)

#### Calculate TTB from posterior simulations

```
/* GENERATE SURVIVAL USING THE RANDOM SAMPLES. */
forv t=1/120 {
    generate surv c`t' = \exp(-(\exp(b0 \text{ control})) * `t'^(\exp(\ln p \text{ control})))
forv t=1/120 {
    generate surv_t`t' = \exp(-(\exp(b0 \text{ treatment})) * \text{`t'}^{(\exp(lnp \text{ treatment})))
3
forv t=1/120 {
    generate surv_d`t' = surv_t`t'-surv c`t'
/* ESTIMATE LTTBs. */
/* Find the first time difference is bigger than 0.005*/
generate lttb 005=84
forvalues t = 84(-1)1 {
    replace lttb 005=`t' if surv d`t'> 0.005
count if lttb 005==84
pctile lttb 005, percentiles(2.5 25 50 75 97.5)
return list
```

◆□ ▶ ◆□ ▶ ◆ □ ▶ ◆ □ ▶ ◆ □ ▶ ◆ □ ▶ ◆ □ ▶

Two ideas for meta-analyses of TTB, RMST, etc. across multiple studies

- 1. Calculate estimate and CI of TTB (or dRMST) for each study, then meta-analyze with usual random-effects meta command
  - Pros: straightforward to explain given similarity to how one would typically do meta-analysis for hazard ratios
  - Cons: does not easily handle curves that do not separate out in time range of data
- 2. Use hierarchical model for the underlying Weibull parameters (Ouwens 2010). This implies a (meta-analyzed) survival curve in each group. Can calculate estimate and CI for TTB for this pair of meta-analyzed survival curves in same way as was done for single curve
  - Pros: Easily accomodates "null" studies that have arbitrarily long TTB
  - Cons: Need to program using bayesmh so not quite so easy to implement

TTB (1): forest plot (Deardorff et al. 2020)

#### TTB for non-vertebral fracture prevention (ARR=0.01)

14

## TTB (2): fully Bayesian hierarchical model

Data for study i, arm k ~ Weibull regression( $\beta_i^{(k)}, p_i^{(k)}$ )  $(\beta_i^{(0)}, \beta_i^{(1)}, \log p_i^{(0)}, \log p_i^{(1)}) \sim N((\beta^{(0)}, \beta^{(1)}, \log p^{(0)}, \log p^{(1)}), \Sigma)$  $p(\beta^{(0)}, \beta^{(1)}, \log p^{(0)}, \log p^{(1)}, \Sigma) \propto \text{InverseWishart}(\Sigma | \Lambda, \nu)$ 

Fit with bayesmh random effects formulation. The two Weibull survival curves with parameters  $(\beta^{(0)}, p^{(0)})$  and  $(\beta^{(1)}, p^{(1)})$  are thought of as the underlying survival curves for the control and treatment arms

## TTB (2): raw figures (Growdon et al., 2023)

## Summary

- Use external digitization software and ipdfc to turn published Kaplan-Meier curves from two arm trials into Stata datasets
- Analyze these data in Bayesian framework using the bayes commands (i.e. create MCMC realizations of underlying parameters)
- Use the simulated parameter realizations for inference on less traditional metrics such as TTB(r) and dRMST(t)
- Can do this for single studies or in meta-analysis of multiple studies
